Particle size distribution is one the most important properties of soils. The size of soil particles and their packing affect the pore distribution in the soil, and thus determine, among other things, the possibility of gas exchange, water retention, as well as the thermal and sorptive properties of the soil. An important feature of particle size distribution is its stability in time and relatively easy measurability, thanks to which it serves as a parameter for many models, for example, for the estimation of water retention curves or hydraulic conductivity. The most important methods for measurements of soil particle size distribution are the following: (a) sieve methods; (b) methods based on Stokes law (aerometric and pipette ones); and (c) the new laser diffraction method.

SOIL TILTH: WHAT EVERY FARMER UNDERSTANDS BUT NO RESEARCHER CAN DEFINE

Douglas L. Karlen

Synonyms

Soil condition; Soil quality

Definition

Tilth – The physical condition of soil as related to its ease of tillage, fitness as a seedbed, and its impedance to seedling emergence and root penetration.

Introduction

The farmer's understanding of soil tilth is nearly as old as agriculture itself. For example, Fitzherbert wrote in his 1523 *Boke of Husbandry* that a farmer could determine if soil was ready to be sown by going onto the plowed land and “if it syng or crye, or make any noise under thy fete, then it is to wete to sowe: and if it make no noyse, and wyll beare thy horses, thane sowe in the name of God.” Similarly, in the seventeenth century, Thomas Tusser is reported to have stated that “good tilth brings seeds, ill tilture weeds.” Evidenced by these quotes and many other examples, tilth has a long history of intriguing people because of its connection with the soil (Karlen et al., 1990), yet the concept confuses scientists because of their inability to provide an exact definition or protocol for measuring it. Soil tilth thus describes a soil property that is better visualized than quantified; however, the principles that underlie tilth are fundamental to the quality of all soil resources.

In the 1930s, several authors began to describe how climatic conditions and various soil, crop, and animal management practices affected soil tilth. Keen (1931) provided a summary of previous observations regarding the importance of tilth for the planting of crops into a proper seedbed, the impact of frost on soil, how hard rains after plowing would create a crust, and how grazing animals could compact soils. Keen's treatise on soil physical conditions was followed by Yoder's, 1937 paper that described soil tilth as a “blanket” term describing the soil conditions that determine the degree of fitness for growth and development of crop plants. By sieving soil samples and separating the material into different sizes, researchers showed how freezing, drying wind, rainfall, tillage, animal compaction, and other management factors affected the soil. Tilth was ultimately recognized as providing a fundamental understanding of soil structure and how it changes in response to tillage, organic matter additions, crop rotations, and environmental factors such as rainfall or temperature. Changes in soil structure and the impact on soil tilth are probably most quickly recognized by

gardeners and small farmers because they work their soil either by hand or with small tools. Effects of improving soil tilth are readily apparent because hard soil requires more energy to prepare a seedbed and generally produces less vigorous plants. It has also been recognized that not all soils respond to inputs and management practices in the same way because of fundamental differences in their sand, silt, clay, and organic matter composition.

Yoder (1937) defined the ideal tilth as offering minimum resistance to root penetration, allowing for good infiltration and storage of soil water, having good exchange of gases between the soil and atmosphere, sustaining an adequate air supply in the soil, having a proper balance of water and air in soil pores, resisting erosion, promoting biological activity, facilitating decomposition of green manure and other organic residues, and providing a stable foundation for farm implements. This is a very inclusive list that covers many soil functions and demonstrates the interactions among the physical, biological, and chemical processes that are occurring within a profile. Yoder also recognized that green manure and crop residue additions were crucial for developing good soil tilth.

Soil tilth has gradually become recognized as a dynamic soil condition. As virgin grassland or forest soils were cultivated, organic matter concentrations, base (cation) saturation, and porosity decreased while bulk density increased. These changes reduced the tendency of soil to form stable aggregates and gradually resulted in a deteriorated soil structure. Declining soil tilth became associated with increased runoff, erosion potential, need for tillage to prepare an adequate seedbed, and fertilizer to sustain reasonable and profitable crop yields. Conversely, as soil tilth is improved, water exchange, gas exchange, and the ability of a plant to explore the profile and capture nutrients and water were enhanced. Soils with good tilth generally have greater biodiversity and provide structural support for land management operations. Soil tilth continues to be important as humankind depends on soil resources for food, feed, fiber, and most recently fuel (i.e., bioenergy). Understanding how to manage soils for long-term improvement and enhanced sustainability of tilth are lessons that all must be aware of now and in the future (National Academy of Sciences NAS, 2009).

Critical soil tilth concepts

Organic matter is one of the primary factors affecting soil tilth because of its role in soil aggregation. Studies with disturbed and undisturbed soils show that as organic matter increases, compaction decreases and there is more space for air and water exchange. The constant addition of organic matter throughout the soil profile is one reason that virgin grassland soils generally have excellent aggregation and structure. Those soils, especially in humid regions, generally have higher organic matter content, an increased percentage of water-stable aggregates, and

a structure that accommodates rapid plant growth with unlimited root proliferation. Those soil characteristics occur because in humid regions, grasses replace most of their roots and top growth each year. Also, when the above ground plant material dies, it falls on the soil surface where it is decomposed or mixed into the upper part of the soil by earthworms and other soil organisms. The dead roots and plant residue provide a food source for fungal and bacterial decomposition processes leading to the formation of soil aggregates, which modify effects of soil texture with regard to water and air relationships and root penetration. Increased water-stable aggregation, annual proliferation of plant roots, and the associated wetting and drying cycles gradually develop a soil structure that is stable and with good management resists degradation.

Whiteside and Smith (1941) were among the first to examine how crop production affected soil productivity. They cited several reports showing that total N and organic matter in the surface of tilled soils decreased relative to adjacent untilled forest and grassland areas. They found that cropping systems had a great influence on the amount and direction of change in soil N and organic C. The greatest changes were associated with continuous row crops, followed by cereal crops, then legume and sod crops. These and similar studies gradually led to development of conservation practices with an increased emphasis on incorporating perennial crops into extended rotations, reducing tillage intensity and frequency, using cover crops and optimizing nutrient and water management.

Surface mulch from crop residues, cover crops, animal manure, municipal sludge, leaves, or other carbonaceous sources can enhance soil tilth by providing physical protection from raindrop impact and a food source for earthworms and other soil fauna. Surface mulch also moderates soil temperature and moisture extremes at the soil-air interface. If soils are left bare and exposed, surface temperatures can be very high causing the soil to become very dry. When this occurs, earthworms and other soil insects will move deeper into the soil leaving a surface zone that contains very few active organisms. Bacteria and fungi that live in thin films of water will die or become inactive, slowing the natural process of organic matter cycling and aggregation.

Tillage effects on soil tilth

Tillage can improve tilth over the short term by loosening surface soil, disrupting crusts and creating a more favorable soil-water-air environment for plants, but it is also a primary cause for the long-term deterioration of tilth. The loosening process that often has positive short-term plant production benefits has negative long-term effects because it increases the rate of organic matter decomposition through chemical and microbial mineralization. This occurs because previously protected organic matter is exposed by the tillage and subsequently used as a food source by many

microorganisms. The loss of organic matter decreases aggregate stability, thus increasing the potential for surface crusting, poor seedling emergence, runoff, erosion, and other indicators of poor soil tilth (e.g., decreased infiltration of rainfall or irrigation water, decreased soil water retention, and decreased nutrient cycling). Tillage itself or the wheel-traffic associated with tillage operations can further reduce tilth by increasing compaction. This reduces total pore space and frequently increases water-filled pore space leading to reduced aeration, slower nutrient cycling, and a decreased volume of soil for plant root proliferation. Traffic-induced compaction obviously occurs in fields used for crop production, but similar negative effects can be found at construction sites, in forests due to logging operations, on campgrounds, athletic fields, or even desert areas where off-road recreational vehicles are allowed.

Extended crop rotation effects on soil tilth

Soil tilth is affected in two ways by incorporating forage or hay crops into an extended rotation. First, soil organic matter decomposition decreases because the soil is not disturbed or tilled each year. Second, grass and legume sods develop extensive root systems, part of which dies each year, adding new organic matter to the soil. The dead roots provide a food source for fungal and bacterial decomposition processes leading to the formation of soil aggregates and improved tilth.

To demonstrate the effect of perennial root systems on soil aggregation, researchers compared aggregate size distributions for soils under continuous corn (*Zea mays* L.) with those where corn was grown in rotation with oat (*Avena sativa* L.) and meadow. The data showed that with continuous corn aggregate size was less than half that for corn grown in rotation. The studies also showed that aggregation decreased slowly but consistently over a 7-year period of continuous corn. In related studies, comparisons among crop sequences showed that aggregation increased by switching to a corn-oat-meadow rotation after 11 years of continuous corn (Karlen et al., 1990). Also, it took only 4 years of continuous corn to decrease the aggregation established under either bluegrass or alfalfa to less than that found after 18 years of the corn-oat-meadow rotation. The highly significant correlation between crop yield and aggregate size confirmed that soil tilth and productivity were both affected by crop rotation.

Cover crop effects on soil tilth

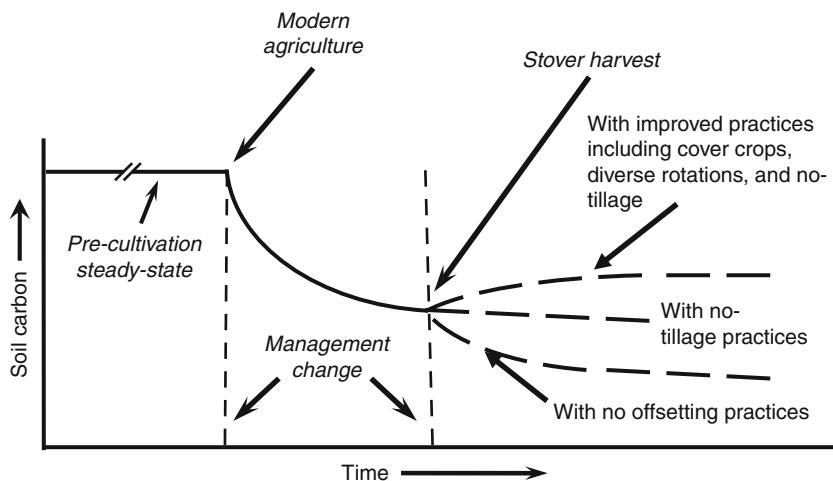

Growing cover crops can improve soil tilth by decreasing erosion, increasing infiltration, and adding organic residues to the soil. Although in orchards and vineyards the cover crops are frequently grown year-round, they are most often grown only during seasons when the soil is especially susceptible to erosion. The leaves and stems of the cover crop intercept rainfall and dissipate the energy while roots bind the soil and hold it in place. The amount

of benefit from cover crops depends on the above and below ground biomass and rooting structure of the plant being grown and the length of time before the soil is prepared for the next crop. For example, in the southeastern US crimson clover (*Trifolium incarnatum* L.) can be grown successfully as a cover crop prior to cotton (*Gossypium barbadense* L.). Initially planted in late autumn, the clover grows slowly throughout the winter and early spring, often reseeding itself for the next year before the cotton crop is planted. In more northern areas such as the US Corn and Soybean Belt where cold temperatures significantly shorten the growing season, crops such as crimson clover simply cannot survive. Oat, rye (*Secale cereale* L.), and hairy vetch (*Vicia villosa* L.) are some of the possible cover crops for the northern states, but the amount of protection against soil erosion and especially the amount of nitrogen supplied by the vetch are generally much less than in the southern USA. Also, in semiarid regions where water is often the most limiting factor, growing cover crops may not be a viable management practice.

Additional benefits of cover crops include sequestering nutrients (especially nitrate N) so they cannot be leached below the crop root zone, suppressing weeds, breaking pest cycles, providing habitat for beneficial insects and other fauna, and supplying nutrients (usually N) to the following crop. However, before a farmer or anyone else decides to grow a cover crop to maintain or improve soil tilth, it is important to determine what needs to be accomplished. Is the main purpose to add available nitrogen to the soil or to provide large amounts of carbon? Is erosion control during the late autumn and early spring the primary objective? Does the soil have a compaction problem that needs to be alleviated? Will the combination of cover crop, climate and water-holding capacity of the soil result in excess water depletion that adversely affects the primary crop? Once the primary purpose for growing a cover crop has been determined, decisions on plant species (i.e., legume or grass), the optimum date of planting, and when to kill the cover crop will be easier to make.

Potential biofuel feedstock production effects on soil tilth

Increasing worldwide energy demand, high commodity prices, rapid economic growth in developing countries, and growing evidence that atmospheric carbon dioxide (CO₂) is an important contributor to global climate change have significantly increased interest in using agricultural biomass to simultaneously increase energy supplies and reduce worldwide greenhouse-gas emissions (NAS, 2009b). Figure 1 illustrates the potential impact of meeting these needs on soil tilth because of their effect on the soil carbon balance. Worldwide, the pre-agriculture soil carbon content was generally at least twice that found in soils approaching equilibrium with current tillage and cropping practices. Harvesting additional stover or crop residues as

Soil Tilth: What Every Farmer Understands but no Researcher Can Define, Figure 1 Changes in soil carbon content (a primary factor influencing soil tilth) as native soils are subjected to cultivation and management changes including stover removal.

feedstock for biofuels or other bioproducts will have a negative impact on the C balance unless offsetting practices such as reduced tillage, cover crops, or diversified crop rotations are also implemented. Initial efforts to produce biofuel from corn, soybean (*Glycine max* [L.] Merr.) or other food crops have been questioned from social, economic, and environmental perspectives and induced fear of having global competition between food and fuel (Doornbosch and Steenblik, 2007).

As a feedstock, cellulosic biomass has numerous advantages over corn, soybean, and other grains, including its availability from sources that do not compete with food and feed production. Biofuels made from renewable feedstock are an attractive alternative to gasoline because they can decrease the net release of greenhouse gases (GHG) from the transportation sector. An unknown and current research question is what impact harvest of this material will have on soil tilth.

Corn stover, the aboveground material left in fields after corn grain harvest, was identified as a primary biomass source (Perlack et al., 2005), because it and other crop residues are frequently referred to as “trash” or agricultural waste (Wilhelm et al., 2007). This would suggest that stover has minimal value (Lal, 2004) but, when returned to the land, crop residues replenish soil organic carbon (SOC), a soil quality indicator that has been reduced by 30–50% (Schlesinger, 1985) compared to pre-cultivation levels. These decreases have occurred because of crop production activities that include artificial drainage, intensive annual tillage, and less diverse plant communities; factors also affecting soil tilth.

Removing crop residues for biofuel feedstock or any purpose will decrease the annual carbon input, and gradually diminish soil organic carbon and threaten the soil’s production capacity (Johnson et al., 2006). Therefore,

even though harvesting corn stover or any other crop residue as a feedstock for transportation biofuels could have many benefits, these must be evaluated in the context of other ecosystem services that crop residues provide. This includes conserving soil water, reducing surface runoff and evaporation, increasing infiltration rates, controlling soil erosion, recycling plant nutrients, providing habitat and energy for earthworms and other soil macro- and microorganisms, improving water quality by denaturing and filtering of pollutants and improving soil structure, preserving native habitats, maintaining biodiversity, and sustaining soil tilth. Crop residues also help reduce non-point source pollution, decrease sedimentation, minimize risks of anoxia and dead zones in coastal ecosystems, increase agronomic productivity, advance food security, and mitigate flooding by holding water on the land rather than allowing it to run off into streams and rivers (Kimble et al., 2007).

So why is soil tilth important?

Good soil tilth provides a stable base for agricultural production. The ability of a plant to explore the soil profile to extract water, nutrients, and air reduces a potential limitation to plant growth. A limited soil profile reduces the amount and vigor of plant growth. Good soil tilth is also associated with good soil structure. This is important because a vast majority of the world’s agriculture depends upon rainfall to produce a reliable supply of food, feed, or fiber and when the soil has an unstable structure, infiltration of rainwater into the soil is often very limited. This is critical when rainfall occurs in intense storms. The other limitation comes when soil water holding capacity is diminished by reductions in organic matter and the rainfall leaches through the profile and is not available to the plant. The simple change in the soil creates a limitation to plant

growth and yield because of reduced water availability. Fields with poor soils often show poor plant growth because of water limitations even in years that have normal rainfall for that location. Efficient use of stored soil water is critical to providing food, feed, and fiber for the world's population and the process begins with a soil that has good tilth. Soil with good tilth has improved nutrient cycling because of the role of the microbiological activity within the soil and supply of nutrients to plants is as critical as water in terms of sustaining plant productivity.

Conclusions

Soil tilth has both direct and indirect effects on plant production often overlooked or even ignored. Healthy soils with good tilth have better resistance to insects and diseases. This aspect has not been fully studied and offers an additional piece of evidence for the proper management of the soil resource. It is also critical to consider soil tilth as part of the ecosystem that contributes to improved ecosystem health and ecosystem services, e.g., water quality, air quality, biodiversity, and efficient use of resources. Soil provides the foundation for existence of humankind, but it is the soil tilth that increases the value of that foundation with regard to its ability to produce a reliable and sustained supply of food, feed, fiber, and now fuel from the soil. Soil is precious and good tilth increases the value of the soil for all future generations.

SOIL WATER FLOW

Miroslav Kutílek
Prague 6, Czech Republic

Definition

Soil water flow is conditioned by the existence of a gradient of the total potential of soil water in both, the soil fully saturated by water (saturated flow) as well as in soil not fully saturated by water (unsaturated flow).

Basic concepts

The flow of water in soil can be described microscopically and macroscopically. On the microscopic scale, the flow in each individual pore is considered and for each defined continuous pore, the Navier–Stokes equations apply. For their solution, we lack detailed knowledge of the geometrical characteristics of individual pores to obtain a solution for the bulk volume of soil of the size about $0.1\text{--}1\text{ m}^3$, derived theoretically as the representative elementary

volume (REV). This type of procedure is applied in some theoretical investigations where the basic laws of fluid mechanics are invoked. In such studies, the real porous system is usually defined by a very simplified model.

The macroscopic or phenomenological approach of water transport relates to the entire cross section of the soil in REV. In order to emphasize the fact that water does not flow through the entire macroscopic areal cross section (REA), the term flux density (or flux ratio, or macroscopic flow rate) is used to describe the flow realized through only that portion of the area not occupied by the solid phase and, by the air phase eventually when we deal with unsaturated soil. The size of REA in soils is usually in the range of 100 cm^2 to m^2 . The dimension of the flux density is the volume of water (L^3) flowing through the area (L^2) in time (T), i.e., $(\text{L}^3/\text{L}^2 \text{T}) = (\text{LT}^{-1})$. The principal equation derived for this macroscopic approach is Darcy's equation developed in 1856. Water flow in soils is comparable to other transport processes such as heat flow and molecular diffusion when the appropriate driving force is defined. For water flow, it is the difference of total potentials between two points in the soil.

Saturated flow

We assume that water is flowing in all pores of the soil under a positive pressure head h . In field situations, the soil rarely reaches complete water saturation. Usually it is quasi-saturated with the soil water content $\theta = mP$ where m has values of 0.85–0.95 and P is the porosity. Entrapped air occupies the volume $P(1 - m)$. Further on we assume for the sake of simplicity that $m = 1$ and the impact of entrapped air is not considered. Darcy equation governing the saturated flow in the vertical direction is

$$q = K_S \frac{\Delta h}{L} = K_S I_h$$

where $\Delta h/L$ is the hydraulic gradient I_h , Δh the difference between water levels in piezometers at the vertical distance L . Since the dimension of h is (L) and of the distance L is also (L), the hydraulic gradient is dimensionless and the saturated hydraulic conductivity K_S has the dimension of q (LT^{-1}). When we read piezometer levels (or pressure heads) h_1 and h_2 at elevations z_1 and z_2 , respectively, we have in terms of the total potential $H = (h + z)$ a general form of the Darcy equation

$$q = -K_S \text{grad}H$$

When K_S is constant in the studied domain, then with $\Phi = K_S H$ is

$$q = -\text{grad}\Phi$$

The value of K_S depends upon the nature of the soil and is numerically equal to the flow rate when the hydraulic gradient is unity. Values of K_S commonly range from

less than 0.1 cm day^{-1} (10^{-8} m s^{-1}) to more than 10^2 cm day^{-1} (10^{-5} m s^{-1}). If the total potential H is not expressed as the height of the water column, but when we use $J \text{ kg}^{-1}$ ($\text{L}^2 \text{T}^{-2}$) then the potential gradient is $J \text{ kg}^{-1} \text{ m}^{-1}$ (LT^{-2}) and K_S has the dimension (T), usually s . K_S should be considered a scalar quantity for isotropic soils, and a tensor of rank 2 for anisotropic soils with the value of K_S dependent upon the direction of flow. When the tensor K_S is assumed to be symmetric, its principal axes, defined by six values, are identical to those of an ellipsoid of conductivity. If the gradient of the potential is not in the direction of a principal axis, the direction of flow is different from that of the gradient. The simplest expression of K_S was derived by Kozeny (1927) for the soil porosity modeled as a bundle of parallel capillary tubes. The flow is assumed to be laminar and its mean value is expressed by the Hagen-Poiseuille's equation. For P porosity [dimensionless], specific surface A ($\text{L}^2 \text{ L}^{-3}$) = (L^{-1}), g the acceleration of gravity (LT^{-2}), ρ_w the density of water (ML^{-3}), and μ the dynamic viscosity ($\text{ML}^{-1} \text{ T}^{-1}$) is

$$K_S = \frac{\rho_w g P^3}{2 \mu A^2}$$

Since the real flow paths in soil are curved and not straight as in the model, the term tortuosity τ was introduced as the ratio between the real flow path length L_e and the straight distance L between the two points of the soil. Because $L_e > L$, then $\tau > 1$. For example, in a monodispersed sand, $\tau = 2$. The permeability K_P valid for all fluids is

$$K_P = \frac{c P^3}{\tau A^2}$$

with c taken as an empirical constant. Permeability K_P has then the dimension (L^2). The unusual dimension represents the cross-sectional area of an equivalent pore. Although now almost obsolete, the historical unit of 1 Darcy = $1 \mu\text{m}^2$ was used for describing permeability. Kozeny's equation shows that K_S is sensitive to porosity. However, in his model the pore radii are considered uniform while those in real soils have great variability of pore size distribution, which is changed due to the aggregation or disaggregation of soil, by the compaction, etc. Due to the aggregation of soil, K_S may increase by orders of magnitude, yet the porosity may change slightly or even remain nearly the same. And, vice versa, soil dispersion or disaggregation substantially decreases K_S . For example, in a loess soil, the saturated hydraulic conductivity of its surface after a heavy rain decreases three to four orders of magnitude compared with its original value owing mainly to two processes – disaggregation and the blockage of pores by the released clay particles. Compaction of soil in the A-horizon and in the bottom of the plowed sub horizon causes a much greater decrease of K_S than that predicted from a decrease of porosity in the

simple Kozeny equation because compaction reduces primarily the content of large soil pores associated with values of pressure head $h=0$ to -100 cm. Although the textural class of a soil may have a large influence on the value of K_S , any attempt to establish a correlation between them usually fails. Only for those soils and soil horizons of the same genetic development occurring in the same region and being similarly managed will a correlation between texture and K_S be manifested. In sandy soils, the lowest value of K_S is about 100 cm day $^{-1}$, in silty loams about 10 cm day $^{-1}$, and in clays about 0.1 cm day $^{-1}$. In peats, K_S decreases with an increasing degree of decomposition of the original organic substances. When the degree of decomposition of a peat is more than 50%, the value of K_S diminishes to values of K_S of nonconsolidated clays. In loams and clays, the nature of the prevalent exchangeable cation plays an important role upon the value of K_S . In vertisols, an increase of the percentage of exchangeable sodium (ESP) is accompanied by a significant decrease in K_S when the ESP reaches 15–20%, provided that the soluble salt content of the soil water is small. For example, with the electrical conductivity of the soil paste EC = 1 mS cm $^{-1}$ or less, the value of K_S can decrease two or three orders of magnitude (Hillel, 1998). In not frequent events the linear relationship of Darcy equation is not applicable. This non-Darcian flow in clays is caused by the shift of clay particles due to the imposed hydraulic gradient and due to the changed of the water viscosity in clays having extremely large specific surface. In coarse sands, the nonlaminar flow could exist causing the deviation of linearity of Darcy equation (Kutilek and Nielsen, 1994).

Unsaturated flow

When the soil is not fully saturated by water, the Darcy equation was modified by Buckingham in 1907 to the form

$$q = -K(h)\text{grad}H$$

or with the relationship $\theta(h)$ known as the soil water retention curve is

$$q = -K(\theta_E)\text{grad}H$$

where q is flux density (LT $^{-1}$), h is the pressure head (L), and since the soil is not fully saturated with water, it is negative, sometimes denoted also as soil water potential. H is the total potential (L), the same as for saturated flow, but with h negative. K is unsaturated conductivity (LT $^{-1}$), no more a constant value, but functionally dependent either upon h or physically better expressed as dependent upon the relative saturation of soil by water $\theta_E = \theta/\theta_S$. The volumetric soil water content is the volume of water in the volume of soil (L 3 L $^{-3}$) and θ_S is soil water content at the full saturation of soil by water. In rigid soils is then $\theta_S=P$, porosity. Both equations are usually named Darcy-Buckingham equations.

When the soil is modeled as the bundle of capillary pores of variation of pore radii with radius size distribution $f(r)$ and when the laminar fluxes in individual capillaries are summed then the model of relative unsaturated conductivity is

$$K_R = \theta_E^\alpha \left[\frac{\int_0^r r^\beta f(r) dr}{\int_0^\infty r^\beta f(r) dr} \right]^\gamma$$

where $K_R = K/K_S$, α , β represent tortuosity, and γ is assumed to express the pores connectivity (Mualem, 1976). When $f(r)dr$ is approximated by $d\theta_E(h)$, i.e., by the derivative of the soil water retention curve and for the relation between the pore radius and the pressure head ($r=c/h$), we obtain

$$K_R = \theta_E^\alpha \left\{ \frac{\int_0^{\theta_E} \frac{d\theta_E}{[h(\theta_E)]^\beta} dr}{\int_0^1 \frac{d\theta_E}{[h(\theta_E)]^\beta} dr} \right\}^\gamma$$

among the various models of the soil water retention curve $h(\theta_E)$ the most frequently used is the equation of van Genuchten (1980)

$$\theta_E = \frac{1}{[1 + (a|h|)^n]^m}$$

where a , n , m are empirical fitting parameters to the soil water retention curve determined on the undisturbed soil sample. The value of K_R sinks in orders of magnitude when the soil water content decreases, e.g., when its value is lowered to the for plants still well available water content at $h = -500$ cm, then K_R falls by about three orders of magnitude in loams and to seven orders of magnitude in sands.

Richards' equation

The above Darcy–Buckingham equation of flux density is fully applicable to steady unsaturated flow when $\nabla q = 0$, $dq/dt = 0$ and $d\theta/dt = 0$. In practical situations, unsteady flow frequently exists with one of the conditions not fulfilled. In these situations, two equations are needed to describe the flux density and the rate of change of θ in time. The flux density is described by the Darcy–Buckingham equation and the rate of filling or emptying of the soil pores is described by the equation of continuity. The final equation derived by Richards (1931) is

$$\begin{aligned} \frac{\partial \theta}{\partial t} &= \frac{\partial}{\partial x} \left[K(h) \frac{\partial H}{\partial x} \right] + \frac{\partial}{\partial y} \left[K(h) \frac{\partial H}{\partial y} \right] \\ &\quad + \frac{\partial}{\partial z} \left[K(h) \frac{\partial H}{\partial z} \right] \end{aligned}$$

provided that the soil is homogeneous on REV scale and isotropic. In one-dimensional form for $H=h+z$ the above equation becomes

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z} \left[K(h) \frac{\partial h}{\partial z} \right] + \frac{\partial K}{\partial z}$$

The equation is sometimes used as the Fokker–Planck equation (Kutilek and Nielsen, 1994) either in the capacitance form with water capacity $C_w = d\theta/dh$ (L^{-1})

$$C_w \frac{\partial h}{\partial t} = \frac{\partial}{\partial z} \left[K(h) \frac{\partial h}{\partial z} \right] + \frac{\partial K}{\partial z}$$

or in the diffusivity form

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z} \left[D(\theta) \frac{\partial \theta}{\partial z} \right] + \frac{dK \partial \theta}{d\theta \partial z}$$

with the soil water diffusivity D ($L^2 T^{-1}$)

$$D(\theta) = K(\theta) \frac{dh}{d\theta}.$$

Preferential flow

The soil porous system is rarely homogeneous even on the REV scale and rigid, with pore size distribution constant and not dependent upon soil water content. Various types of irregularities cause the existence of small domains with a more rapid flow rates responsible for accelerated transport of pollutants or pathogens and dispersed clay particles than obtained by a simple application of the Richards' equation. This rapid flow is named preferential flow. It is realized in four physically defined types (Kutilek et al., 2009):

1. Preferential flow in the structural domain containing inter-pedal (inter-aggregate) pores, a subcategory of capillary pores. Richards' equation has been applied for this domain in simulation models since the pores belong to capillary pores. However, there is an indication that the flow in those pores could exist as transition to flow defined in item 2. The fluxes are accelerated when compared to fluxes in the matrix (intra-pedal) pores, if infiltration and redistribution are considered.
2. Preferential flow in real macropores (or non-capillary pores). Richards' equation is not applicable. Kinematic wave equation is mainly used. The fluxes are usually accelerated even when compared to fluxes due to item 1 (inter-pedal fluxes).
3. Preferential flow due to the unstable wetting front.
 - (a) Fingering, which occurs most frequently at the interface of less permeable layer above more permeable layer. Solution by Richards' equation exists provided that the geometry of fingering is defined. Rate of fluxes is comparable to item 1.
 - (b) Preferential flow due to irregularities in hydrophilicity. It occurs when initial soil water content is below critical value. Rate of fluxes is comparable to item 1.

In the majority of instances, the flow in matrix system of pores coexists with the flow in the structural system of pores. In each of the domains the unsaturated conductivity is expressed by the equation where the pore size distribution function $f(r)_i$ belongs either to matrix pores with $i=1$ or to the structural pores with $I=2$ and the unsaturated conductivity is then composed of matrix conductivity K_1 and of structural conductivity K_2

$$K = K_1 + K_2.$$

Summary

Soil water flow is described by the application of the Darcy's equation. In soils fully saturated with water, a constant hydraulic conductivity is defined. In unsaturated soils, Darcy's equation is modified by defining the unsaturated conductivity as a characteristic dependent upon the partial saturation of soil pores by water. Unsaturated conductivity is then no more a constant for the given soil. Its value decreases up to by order of magnitude with the decrease of soil water content. The governing equations of the solution of the water transport and soil water content change are partial differential equations. The existence of different domains of soil pores leads to the existence of bimodal or multimodal porous systems causing preferential flow.

SOIL WATER MANAGEMENT

Willibald Loiskandl, Gerhard Kammerer

 Institute of Hydraulics and Rural Water-Management,
 University of Natural Resources and Life Sciences,
 Vienna, Austria

Definition

Soil water management can be defined as active involvement in controlling soil water content at an optimal state for all given purposes, including environmental needs. An optimal state is often a compromise between competing uses and needs to account for long-term sustainability of the soil water system.

Progression of soil water management

Endeavors to maintain soil water balance have a long tradition and have been performed in many parts of the world. The irrigation schemes of the Mesopotamian plain are a well-documented example, but there is also evidence that drainage measures – the counterpart to irrigation – were undertaken in the same region. Lugalbanda, king of Uruk, an early settlement at the river Euphrates in ancient Mesopotamia ordered melioration of the swamps as a land reclamation measure over a 50-year period (C. Wilcke, Wiesbaden 1969, cited by Strommenger, 1980). In the past, irrigation with saline or brackish water and neglected drainage led to soil salinization; productive farmland had to be abandoned and some early civilizations declined or even disappeared (Evans and Fausey, 1999). Strictly speaking, this was not sustainable soil water management and until recently, water and soil were incorrectly considered as inexhaustible resources in many parts of the world.

It cannot be overemphasized that good drainage is an indispensable requirement for irrigation practice as well. As an example, an irrigated field in Ethiopia is highly at risk of crop failure due to nonexisting drainage and therefore, farmers decided to dig an “emergency drain” (Loiskandl 2006; Figure 1).

The beginning of modern land management practices in Central Europe (German “Kulturtechnik” = land preparation for agricultural and in a broader sense for human use including infrastructure) can be dated with the works of Dünkelberg (Kastanek, 1998). In the humid environment of his sphere of activity, the excess water was dominant and hence soils were drained intensively. However, he proposed the use of the drain systems for irrigation during dry periods (Dünkelberg, 1865).

A recent way to control soil water in certain cases is the application of soil additives. By mixing water retaining particles with soil, the hydraulic properties of the substrate should be improved and two hydrological effects should be achieved: (1) minimization of seepage losses and (2) reduction of evaporation, that is, water is kept in the root zone for the productive use by plants.

In a changing world, due to climate change and human interventions on land use, soil water management is still of growing importance. Subsurface water (water in the vadose zone and groundwater) forms the major volume of terrestrial water resources. For soil water Gusev and Novak (2007) distinguished three major functions in terrestrial ecosystems:

- Soil water is the most active link in the interchange of continental waters.
- Soil water is an element of the global climatic system (owing to its location at the atmosphere–lithosphere interface, soil water notably contributes to the formation of climate).
- Soil water is the most important factor governing the existence and development of the vegetation cover, which is the basic link in the trophic chain of land ecosystem.

To quantify the stress to which soil water is objected in an indicator-based assessment (EEA, 2008), the following key messages were delivered:

- Water retention capacity and soil moisture content will be affected by rising temperatures and by a decline in soil organic matter due to both climate change and land-management changes.
- Projections (for 2070–2100) show a general reduction in summer soil moisture over most of Europe, significant reductions in the Mediterranean region, and increases in the north-eastern part of Europe.
- Maintaining water retention capacity is important to reduce the impacts of more frequent intense rainfall and droughts.

Water in general, and soil water in particular, is fundamental to all life. It is vital to maintain its various functions in an optimum and sustainable manner and to safeguard its

Soil Water Management, Figure 1 Farmers at Godino are working on an emergency drain of an over-irrigated field to conduct excess water (Loiskandl, 2006).

use and protection. Modern soil water management has to acknowledge this fact.

Management and soil water

Soil water management has to be seen in the frame of the hydrological water cycle, especially when an integrated approach is proposed. It takes place in that part of the water cycle where water interacts with soil. In the hydrological glossary of UNESCO (2009), watershed management is defined as controlled use of drainage basins in accordance with predetermined objectives. In a process understanding, soil water is a subsystem of the hydrology of a basin (Figure 2), and soil water management activities are determined by the prevailing conditions and dynamics in the system in which it is embedded.

Classical melioration is defined as a long-term measure to maintain or to increase a higher productivity of the soil to enable an easier agriculture and to protect the soil from devastation and deterioration (Hunkeler et al., 1970). Drainage can be defined as artificial or natural, surface or subsurface dewatering with the aim to achieve a sustainable soil water condition at a certain location, whereas the Austrian standard ÖNORM B 2580 (ON, 1972) describes it as diversion of excessive soil water to ensure a better soil structure und aeration. Technical devices are required to control of soil water and are a major topic of rural water systems management. This classical approach is dominated by the planning and construction of hydraulic structures. Soil water management consists not only in technical measures, but aims to optimize the utilization of water for all purposes. Such an integrated water management approach is proposed by many authors (e.g., Bouwer, 2000). Management has to take into account that soil water governs the transport of solutes like

nutrients and contaminants and influences chemical and biological processes, hence water quality aspects are also object of soil water management activities.

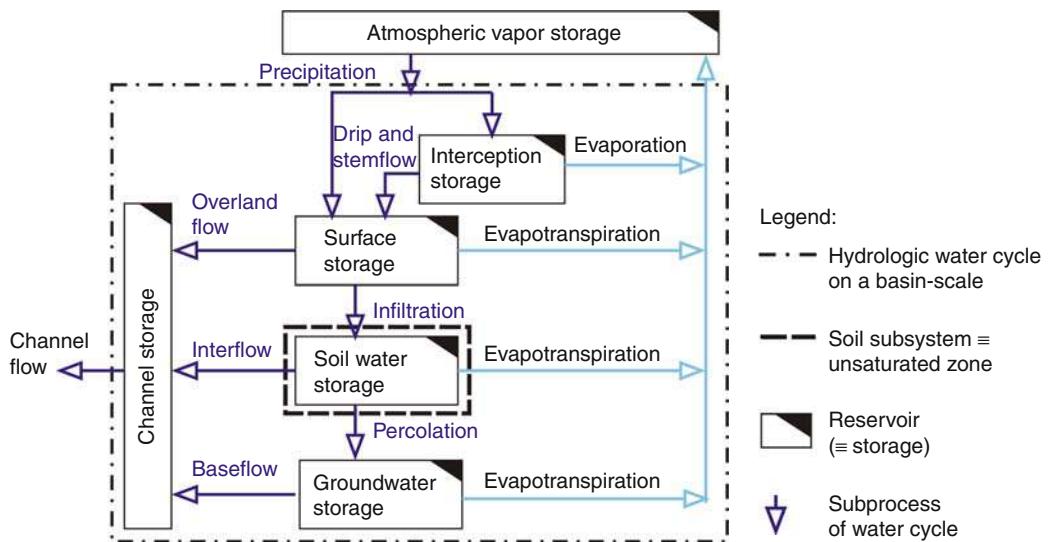

Agriculture and soil water

Agriculture may not be the most important user of soil water in economic terms, but due to its impact on the environment it is treated separately. Agricultural soil water management comprises traditionally irrigation and drainage.

In Europe, the purpose of water controlling has changed in the last decades from an application for agricultural production and purely technical measures to soil water management as an integrated and multipurpose task. Modern soil water management includes other elements like land use, variation of tillage operations, and adapted vegetation covers.

Good agricultural practice refers to establish optimum soil water content, fertilizer application, plant protection, soil conservation, and livestock production. Adequate technology is required for a homogeneous distribution of mineral or organic fertilizers. A combination of cover cropping with reduced tillage, thereby leaving part or all of the residues on the soil surface, is particularly recommended to achieve an optimum control of surface runoff losses and erosion.

A main concern of farmers in semiarid regions is the additional water consumption of cover crops, which is supposed to deplete soil water to the detriment of the succeeding cash crops. However, it could be shown by perennial monitoring of soil water dynamics under different cover crops in a low-rainfall region of eastern Austria that yield losses due to competition for soil water in the crop rotation are an exception (Bodner et al., 2008). On

Soil Water Management, Figure 2 Soil water management subsystem within the hydrologic cycle for a basin. (Adapted from Thompson, 1999.)

the contrary, also bare soil can undergo high evaporation losses during late summer and early autumn without providing the benefits of a plant covered field. Site characteristics such as soil water storage capacity and rainfall distribution have to be considered to accurately assess the impact of cover crops on soil water dynamics. "Storage driven" environments – i.e., climatic conditions with a distinct minimum of precipitation in summer and soil water storage in winter, making up a high percentage of total cash crop water use – are more prone to result in yield losses due to cover crop induced soil water depletion than "input driven" ecosystems, where crop growth usually relies on timely rainfall input during the vegetation period.

Reuse of water is a common practice in water-scarce regions for a long time. The problems that have to be solved in this context include available effluent flow, crop water requirements, storage, chemical composition of the treated wastewater (heavy metal and salt concentrations), hygienic conditions, potential health risks, as well as plant, soil, and groundwater protection.

In the dry areas, water, not land, is the limiting factor in improving agricultural production. Appropriate measures are irrigation or – where not enough water is available – increasing of water productivity. It was shown by Oweis and Hachum (2003) that substantial and sustainable improvement in water productivity can only be achieved through integrated farm resource management. In order to increase plant available soil water, current policies look at the whole set of technical, institutional, managerial, legal and operational activities required to plan, develop, operate and manage the water resources system at all scale, i.e., farm, project, basin, and national scale, while considering all sectors of the national economy that depend on water.

Economy and soil water

Long-term water storage – also referred to as water "banking" – is an option to remediate climate change impacts on temporal rainfall distribution. Compared to storage basins, underground storage of water has some advantages: it is not related to a land loss and evaporation losses are prevented. Using the word "banking" indicates that water gets a value in an economic term. Pratt already (1994) introduced the concept of water banking (Pratt, 1994), and a working definition for it is provided by Singletary (2009): water banking is a tool for leasing water for a limited period of time on a voluntary basis between willing water rights holders and users. It provides temporary transfers of water entitlements based on how much water a user needs and when it is needed without a permanent change in water rights. The result is that an individual can decide to lease water, based upon a personal perception of

- Operational needs
- Current market value of the water
- Risk involved in the transaction
- Market value of the crop or product requiring water input
- Cost of the transaction

Saving or exchanging currency through monetary banks is strictly a choice. Similarly, water banking is strictly a choice. Water banking transactions take place without the threat of outside coercion.

Legislation and soil water

Growing environmental concerns led to regional and European regulations and consequently to the European Water Framework Directive (WFD), which provides a comprehensive legislative instrument. In this respect, soil water protection is equal to groundwater protection and is part of land use. Measures for groundwater protection are connected to the functioning of soil as buffer and filter zone. As an immediate result, a code of good agricultural practice which refers to fertilizers, plant protection, soil conservation, and livestock production is defined (BMLFUW, 2007). Adequate spreading technology and homogeneous fertilizer distribution are required. Special threshold values of heavy metal contents in mineral fertilizers are introduced and the application of liquid fertilizer and liquid manure are allowed only on fallow land and if runoff is not possible. If sewage sludge is applied a certified quality has to be ensured.

The view of legislation on agricultural practices is mostly negative as potential contaminator. The positive aspects of nutrient supply into the agro-ecosystem for securing soil fertility, increasing the organic matter not only for agricultural productivity, but also for maintaining the vital functions of soil as filter, buffer, gene reserve and the role in carbon sequestration are often not seen alike.

Conclusions

Increasing pressure on the environment needs measures to protect soil water in terms of quantity and quality. Soil water management needs to be embedded in the bigger frame of catchment resource management. Besides traditional hydro-melioration practices like irrigation and drainage, other measures like tillage, cover cropping soil amendments, crop rotation and plant adaptations are equally important to keep the soil water content in an optimal state.

SOIL WATER POTENTIAL (PRESSURE, HEAD)

The amount of work that must be done per unit of a specified quantity of pure water in order to transport reversibly and isothermally an infinitesimal quantity of water from a specified source to a specified destination. If the specified quantity is volume, the potential is referred to as pressure (Pa). If the specified quantity is weight, the potential is referred to as head (m). If the specified quantity is mass, the potential is the term used ($J \text{ kg}^{-1}$).

Soil–plant–atmosphere system

Definition

Soil–plant–atmosphere continuum is the near-surface environment in which water and energy transfer occurs from soil through plants to the atmosphere.

Introduction

John Philip (Philip, 1966) was the first to use the phrase “soil–plant–atmosphere continuum” (SPAC). According to his concept, SPAC integrates all components (soil, plant, animals, and the surrounding atmosphere) into a dynamic system in which the various transport processes involving energy and matter occur simultaneously.

The purpose of human activity in the areas being under agricultural use is plant production. The main aim of utilization of all agro-technical treatments is to create in the

soil an optimal condition for plant growth and development. This activity influences all constituents of SPAC.

The specific feature of soil–plant–atmosphere system parameters is their time and space variability and biological activity.

The soil system is composed of three major components: solid particles (minerals and organic matter), water with various dissolved chemicals, and air. The percentage of these components varies greatly with soil texture and structure. An active root system requires a delicate balance between the three soil components; but the balance between the liquid and gas phases is most critical, since it regulates root activity and plant growth process. It is necessary to mention about soil biota, which defines all organisms living within the soil. Soil organisms play a key role in cycling nutrients, which in turn impacts soil fertility and soil physical properties. They are also the indicators of soil health.

The role of soil in the soil–plant–atmosphere continuum is crucial. It is known that soil is not an essential factor for plant growth, and indeed plants can be grown hydroponically just with the application of water with proper fertilizers. However, usually plants are grown in the soil and soil properties directly affect the availability of water and nutrients to plants. Soil water affects plant growth directly through its controlling effect on plant water status and indirectly by its effect on oxygen availability through aeration, temperature variation, nutrient transport, uptake, and transformation. The understanding of these properties and processes is indispensable for irrigation system design and management.

Plants in SPAC play the role of water transmission from soil to the atmosphere. Actually few stages of long-distance translocation in plants are recognized, e.g., uptake of water by root system and its transport across root to the xylem, continued transport through xylem often several meters distance to the leaves and then transpiration. Some amount of water takes part in biochemical reactions in plant and in transport of assimilation products through phloem from leaves to organs where assimilation products are utilized.

The problem of scale

Environmental processes, their intensity and direction, originate from the basic processes of mass and energy transfer like evaporation, diffusion, and heat transport. These processes can be, in principle, described in a leaf scale with accurate physical equations. Most of the practical models are defined in a large scale of landscape or region. When scaling up the spatial coordinates, one is forced to include the description of more and more heterogeneous objects, which makes the model intractable. The way to solve this problem is hierarchical modeling of processes in different scales.

There are several scales of practical interest defined (Anderson et al., 2003):

- Leaf scale
- Plant scale

- Canopy scale
- Landscape scale
- Mesoscale

In each scale, processes and objects can be treated uniformly. Measurement data can be collected to provide parameters for the models specific for certain scale. The model results are then applied as part of input, or boundary description, to a higher scale model. Thus, the chain of hierarchical models allows spatial upscaling without loss of details of lower scale objects.

This kind of coupled model structure allows to gain reliable results for models like weather prediction model or yield prediction model from detailed data gained on a local scale.

Downscaling is also of practical interest. Remotely collected data by satellite means carry a lot of information, which in a sense is mixed due to the heterogeneity of area envisioned in pixels. Multi-scale model framework can be applied to support remote sensing data interpretation.

Soil–water–plant relationship

The soil is the main object that decides about water circulation in biosphere. It is a distributor of water, i.e., it receives and retains rainwater, transmits the water into deeper layers supplying underground water, as well as releases water into the atmosphere by evaporation and transpiration. Soil hydrophysical characteristics play a key role in the creation of plant growth conditions. They determine water availability for plant root system and water movement in soil profile.

Climatic factors such as air temperature, solar radiation, and wind speed control soil temperature. Solar radiation increases soil temperature, while other factors can cause increase or decrease of soil temperature. Temperature of soil under given conditions of thermal factors depends on soil thermal parameters: heat capacity and heat conductivity. Soil thermal properties in natural conditions are usually heterogeneous, and conditions of heat transfer are different in different positions in soil profile. This causes soil temperature spatial variability.

Water plays a crucial role in the process of plant growth, which involves cell division and cell expansion. The latter process occurs as each pair of divided cell imbibes water. The resulting internal pressure, called turgor pressure, stretches the elastic walls of the new cells, which thicken on account of the deposition of newly synthesized material.

Various terms used to characterize the status of water in different parts of the soil–plant–atmosphere system are merely alternative expressions of the energy level or potential of water. In order to describe the interlinked processes of water transport throughout the soil–plant–atmosphere continuum, one should evaluate the pertinent components of water energy potential and their effective gradients as they vary in space and time.

Soil water content and water potential, which is defined as the potential energy of water per unit volume relative to pure water in reference conditions gives the information

about amount of water present in the root zone and its availability for plants root system. Therefore, soil water content along with soil water potential should both be considered when dealing with plant growth and irrigation. For a specific soil, the soil water content and soil water potential are related to each other, and the soil water characteristic curve provides a graphical representation of this relationship.

The mechanisms of mass and energy transport in soil include molecular liquid diffusion, molecular vapor diffusion, capillary flow, convective transport, evaporation-condensation processes together with latent heat flow, pure hydrodynamic flow, and movement due to gravity. It is necessary to refer to freezing-thawing processes, which modify water transport through soil profile.

The mass flux is affected by the temperature and temperature gradient due to temperature dependence of bound water properties, as well as by the complicated pore network, which is difficult to describe in a given soil. The dominant mechanism under a specific set of conditions in a particular material often does not exist, and it is more likely that the mass and energy transport results from a combination of mechanisms. Due to this inherent complexity, theoretical models generally require assumptions that limit their applicability and a lot of measurement to verify them.

Water uptake by plants

A plant takes water mainly by the root system (Baranowski et al., 2005). At the first stage of water transport it finds its way along the root radius to the xylem, i.e., the bunch of conducting vessels. Then, water moves in xylem towards leaves. It is evaporated through the cells of mesophyll and cuticula and mainly through stomata into the atmosphere. A part of water taken by the plant is transported through phloem into cells, where the photosynthesis takes place.

Both passive and active water movement from the soil into the plant are the result of transpiration into the atmosphere. The passive process of water movement in the soil–plant–atmosphere system occurs under intensive transpiration. The intensity of transpiration is influenced by the difference of water potential in the plant and the water potential in the atmosphere. The water vapor potential in the atmosphere at the relative air humidity of 50% in temperature of 20°C is -94.1 MPa . In plant leaves in the same conditions, the water potential can reach values of minus several MPa. Such large difference of potentials confirms that the atmosphere is a huge “pump,” causing the water movement from plants into the surrounding air. Water losses in plants are compensated with water taken from soil, depending on the difference of water potentials between the soil and plant.

Water evaporates from plants by pores in the cell walls of mesophyll and cuticula. In these pores, concave menisci are created as a result of surface tension. In this case, the pressure lower than atmospheric arises, causing upward water movement in the xylem of whole plant. The pressure

of capillary rise reaches the value of -3 MPa . It is a cohesive mechanism of water uptake and conduction in plants.

The active water uptake and conduction in plants is based on root pressure. The root pressure is the result of water potential difference between the root xylem (higher solution concentration) and the soil (lower concentration). The osmotic movement is responsible for the water transfer from soil into roots. In case of strong salinization, the concentration of solution in the root can be much lower than in the soil solution. Then, the plant cannot take the soil water.

The soil water uptake can be hampered by the small coefficient of soil water diffusion. Despite high difference of water potentials in plant and soil, and therefore high potential evapotranspiration, the rate of water flow in soil towards roots can be too small, and the actual evapotranspiration can be strongly limited. Such situation leads to plant water stress.

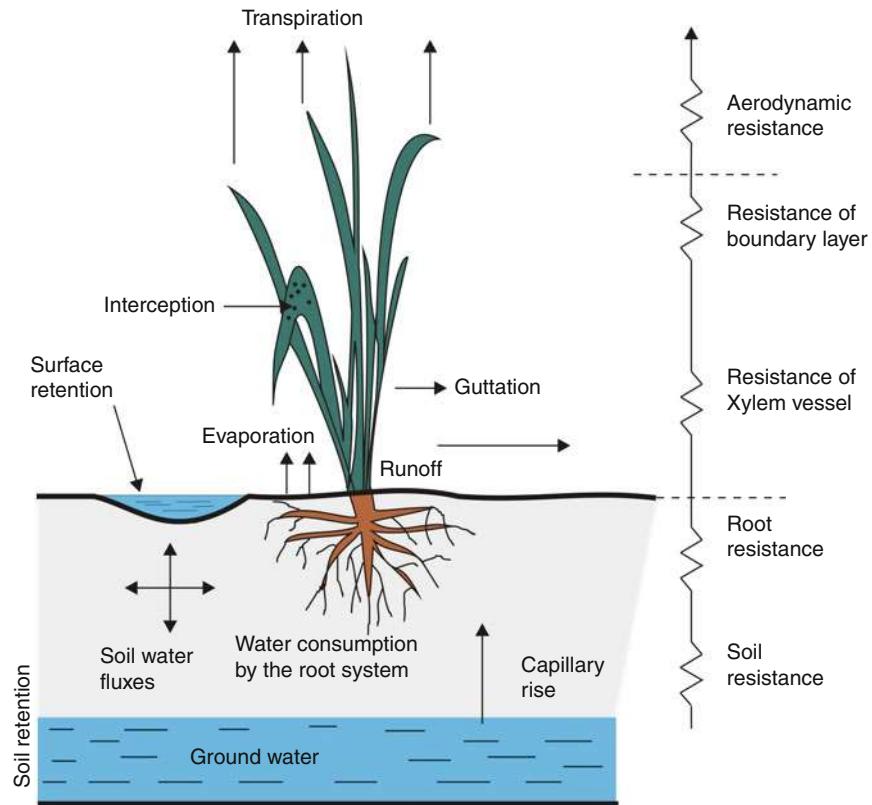

To explain the phenomenon of root pressure, many models were created, in which the transition into particular anatomical parts of the root, such as epidermis, endodermis, or xylem are treated as semipermeable membranes.

Another attempt to explain water uptake and conduction in plants is the theory of graviosmosis. The plant xylem is represented by a system of vertically placed compartments filled with solutions of various concentrations, connected by horizontally oriented semipermeable membranes. In this system, the graviosmosis force appears, causing the vertical water movement.

The resistance theory of water transport is used in many models of water flow in the soil–plant–atmosphere system. According to this theory, the flux density of moving water is proportional to the differences of water potential between the succeeding elements of the system, and inversely proportional to the resistance within these elements and at their interfaces. The resistance models are constructed as analogs of electrical circuits, and the role of resistors is played by water transport barriers, whereas the role of capacitors by the elements of water storage. In Figure 1, the water movement from the groundwater level through the plant into the atmosphere as well as accompanying resistances are presented. The groundwater enters into the unsaturated zone due the capillary rise. In this zone, water movement takes place in various directions, depending on the soil water potential gradients. The properties of the soil matrix, such as bulk density of the solid phase, grain size distribution, mineralogical and aggregate composition, water content, and water potential determine soil resistance for water transport in the root direction.

The root resistance for water transport is determined by intrinsic root structure which between others influences water potential in root. The resistance of the soil–root interface influences water potential difference in it as well as the quality of the soil–root contact, which is especially important in case of swelling and shrinking soils.

In plants, water is conducted by bunches of conducting vessels. In fact, they are the passive elements of the water

Soil-Plant-Atmosphere Continuum, Figure 1 Water movement in soil-plant-atmosphere system.

transport, and the resistance of the conducting vessels has an impact on the root pressure and the water potential in leaves. In a special case of some plants, where the root pressure occurs and simultaneously the water potential in leaves is equal to zero, which place under the relative air humidity close to 100%, water flows out on the plant's surface. This phenomenon is called guttation.

The resistance of the boundary layer includes the resistance for the water vapor transfer from the inside of the stoma chamber to the outside, which determines the pressure difference within the stoma chamber and on the leaf's surface, and the aerodynamic resistance of the air which has an effect on the water vapor pressure difference on the leaf's surface and in the atmosphere. The aerodynamic resistance depends on wind speed, atmospheric stability over the plant cover, and the architecture of the crop (its height and roughness).

Gas exchange in SPAC

It is generally agreed that soils play an important role in gaseous exchange and water and matter dynamics in terrestrial ecosystems. Much experimental work has been undertaken in the last few years in attempts to quantify the emission of greenhouse gases in terrestrial ecosystems and to identify the key factors that govern them. However,

fluxes vary greatly between ecosystems, and are often subject to great spatial and temporal variations within ecosystems. Consequently, there is an essential role for modeling, to scale-up observations made on relatively small areas to larger regions and ultimately to global level, and also to be able to predict the effects of environmental changes and changes in land management on future emissions.

The main components of soil oxygen demand are the microbial respiration of soil and the respiration of plant roots (Stepniewski et al., 2005). The contribution of the respiration of mezofauna as well as the contribution of chemical reactions is considered to be negligible and is usually neglected in models. Thus, the soil oxygen demand is used as synonymous for the soil respiration rate. Soil respiration rate is often expressed also as carbon dioxide production, as under aerobic respiration consumption of oxygen by volume is equivalent to that of carbon dioxide produced. The intensity of root respiration is usually higher by two orders of magnitude compared to the soil microbial respiration. Thus, the roots present themselves as linear objects of high oxygen demand on the background of the much less active soil matrix. Soil oxygen demand decreases with soil depth because both its components, i.e., microbial respiration and root density (and thus root respiration), decrease with depth.

Details of mass flux in SPAC

There is still a limited knowledge about mass flux details in SPAC and especially in plants. New investigations clarify some topics. Schroll and Kuehn (2004) developed a method and test system for determination of mass balance for organic compounds marked with isotope C14 in SPAC. Their experiment applies a lysimeter for the determination of C14 flux thus concluding the soil or the plant as the source of carbon in the flux. The stable oxygen isotopes were tracked to provide information on water use in walnut trees in paper (Lauteri et al., 2006). Analysis of concurrence conditions in a complex canopy is provided. Another attempt to investigate iodine isotope fate in plant is shown in Muramatsu et al., (1995) where the transfer factors of iodine were widely varied dependent on the plant type. Accumulation effects were discovered for the different plants in leaves. An important aspect of chemical compounds movement in the SPAC is phyto-remediation. Ouyang (2002) analyzed the fate of 1,4-dioxane with the application of SPAC idea with the application of model for coupled transport and accumulation of this pollutant. It comes out again that lives are very important in the accumulation of various pollutants.

Water and heat balance

The heat balance that includes radiation usually refers to a layer of the medium at the boundary with the atmosphere (water, soil, plant cover). Theoretically, it can be infinitely thin or it can have a specific thickness, e.g., corresponding to the thickness of plant cover. To express the basic processes of energy exchange in the system, the following form of the heat balance equation is used.

$$R_n - L \cdot E - H + L_p \cdot F_p - G + A_h = \frac{\partial W}{\partial t}$$

where R_n is the net radiative flux density at the upper surface of the layer (W m^{-2}), H is the sensible heat flux density (W m^{-2}), G is the density of the heat flux in the soil (W m^{-2}), L is the latent heat of vaporization ($2,448,000 \text{ J kg}^{-1}$), E is the water vapor flux density ($\text{kg m}^{-2} \text{ s}^{-1}$), L_p is the thermal conversion factor for fixation of CO_2 (J kg^{-1}), F_p is the specific flux of CO_2 ($\text{kg m}^{-2} \text{ s}^{-1}$), A_h is the energy advection into the layer expressed as specific flux (W m^{-2}), $\frac{\partial W}{\partial t}$ is the rate of change in energy storage per unit area in the layer (W m^{-2}).

Depending on the application, some components of this equation may be relatively less important and can be omitted. The most frequently used form of the heat balance equation takes into account four quantities: $L \cdot E$, H , R_n , and G .

The methods, which are based on the heat balance equation, assume one component of this equation as the unknown (usually it is $L \cdot E$ or H) and determine other components by direct or indirect methods.

A qualitatively new approach towards the problem of evapotranspiration determination with the use of the heat balance method was developed to measure remotely the

evaporating surface temperature. The radiation temperature, measured by remote sensing instruments with high accuracy and for large areas, creates an opportunity to modify the heat balance method to apply it for regional scale. The sensible heat flux, expressing the transport of heat energy from the evaporating surface into the atmosphere, is proportional to the difference of the air temperature at some level and the temperature of the studied surface.

Modeling of mass and energy transfer in SPAC

For the description of physical processes taking place in the SPAC, the constitutive physical equations are used, expressing the laws of momentum, mass, and energy conservation. The equations resulting from the conservation laws, describing a chosen phenomenon in this system, e.g., transport of water, salt and heat in the soil, soil deformation and stress as a result of reaction of wheels and working parts of machines and cultivation tools, need for their solution, the knowledge of transport coefficients characterizing the investigated object. Furthermore, for the proper verification of the solution of the applied equation, the knowledge of the dynamics of a studied physical quantity is indispensable, e.g., the dynamics of soil water content, salinity, gases and temperature, agro-climatic parameters such as amount of rainfall, radiation, air humidity, and temperature. Therefore, it is necessary to monitor the parameters of the investigated systems.

For modeling of mass and energy transport in SPAC, different transport processes should be taken into consideration occurring in soil as porous medium, in plants on short and long distances and from plants to ambient atmosphere.

Modeling processes taking place in the soil profile is an important and difficult task due to many transport processes occurring simultaneously and interacting with each other. These processes, among others, are transport of liquid water and water vapor, heat, soil air, dissolved salts and others chemicals. Which processes we are to consider depends on physical problem one wants to solve.

The common mathematical and physical framework for describing multicomponent and multiphase transport in porous medium is the linear thermodynamics of nonequilibrium processes. The partial differential equations, which describe such processes after several simplifications, are in general of the advection-diffusion nonlinear type with source terms.

The transport of water and heat are the basic processes, which must be taken into consideration almost independently apart from physical problem one is solving. Soil physical parameters depend on water content and/or temperature, whereas nonisothermal conditions in the soil influence nearly all the transport phenomena in the soil.

Water transport is described by Richard's equation of the form:

$$Cw(h) \frac{\partial h}{\partial t} = \nabla(K(h)\nabla(h - z))$$

where h is a pressure head [mH_2O], z is a distance from reference level, positive downward [m], $Cw(h) \equiv \frac{\partial \theta}{\partial h}$ is a soil water differential capacity function [m^{-1}], θ is volumetric soil water content [$m^3 m^{-3}$], $K(h)$ is an unsaturated hydraulic conductivity function [$m s^{-1}$].

The heat transport in soil occurs due to heat conduction and radiation. The heat flux caused by these phenomena is proportional to the gradient of soil temperature. The mean heat conductivity function describes soil heat transport properties. But apart from conduction and radiation, there may be also the convective heat transport, caused by liquid soil water migrating through the soil [4,5,8].

The equation which takes into account that transport phenomena has the form:

$$Cv(h) \frac{\partial T}{\partial t} = \nabla(\lambda(h, T) \nabla T) - c_{lw} \rho_{lw} \vec{q} \cdot \nabla T$$

where $C_v(h)$ is a volumetric heat capacity ($J m^{-3} \circ C^{-1}$) T is a temperature $\lambda(h)$ is the soil conductivity ($W m^{-1} \circ C^{-1}$) c_{lw} is a specific heat of liquid water ($J kg^{-1} \circ C^{-1}$) ρ_{lw} is a liquid water density ($kg m^{-3}$) The \vec{q} is Darcy velocity described by equation

$$\vec{q} \equiv K(h) \nabla(h - z)$$

which expresses the soil water movement velocity.

Summary

The concept of SPAC recognizing soil–plant–atmosphere system as integrated, dynamic system of all constituents, including living entities is widely accepted as way of understanding the system. In this sense, all the constituents and processes in the system should be considered together as embedded in it, interconnected mutually, and dependent of each other. Dynamic properties of each part of the system influence all other parts. Constituents and processes may be considered on various time or space scales. Mathematical description on different scales can vary according to the importance of constituents and processes at a given scale.

SOIL-WHEEL INTERACTIONS

Hiroshi Nakashima

Agricultural Systems Engineering Laboratory, Division of Environmental Science and Technology, Graduate School of Agriculture, Kyoto University, Oiwake-cho, Kitashirakawa, Sakyo-ku, Kyoto, Japan

Synonyms

Off-road wheel locomotion; Soil–tire interactions

Definition

Soil–wheel interactions are action and reaction relations between two contacting bodies – soil and a wheel – that occur during off-road locomotion and are foundations for the evaluation of the performance of wheeled vehicles.

Introduction

In agricultural operations in natural open fields, soil is a working material that is often encountered, the types of which are classifiable from clay to sand depending on the particle size distribution. In fact, softening of soil is the main purpose of tillage work. For agricultural vehicles, however, the capability of locomotion should be maintained in all soil conditions at the time of machinery operations. This kind of off-road wheel locomotion is often observed not only in agricultural vehicles but also in construction and military vehicles on earth and in extraterrestrial exploration vehicles. In principle, the

performance of wheeled vehicles depends on the contact mechanics at soil–wheel interfaces, where normal and tangential reactions play an important role. The analysis of contact interactions in relation with off-road vehicle performance is called terramechanics, which originated from rational studies by Bekker (1956, 1960). However, terramechanics belongs to typical nonlinear problems, in which the shape of the contact surface as well as the contact reaction can be determined only after the contact of two bodies – the soil and a wheel. Consequently, a simplification procedure should be applied to solve such problems approximately to reach an engineering solution. Two mathematical expressions of contact reactions – namely pressure–sinkage relations and shear stress–shear displacement relations – were introduced into the soil–wheel interface with the a priori assumption of the contact surface, which is now known as the semiempirical method (Wong, 1989). Moreover, further intensive studies of this framework have realized the development of a computer-aided performance prediction model for off-road vehicles based on the semiempirical method (Wong, 1989; Wong, 2008). Regarding numerical methods for soil–wheel interactions, the discrete element method (DEM) has recently become popular in performance analysis of wheels for off-road locomotion with various tread patterns (e.g., Oida and Ohkubo, 2000). For simplicity, the following explanation is limited to two dimensions unless otherwise stated.

Semiempirical model of soil–wheel interactions

The semiempirical method proposed by Bekker has contributed considerably to the understanding of soil–wheel interactions by introducing mathematical expressions for pressure–sinkage and shear stress–shear displacement relations on a simple contact interface with experimental identification of parameters used in those expressions.

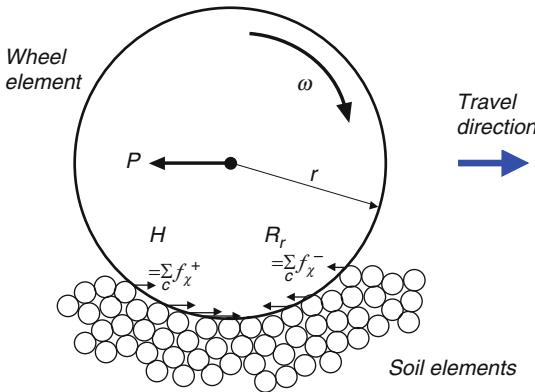

The pressure p in the pressure–sinkage relations might be understood as the contact pressure at the lowest wheel sinkage, which can be expressed as the given wheel contact load over a horizontally projected contact area, and which is a function of sinkage z to the n -th power, namely $p = k_{\text{eq}} z^n$, where $k_{\text{eq}} = k_c/b + k_\phi$ (Wong, 1989). Parameters k_c , k_ϕ , and n are obtained from measurement data using a *Bevameter*; b is the smallest width of a plate used in the measurements (Bekker, 1960). Moreover, the pressure distribution at the soil–wheel contact interface is assumed to be the same as the normal stress distribution over the contact length of the wheel as a function of sinkage. Therefore, for any value of parameter n , the maximum contact pressure is always generated at the largest wheel sinkage, or at the bottom dead center of a rigid wheel, as far as the pressure–sinkage relation is concerned. It is noteworthy that previously reported experimental results exhibited no such behavior and that the peak of contact pressure was generally observed before the bottom dead center of the wheel (e.g., Onafeko and Reece, 1967).

Shear stress–shear displacement relations were first incorporated from the response of a damping vibration model with explicit overshoot, or hump, behavior to express the brittle soil response. However, because of the difficulty in its use and because of the fact that plastic soils show rather monotonous response of shear stress without overshooting, a simpler and more useful exponential expression presented by Janosi and Hanamoto (1961), $\tau/\tau_{\max} = 1 - \exp(-j/K)$, has become popular to characterize the shear stress–shear displacement relation. In that equation, K is the shear deformation modulus, and τ_{\max} is the maximum shear strength, which might be expressed as $\tau_{\max} = c + p \tan \phi$ using the Mohr–Coulomb equation, where c signifies cohesion and ϕ denotes the angle of internal friction. The shear strength of soil depends on the loading condition. Therefore, the deviation of shear stress–shear displacement curves was introduced as a function of the applied normal contact stress p at the soil–wheel interface to connect two separate relations (Wong, 1989).

Although the semiempirical method depends on the assumption of two simple relations and although there exist different behaviors of the pressure–sinkage relation as evidenced from the experimental observations stated above, the analysis of traction performance for an off-road wheel using this method has been updated for use as a practical tool in terramechanics (e.g., Wong and Asnani, 2008).

Recent developments in traction analysis

Wheel performance depends on the wheel's surface condition as well as soil properties such as the soil shear strength. A lug-patterned wheel, called a lugged wheel, is generally assumed as a basic model for off-road wheels. Various tread patterns on a wheel might also be introduced depending on the mission of off-road vehicles for a given terrain condition. With improved performance of computers, numerical methods have been applied increasingly to various interaction problems in terramechanics. Among others, the discrete element method (DEM) developed by Cundall and Strack (1979) has become popular for analyses of lugged wheel performance on off-road terrain because the action of the tread pattern can be modeled easily using DEM. In DEM, virtual elements of a circle (Oida and Ohkubo, 2000; Nakashima et al., 2007), sphere (Horner et al., 2001), ellipsoid (Hopkins et al., 2008), clumped circles (Asaf et al., 2006), or other shape might be used as the soil element. Contact reactions between soil elements and between soil and wheel elements can be expressed simply as a parallel-connected linear spring and damper system in normal and tangential directions. Alternatively, nonlinear expressions such as the normal contact model of Hertz (Johnson, 1987) or the Mindlin–Deresiewicz tangential contact model (Mindlin and Deresiewicz, 1953) might be introduced. Coulomb friction is also installed in a tangential direction. Moreover, a tensile spring might be added to express the cohesive

Soil-Wheel Interactions, Figure 1 Soil-wheel interface.

effect between soil elements for analyses of cohesive soil-wheel interactions. Once all contact reactions are obtained, the equations of motion are constructed for all DEs; they are then integrated explicitly with a stable time step to obtain updated accelerations, velocities, and displacements. Parameters used in DEM must be prepared, but they cannot be determined through experiments because the radii of soil elements are usually larger than those of the soil particles.

Traction analysis of wheels using DEM is usually conducted as follows: (1) generation of discrete elements and consolidation of soil elements by their own weight, (2) free sinkage of wheel on soil elements until the vertical contact load condition is satisfied, and (3) wheel travel analysis with a given drawbar load condition. **Figure 1** portrays a typical soil-wheel interface in the wheel locomotion by DEM. To maintain simplicity, the tread pattern on the wheel surface is not presented in the figure.

For analysis of wheel performance using DEM, the gross tractive effort H of the wheel is calculated as the summation of all positive components of contact reactions at contacting wheel and soil elements. The running resistance R_r of the wheel is obtainable as the summation of all negative components of contact reactions. Then, the net traction P_n of wheel is calculable as $P_n = H - R_r$ (Oida and Ohkubo, 2000; Nakashima et al., 2007). The net traction P_n equals the drawbar load P shown in the figure. The expression of tread patterns can be realized by additional virtual small discrete elements embedded into the wheel rim surface (Nakashima et al., 2007). The result of DEM in general shows vibratory behavior of data. It should be averaged to obtain the required traction-related interactions at soil-wheel interfaces. The accuracy of analysis by DEM must be verified through precise experiments to assess the common conditions between experiments and simulations. For necessary verifications, the recent development of small force sensors is expected to contribute to such measurement of local normal and tangential contact reactions on the contact surface of a wheel or tire running on soil (Kasetani et al., 2010).

Summary

Soil-wheel interactions were analyzed traditionally using semiempirical methods from an engineering perspective. The development of computer capabilities will surely contribute to a deeper understanding of soil-wheel interactions. Moreover, it seems clear that not only conventional conditions but also some extended conditions related to soil-wheel interactions are solvable using such numerical methods as the discrete element method. Through these parametric analyses, we will be able to construct a new perspective for innovative running devices that might yield higher traction performances than conventional wheel systems.

Soil disinfestation; Soil pasteurization

Definitions

Soilborne pathogens. Soil-dwelling organisms (e.g., fungi, bacteria, or nematodes), which attack the roots of host plants and cause damage.

Root diseases. Malfunction in plant development and production caused by soilborne pathogens.

Disease control. Management of plant malfunction that aims at killing the pathogen or suppressing its activity, hence resulting in reduced disease incidence or severity.

Introduction: soilborne diseases and their control (management)

Soilborne pathogens (fungi, bacteria, nematodes) cause plant diseases, and consequently severe losses, in all major economic crops. These pathogens live in the soil and are therefore affected by the soil's physical, chemical, and biological characteristics, as well as by the agricultural practices applied to it, for example, irrigation, fertilization, and tillage. The close connection between soilborne pathogens and soil, their natural habitat, complicates their control, since it is difficult to reach all of the propagules at all soil sites. The basic principle of root-disease control is to manipulate or interfere with the interactions between pathogen, host, and their biotic and abiotic environments, in order to achieve an economic reduction in disease. The basic means used to achieve this goal are chemical, physical, biological, and cultural. There is increasing public concern over environmental pollution by pesticides. Consequently, there is increasing interest in physical methods of disease control which do not pollute the environment with chemicals. However, their use may involve problems of safety, energy transfer, technology, and cost.

Soil disinfestation in its present form was established at the end of the nineteenth century. Two approaches were developed at that time: chemical, for example, the use of fumigants, and physical, for example, soil steaming. It was only about 100 years later that a third approach for soil disinfestation – soil solarization, which involves heating the soil by solar energy – was developed. The amount of time taken for this third approach to emerge emphasizes the difficulties involved in introducing new approaches for soil disinfestation. Chemical soil disinfection, which is still the major soil-disinfestation practice, is not the focus of this entry and will therefore not be discussed.

Soil disinfestation involves the use of drastic means to treat the soil (Katan, 1984; Tjamos et al., 1999). It is carried out before planting, and is aimed at maximal reduction of the pathogen population in the soil to the desired soil depth (30–50 cm in soil or 10–20 cm in soilless culture). Soil disinfestation should create minimal disturbance of the biological equilibrium as a whole (especially beneficial microorganisms), and minimal changes in the soil's chemical or physical properties. Moreover, the control agent, or its decomposition product, has to dissipate before planting to avoid harmful residual effects. The execution of soil disinfestation is sophisticated and expensive, but it is also an effective method of eradicating soilborne pathogens, as well as other pests, for example, soil arthropods and weeds. Soil disinfestation was initially developed only for the control of harmful biotic agents. However, later on, its effects on abiotic soil components, for example, improvement of the plant's mineral nutrition status, were reported (Chen et al., 1991 and see further on). Although soil disinfestation should control a wide spectrum of soilborne pests, it does not protect the soil against contamination from outside sources once the disinfestation effect has ceased. Hence, a supplementary step needs to be taken, following soil disinfestation and during crop production to avoid reinfestation by soilborne pests from outside sources.

Physical methods of soil disinfestation: soil heating

The main approaches to disinfecting soil, which involve the utilization of heat energy in the form of hot water are the application of steam or flooding the soil with hot water. Heating the soil by applying hot air or microwave radiation has also been tested, but commercial implementation is questionable. Steam sterilization consists of applying pressurized steam under a mulched cover, and its penetration to the depth of the cultivation layer (Baker, 1962; McGovern and McSorley, 1997). Steam disinfection is very expensive as it consumes a high rate of energy (fuel), and involves expensive and sophisticated machinery. In sandy soils, penetration of the steam to deep soil layers requires a sucking infrastructure which is buried in the soil as a permanent

component of the greenhouse. Furthermore, the capacity of this process is low, enabling its application only on a small-farm scale.

Hot water treatment consists of a similar energy of water heating, but to a much lower water temperature. This soil-disinfestation approach consists of pouring water at a temperature of 70–95°C on the soil. Hot water treatment was developed in Japan, where it showed high control efficacy of fungal and bacterial pathogens and nematodes down to a soil depth of 30 cm (Nishi et al., 2003). However, the use of this approach did not expand beyond that country. The practical aspects of steam disinfection (energy consumption, equipment, etc.) also apply to hot water treatment.

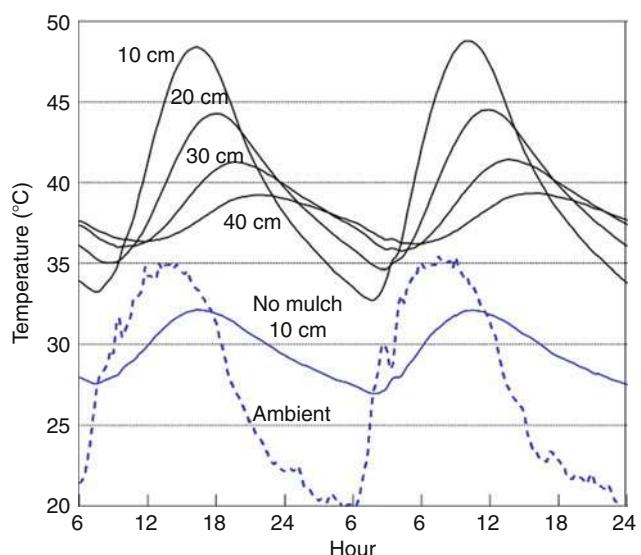

Attempts have been made to utilize electromagnetic energy as a means for dry heating. However, the energy and time needed to achieve pathogen control makes this approach impractical for soil disinfestation.

Soil solarization

Soil solarization in its present form for soil disinfestation was first described and reported in 1976 (Katan et al., 1976). Solarization consists of using solar energy to elevate soil temperatures by mulching a wet soil with transparent polyethylene under the appropriate climatic conditions (hot season with high solar irradiation). The heated soil kills soilborne pests, improves plant health and consequently, increases crop yield. This process has also been variously referred to as: solar heating of the soil, solar pasteurization, and solar disinfestation. However, the term “soil solarization” is the accepted and most widely used term.

Soil solarization can be carried out directly in the open field or in the greenhouse. Solar heating results in relatively mild temperatures, as compared to artificial and intense heating methods which are usually carried out at 70–100°C. The principles of soil solarization have been described in detail in many reviews and books (e.g., Katan, 1981; Katan and DeVay, 1991; McGovern and McSorley, 1997; Stapleton, 2000; Gamliel and Katan, 2009) and are summarized as follows:

1. Solar heating elevates soil temperatures through repeated daily cycles. At increasing soil depths, the maximal temperatures are lower than in the upper layers. In the deep layers, the maximal temperature is achieved later in the day, but it is maintained for longer periods (Figure 1).
2. The best time for mulching the soil and applying soil solarization relies on the appropriate climatic conditions, that is, periods of high temperature and extended daylight. These can be determined experimentally by tarping the soil and measuring the temperatures at various depths. Meteorological data from previous years and predictive models (see further on) are very useful in this decision-making process.
3. Adequate soil moisture during solarization is crucial. The water in the soil enables heat transfer, increases

Soilborne Diseases, Control by Physical Methods,

Figure 1 The daily course of soil heating by polyethylene (solarization) at three soil depths, as compared to nonsolarized (no mulch) soil at a depth of 10 cm. Typical results obtained during July–August in Rehovot, Israel.

the thermal sensitivity of the target organisms, and enables biological activity during solarization.

4. Proper preparation of a soil for planting is essential since after plastic removal, the soil should not be disturbed, in order to avoid recontamination.
5. The soil is mulched with thin, transparent sheets of polyethylene or other plastic material for 3–6 weeks. Mulching the soil in a closed greenhouse (glass or plastic) further improves soil heating. Novel technologies, such as the use of sprayable plastics (Gamliel et al., 2001), can enable plastic mulching of the soil in large-scale areas such as for field crops.
6. Solarization alters the chemical, physical, and biological properties of the soil, which further affects pest control and may benefit plant growth and yield (Chen et al., 1991).

Under appropriate conditions, many soilborne pathogens, such as fungi (e.g., *Verticillium*, *Fusarium*, *Phytophthora*, *Pythium*, *Pyrenophaeta*), nematodes (e.g., *Pratylenchus* and *Ditylenchus*), and bacteria (e.g., *Clavibacter michiganensis*), as well as a variety of weeds, especially annuals, are controlled by solarization and consequently, yields increase.

As with any soil-disinfestation method, soil solarization has its advantages and limitations. It is a nonchemical method that has less drastic effects on the biotic and abiotic components of the soil. Nevertheless, the possibility of negative side effects should not be ignored. Soil solarization is very simple to apply and it is frequently less expensive than chemical disinfestation. The limitations of this method stem from its dependence

on appropriate climatic conditions: it can only be used in certain climatic regions and during limited periods of the year. In addition, during the solarization process (3–6 weeks), the soil remains without a crop. Nevertheless, this method has attracted many researchers from over 60 countries (Gamliel and Katan, 2009) and it is also used by farmers, especially in combination with other methods. It has been commercially adopted and is currently being used in Israel, Jordan, Greece, Turkey, Spain and Latin American countries, among others.

Physical principles

The principles of soil heating and the energy balance of bare and mulched soils have been described in various publications (e.g., Mahrer, 1991). The main factors involved in soil heating are climatic (e.g., solar radiation, air temperature, air humidity, and wind speed), soil properties, and photometric and physical characteristics of the mulch. The fluxes of energy that have to be considered are:

R_g Global radiation (waveband of approximately 0.3–4 μm)

R_L Atmospheric (long-wave) radiation (waveband of approximately 4–80 μm)

S Conduction of heat in the soil (soil heat flux)

H Vertical heat exchanges with the air enclosed between the mulch and soil by conduction and with the surrounding air by convection (sensible heat flux)

E Condensation and evaporation of water (latent heat flux)

The two basic equations describing the energy balance of bare and mulched soils, respectively, are:

$$R_{sn} + R_{Ln} - H - E - S = 0 \quad (1)$$

$$R_{snm} + R_{Lnm} - H_m - E_m - S_m = 0 \quad (2)$$

where subscript m stands for mulched soil and R_{sn} and R_{Ln} are the net fluxes of short- and long-wave radiation at the bare soil surface, respectively; S , H , E are soil heat flux, vertical heat exchanges, and condensation and evaporation of water, respectively.

Using these equations, a one-dimensional numerical model to predict the diurnal cycle of soil temperature in mulched and bare soils was developed, with good agreement between observed and predicted soil temperatures. Calculations showed that increased soil temperature in wet mulched soil is mainly due to a reduction in heat loss through sensible and latent heat fluxes during the day, and partially due to the greenhouse effect of the wet cover (owing to the formation of small water droplets on its inner surface). A model suitable for humid areas was described (Wu et al., 1996).

Application

Continuous mulch is desirable for effective soil solarization as it enables effective disinfestation of a wide area

and also improves control efficacy and reduces soil reinfestation. However, strip solarization applied to raised beds also increases soil temperatures and results in effective pathogen control under appropriate conditions. Moreover, relatively small plots can be covered manually. The edges of the sheet should be firmly embedded in the soil, while ensuring film tightness. For relatively small plots, a continuous plastic covering can be achieved by manually anchoring the edge of two adjacent sheets together in one furrow (Grinstein and Hetzroni, 1991). Mechanized plastic mulch is preferred and used in large plots. It is applied essentially as soil fumigation is performed. The tarp-laying machine unrolls plastic strips (2–4 m width), each of which is anchored to the soil on one side and connected to the other sheet by means of glue or welding. Sheet glue is moist and is sprayed in a 5- to 8-cm strip along the edge of the previously laid sheet near the border of the anchored area. Since solarization requires a minimum period of 30 days, the glue has to be long-lasting. In recent years, suitable glues have been developed and are used for continuous mulching. An alternative system to weld polyethylene sheets together was developed in Israel (Grinstein and Hetzroni, 1991): sheet fusing is accomplished with hot air streams, emitted from a combustion chamber and directed onto the plastic sheets.

Sprayable polymers offer a feasible and cost-effective alternative to plastic tarps for soil solarization. The plastic-based polymers are sprayed on the soil surface in the desired quantity and form a membrane film, which maintains its integrity in soil and elevates soil temperature. Nevertheless, the formed membrane is porous, allowing overhead irrigation. The soil-heating process with sprayable mulch is faster than that with plastic film, but the soil also cools down to lower temperatures at night. The thickness of the sprayed coat is critical to obtaining effective heating mulch. Soil solarization using sprayable mulches was shown to be effective at controlling Verticillium wilt and potato scab in potato (Gamliel et al., 2001). The level of control was as effective as that achieved by solarization using plastic films. Nevertheless, the use of sprayable polymers needs to be further improved.

Another application of soil solarization is structural solarization for controlling pathogens and other pests remaining in the greenhouse structure (Shlevin et al., 2003). This is accomplished by closing the greenhouse between crops and during the hot season. The temperatures are raised to 60°C and higher, resulting in pest control, namely, sanitation. A model simulating the heating process under structural solarization has been developed (Shlevin et al., 2003).

Concluding remarks

Soil disinfestation for controlling soilborne pathogens is much needed for an ever-growing world population. However, there is an urgent need to replace the widely used polluting fumigants with environmentally acceptable

methods. Physical methods can meet this demand, but so far their use has been limited. To further expand their use, we have to further improve their effectiveness in pest control and methods of application in an attempt to reduce their cost and make them economically acceptable.

SOLAR DRYING OF BIOLOGICAL MATERIALS

Istvan Farkas

Department of Physics and Process Control, Szent Istvan University, Gödöllő, Hungary

Synonyms

Solar dehydration; Sun drying

Definition

The solar drying of different grains, fruits, vegetables, and other materials of biological origin plays an important role in influencing energy savings, quality of end-products, and environmental impacts. There is a number of drying methods currently available, but it is worth taking into account the technical and economical benefits of solar drying, with the substantial number of commercially available solar dryers in operation today. However, for some special cases, individually designed solar dryers have also been developed. The applicable temperature range and energy requirement for moisture removal are the most important parameters in designing a safe and cost-effective drying system. During the drying of biological materials, the solar-assisted preheating of drying air fits to such requirements.

Introduction

There is no doubt that using solar energy is a promising solution in attaining the technical, economical, and environmental demands raised in the course of a drying process. For this reason, several new approaches in the application of dryers and biological materials are under development in order to produce a high quality of product at competitive cost. The new approaches include designing of new type of solar dryers, revising of existed traditional dryers with solar preheating unit and use the multipurpose operation of solar units. For example, dried material cases can be as barley, rice, peach, apple, grape, plum, cherry, blackthorn, pineapple, carrot, onion, chili, tomato, pegaga leaf, hay, tobacco, timber, fish sardines, and shark fillets. The feasibility of solar drying must include several additional factors, such as local climate, variety of biological materials, the amount of material to be dried, etc. In addition to the practical issues, the

research and development priorities in solar drying fall into similar directions.

Solar grain drying

The traditional use of solar energy for grain drying is in a forced convection heated air system. A small-scale solar dryer can be used effectively for drying of various agricultural crops (Farkas, 2004, 2008). A design method for sizing solar-assisted crop-drying systems and assessing the combination of solar collector area and auxiliary energy needs that meets the load. Two empirical correlations were compared for their use with high thermal inertia solar collectors, which are cheap and adequate in rural areas. The grain drying with partial air heating by solar energy can provide an annual economy of about 30% in the fuel consumption (Santos et al., 2004).

Solar fruit drying

There are several types and sizes of fruit that often need to be handled together during the drying process, using the same equipment. For that purpose, a modular solar tray dryer was designed (Farkas, 2004, 2008). Two basic variations were considered of which one is a surface dryer, the other one is a batch or “overflowing” solution. The modular construction of a dryer means that the equipment does not need to contain all of its parts for operation. It can be used with or without the solar collector, with natural (without fan) or forced airflow. The dryer has four main sections: a drying chamber with different trays, a photovoltaic (PV) module, a grid connected fan, and a solar collector unit. With a modular construction, the dryer can be operated with natural ventilation by ambient air, artificial ventilation of ambient air with PV module, artificial ventilation of collector preheated air, and combined uses as well. During the drying experiments, several types of fruit were tested, e.g., grape, peach, plum, cherry, and blackthorn. Carrot and apple in the same solar dryer have been studied in order to evaluate the weight losses during the drying period and to present the temperature and moisture content distributions in the modular solar dryer (Romano et al., 2009).

A hybrid solar dryer has been constructed relying on solar energy to heat forced airflow for drying fruits (Amer et al., 2006). A heat exchanger placed inside the collector is used during sunny days to heat water from the heated air and the direct solar radiation. While at night, hot water flows through the exchanger to heat air in the reverse direction. Additionally, electric energy can be applied during the night to complete the heating of water in case the stored energy in the water tank is insufficient for heating the drying air during the night.

Solar vegetable drying

There are several type of vegetables dried in both direct sun drying and in solar dryers all over the world. Due to the long drying time during sun drying, however, the quality parameters as color, flavor, and nutrients are often

affected and solar drying may be preferably recommended (Prakash et al., 2004; Praveenkumar et al., 2006).

A batch type solar dryer was designed for different agricultural products and used recently for drying onion (Bennamoun and Belhamri, 2002). The dryer is constructed from brick walls, supporting ten trays to hold the material to be dried. The solar air collector is constructed from glass Pyrex plate and a black painted aluminum plate serves as the absorber. An auxiliary heater could be mounted to the dryer.

Recently specialists are opting for forced convection solar tunnel drying for drying of various crops (Pangavhane and Sawhney, 2002). A mixed mode type forced convection solar tunnel drier was used to dry hot red and green chillies (Hossain and Bala, 2007). The drier consisted of transparent plastic covered flat-plate collector and a drying tunnel connected in series to supply hot air directly by two fans operated by a photovoltaic module. The drier has a loading capacity of 80 kg of fresh chilies.

Tomato is a widely used vegetable. A vacuum-assisted solar dryer have been developed to study the drying kinetics of tomato slices (Rajkumar et al., 2007). The drying time for drying of tomato slices of 4, 6, and 8 mm thicknesses starting from initial moisture content of 94.0% to a final one of $11.5 \pm 0.5\%$ (w.b.) was 360, 480, and 600 min in vacuum-assisted solar dryer and 450, 600, and 750 min in open sun drying, respectively. Beside the drying time taken for drying the additional benefit of vacuum-assisted drying was that the quality of tomato slices dried in such solar dryer was higher in terms of color retention.

Solar drying of medical plants

Simple solar dryers are the most useful equipment in maintaining the medicinal properties of medicinal herbs. Their construction costs are cheap and maintenance costs tend to be low, whilst being used for drying different sorts of herbs. It has been studied the drying kinetics and quality (color degradation) of the pegaga leaf by varying the inlet air temperature and relative humidity using a solar assisted dehumidification drying system (Yahya et al., 2004). They concluded that there the solar drying system is suitable for drying of pegaga leaf without significant loss of quality.

Solar wood drying

The main parameters affecting the process in a drying kiln are the temperature, humidity, and velocity of the air stream. There are presented several theoretical models for solar drying of timber based on conventional mass transfer equations (Khater et al., 2004; Helwa et al., 2004). The effect of several parameters on the drying rate was studied in order to accomplish minimal drying defects. These parameters include ventilation conditions, wood volume, wood timber thickness, season of drying, and the drying air velocity. It has been concluded that the most influencing parameter using solar energy for timber drying is the drying air relative humidity. It is advised to leave open the fans through the night, especially within

the first period of drying. It is better to load the kiln with its full capacity to save the duration of drying of smaller timber volumes. Proper design is needed for the absorber area and the timber volume to be dried. The experiments showed that timber boards were dried inside solar kiln to moisture content of 12% within 17 days, meanwhile the drying air humidity was limited to 20%.

Solar fish drying

Solar drying of fresh fish sardines was investigated in terms of drying rate and quality (Sablani et al., 2002). Four different solar dryers, namely, rack dryer, multi-rack dryer, wooden, and plexiglas cabinet dryer were used. The wooden cabinet provided the fastest drying rate as it generated higher air temperatures followed by the multi-rack, rack, and plexiglas cabinet dryer.

The sun versus solar drying of salted shark fillets was investigated (Sankat and Mujaffar, 2004). Salted slabs were dried in direct sunlight and compared to drying using two natural convection solar dryers of similar design but employing direct and indirect drying. Of the three drying treatments, slabs dried in the open air dried the fastest, while drying was slowest in the indirect dryer. Sun-dried slabs were of acceptable quality, but somewhat inconsistent in color. Slabs dried in the direct solar dryer had a pleasing and even color and texture. The solar drying of salted shark is therefore an attractive option for small-scale fish processors.

Multipurpose use of solar dryers

An attractive advantage of solar dryer is their versatile use, i.e., the same design of solar dryer can be used for different sorts of crops. A solar assisted indirect dryer may consist of a solar air collector, a heat storage unit, a drying chamber, and a solar chimney, and it can be used for different crops such as rice, tobacco, etc. (Vlachos et al., 2002).

A new solution of a solar, mobile, universal, and ecological chamber dryer that satisfies the basic three requirements in the drying process: maximal process intensity, good quality of the dried material, and minimal energy consumption was designed (Topic and Topic, 2006). The solar dryer characteristics are based on a construction solution which met the following requirements: operation at any location (mobile solution), low costs, possible drying of different products, better quality of the dried material, and a better economic effect. The dryer was successfully used for drying biological materials such as fruits and vegetables, medicinal and aromatic herbs, and spices.

Integrated solar drying systems

In a typical agricultural farm, there is an impetus to maximize collection of all available energy resources, including solar, and distribute them optimally among the different consumers, including dryers, which require a fairly great portion of the total energy. This task requires an integrated solar energy/technology approach (Farkas, 2004, 2008). Setting up a solar preheating system can be economically justified if the solar energy is used throughout the year.

The integration of solar energy into the farm energy system seems to be economically possible.

An indirect type natural convection solar dryer with integrated collector-storage solar and biomass backup heaters have been designed and constructed (Madhlopa and Ngwalo, 2007). The dryer was fabricated using simple materials, tools, and skills, and it was tested in three modes of operation as solar alone, biomass combustion alone, and a combined solar-biomass combustion by drying 12 batches of fresh pineapple. It appears that the solar dryer is suitable for dehydrating pineapples and other fresh foods.

A direct solar-biomass dryer was developed when the biomass burner has a rock slab on the top part which assists in moderating the temperature of drying air (Prasad and Vijay, 2005). Such dryer designs have a backup heater without thermal storage of captured solar energy. Consequently, the air temperature in the drying chamber drops down to ambient after the sunset, requiring backup heating even when the preceding day was sunny. This leads to wasting of both solar and fuel resources.

A solar dryer can be installed with a thermal storage system (El-Sebaii et al., 2002). The air heater part is designed to be able to insert various storage materials (e.g., sand) under the absorber plate. The dryer was tested with and without thermal storage. The thermal storage system reduces the drying period, as for example, in the case of seedless, grapes the reduction was 12 h.

A natural convection solar dyer and a simple biomass burner can be combined for small-scale processing of different fruits and vegetables (Bena and Fuller, 2002).

Summary

The solar drying of materials of biological origin plays an important role in energy savings, quality of end-products, and environmental impacts. The applicable temperature range and energy requirement for moisture removal are the most important parameters in designing a safe and cost-effective drying system. The traditional use of solar energy for drying is a forced convection heated air system, which can be used effectively for drying of various agricultural as grains, fruits, vegetables, medical plants, wood, fish, etc. An attractive advantage of solar dryer is that the same design of solar dryer can be used for different sorts of crops. The integrated use of solar energy means to maximize collection of all available energy resources, including solar, and distribute them optimally among the different consumers, including dryers.

SOLUTE TRANSPORT IN SOILS

Yves Coquet, Valérie Pot
UMR 1091 INRA/AgroParisTech Environment and Arable Crops, AgroParisTech, Thiverval-Grignon, France

Synonyms

Solute transfer in soils

Definition

Solute. A substance dissolved in a solvent, both forming a solution.

Soil solution. The soil water that contains various solutes.

Solute transport. Group of processes by which solutes are transported through a medium.

Introduction

Soil is a natural medium at the interface between rocks, air, water bodies, and biota. As a result of this particular position in the biosphere, soil is crossed through by multiple flows: flow of air, water, heat, energy, solutes, solid particles, cells, organisms. Most of the transport processes in soil occur through its pores, either filled with air in the case of gases, or filled with water in the case of solutes and suspended particles. From the quantitative point of view, the transport of matter in soil is occurring in large majority via the soil solution, which refers to the soil water including all substances that can be found in it (solutes, suspended particles, dissolved gases). Even important gases for soil organisms, such as oxygen, carbon dioxide, and nitrogen, are transported at some stage in dissolved state through the soil solution. Most of the chemical elements and substances are transported in soil as solute in the soil solution. Nitrate, phosphate, carbonates, calcium, potassium, pesticides, etc., are all transported as solutes in the soil solution, but at rate which are largely dependent on their solubility in water. It is in the soil solution that soil organisms, including plants, take up the chemical elements and substances necessary for their growth. It is also through the soil solution that pollutants are put in contact with living organisms and can then enter and contaminate their bodies. Knowledge about solute transport in soils is

therefore essential to the understanding of plant nutrition and environmental contamination.

Solute transport processes

As water moves through the soil, it carries any substance dissolved in it. The transport of solutes together with soil water is referred to as *advection* (from Latin: “transport next to”) or *convection* (“transport with”). From the macroscopic point of view, this process can be expressed by the following mathematical [Equation 1](#) (Hillel, 1998; Jury and Horton, 2004):

$$\mathbf{J}_c = C_l \cdot \theta \cdot \mathbf{J}_w, \quad (1)$$

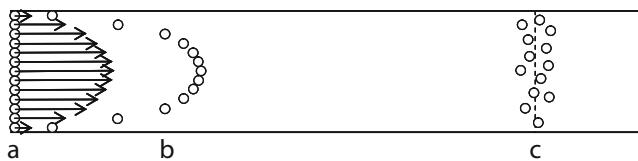

where \mathbf{J}_c is the tensor of solute flux density in soil due to macroscopic convection [$M L^{-2} T^{-1}$], C_l is the solute mass concentration in the soil solution [$M L^{-3}$], θ is the volumetric soil water content [$L^3 L^{-3}$], and \mathbf{J}_w is the tensor of water flux density [$L T^{-1}$]. \mathbf{J}_w may be described by Darcy’s law generalized to unsaturated-saturated soils.

The second process governing solute transport in soil is *molecular diffusion*. This process occurs in soil, disregarding whether water is moving through soil or not. Molecular diffusion is the macroscopic result of the microscopic agitation of molecules due to temperature. It can be expressed by the following [Equation 2](#), also known as Fick’s second law:

$$\mathbf{J}_d = -\theta \cdot \mathbf{D}_s \bullet \overrightarrow{\text{grad}} C_l, \quad (2)$$

where \mathbf{J}_d is the tensor of solute flux density in soil due to molecular diffusion [$M L^{-2} T^{-1}$], and \mathbf{D}_s is the molecular diffusion coefficient tensor of the solute in the soil [$L^2 T^{-1}$].

Convection and molecular diffusion being the two fundamental solute transport processes in soil, one could be tempted of simply adding [Equations 1](#) and [2](#) to get the general solute transport equation in soil. This would be wrong because [Equation 1](#) does not actually describe properly the convection process at the macroscopic scale. As [Equation 1](#) is put, it says that all solute molecules have the same velocity as that of the bulk water, which is obviously wrong because water is a viscous fluid. As a result, not all water molecules in soil move at the same velocity. Those located close to the soil solid surfaces hardly move, while those located far from the soil solid surfaces near the axis of soil pores move faster than the average water velocity. This process, called *mechanical dispersion*, is pictured in [Figure 1a](#), where solute molecules entering a soil cylindrical pore have different instantaneous velocities with the maximum value along the axis. Poiseuille’s law states that for Newtonian liquids, such as water, the solute velocity vector profile in the pore is parabolic, its value on the axis being twice the average value along the profile. A short time after they entered the pore ([Figure 1b](#)), solute molecules will have conserved their initial velocity. After some time ([Figure 1c](#)), solute molecules will have changed their velocity by moving

Solute Transport in Soils, Figure 1 (a) Solute molecules entering a soil cylindrical pore have a parabolic speed vector profile; (b) a short time after entering the pore, each solute molecule keeps its speed vector; (c) after some time, solute molecules move transversally due to molecular diffusion and, thereby, experience different speed values (dashed line shows the average position).

transversally to the pore axis because of molecular diffusion. As a result, some solute molecules will have moved a little bit faster than average and some others slower than average. For the mathematical point of view, this can be described macroscopically with an equation formally similar to that of Fick’s diffusion law ([Equation 3](#)):

$$\mathbf{J}_m = -\mathbf{D}_m \bullet \overrightarrow{\text{grad}} C_l, \quad (3)$$

where \mathbf{J}_m is the tensor of solute flux density in soil due to mechanical dispersion [$M L^{-2} T^{-1}$], and \mathbf{D}_m is the mechanical dispersion coefficient tensor of the solute in the soil [$L^2 T^{-1}$]. To the difference of molecular diffusion, mechanical dispersion vanishes as soon as water is immobile.

Finally, solute transport in soil is the result of three processes: (macroscopic) convection, molecular diffusion, and mechanical dispersion. The general solute transport equation in soil may thus be expressed by [Equation 4](#):

$$\mathbf{J}_s = \mathbf{J}_c + \mathbf{J}_d + \mathbf{J}_m, \quad (4)$$

where \mathbf{J}_s is the tensor of total solute flux density in soil [$M L^{-2} T^{-1}$]. Molecular diffusion and mechanical dispersion being described by the same type of mathematical equations, both processes may be summed up into a single equation. The resulting *hydrodynamic dispersion* process is then written by [Equation 5](#):

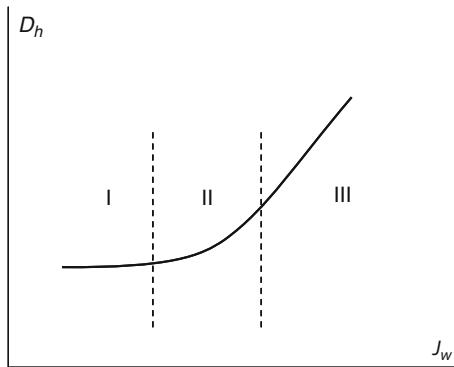

$$\mathbf{J}_h = -\mathbf{D}_h \bullet \overrightarrow{\text{grad}} C_l, \quad (5)$$

where \mathbf{J}_h is the tensor of solute flux density in soil due to hydrodynamic dispersion [$M L^{-2} T^{-1}$], and \mathbf{D}_h is the hydrodynamic dispersion coefficient tensor of the solute in the soil [$L^2 T^{-1}$].

Pfannkuch (1963) demonstrated that \mathbf{D}_h was linearly dependent on \mathbf{J}_w for high values of \mathbf{J}_w ([Figure 2](#)). In this case, \mathbf{D}_m can be written by [Equation 6](#):

$$\mathbf{D}_m = \lambda \bullet \mathbf{J}_w, \quad (6)$$

where λ is the dispersivity tensor of the soil [L]. Soil dispersivity has been shown to be dependent on the spatial scale at which transport processes are studied (Vanderborght and Vereecken, 2007).

Solute Transport in Soils, Figure 2 Evolution of the hydrodynamic dispersion coefficient, D_h , with water flux density in soil, J_w . Three regimes may be distinguished: regime I, where molecular diffusion dominates over mechanical dispersion; regime II, where both molecular diffusion and mechanical dispersion are equivalently important; regime III, where mechanical dispersion dominates over molecular diffusion.

Finally, the total solute flux density in soil may be written as [Equation 7](#):

$$\mathbf{J}_s = \mathbf{J}_c + \mathbf{J}_h = C_l \cdot \mathbf{J}_w - \theta \cdot \mathbf{D}_h \bullet \overrightarrow{\text{grad}}C_l. \quad (7)$$

When coupled to the conservation of mass equation, [Equation 7](#) gives [Equation 8](#):

$$\begin{aligned} \frac{\partial(\theta \cdot C_l)}{\partial t} &= -\mathbf{div}\mathbf{J}_s \\ &= -\mathbf{div}(C_l \cdot \mathbf{J}_w - \theta \cdot \mathbf{D}_h \bullet \overrightarrow{\text{grad}}C_l), \end{aligned} \quad (8)$$

where t is time [T]. [Equation 8](#) is known as the *convection-dispersion equation* (CDE). This equation is more frequently encountered in its vertical mono-dimensional form and for steady-state water regime ([Equation 9](#)):

$$\frac{\partial C_l}{\partial t} = D_h \frac{\partial^2 C_l}{\partial z^2} - V_w \frac{\partial C_l}{\partial z}, \quad (9)$$

where z is depth [L] and $V_w = J_w/\theta$ is the average pore water velocity [$L T^{-1}$].

The formulation of the CDE as [Equation 9](#) is adapted to inert (non-sorbing) conservative (nondegraded) solutes. For solutes that interact with soil solid surfaces, either organic or mineral, such as cations or uncharged organic micropollutants, or for solutes that are degraded or transformed by the soil microflora, such as nitrate or most organic molecules, the CDE must be coupled to other equations describing sorption and/or degradation processes in soil.

Coupling with physicochemical and microbiological processes

The vast majority of solutes in soils interacts with soil solid surfaces and/or undergoes transformation. The main

interaction of solutes with soil solid surfaces is through *adsorption*, the process by which solutes may be retained at the surface of soil particles due to weak physicochemical interactions (hydrogen bonds, van der Waals' forces). Adsorption is considered to be instantaneous and fully reversible. In soils, adsorbed solutes may be subjected to further processes like molecular diffusion inside the soil "solid" particle, such as diffusion into the interfoliar space of clay particles or diffusion into organic macromolecules. Interaction with the adsorbing surfaces may evolve toward strong physicochemical interactions such as covalent bonds. Finally, interaction of solutes with soil solid surfaces covers a large array of processes themselves in interaction, which are referred to globally through the term of *sorption*. The simplest way to describe sorption is by limiting it to adsorption, i.e., by considering it as an instantaneous reversible process. Adsorption is described by an *adsorption isotherm*, which relates the concentration of the solute adsorbed onto soil solid surfaces, C_s [$M M^{-1}$], to C_l . The term "isotherm" refers to the fact that adsorption is sensitive to temperature, so that the relationship between C_s and C_l is measured experimentally at constant temperature. The solute adsorption isotherm may be linear or non linear. In the first instance, it can be described by [Equation 10](#):

$$C_s = K_d \cdot C_l, \quad (10)$$

where K_d is the linear adsorption coefficient or partitioning coefficient [$L^3 M^{-1}$]. Non linear isotherms are often described by the Langmuir isotherm, if C_s values reach a plateau for large C_l values, or by the Freundlich isotherm, if C_s does not reach any plateau for large C_l values. The Freundlich isotherm is written as [Equation 11](#):

$$C_s = K_f \cdot C_l^{n_f}, \quad (11)$$

where K_f is the Freundlich adsorption coefficient [$L^{3n_f} M^{-nf}$] and n_f the Freundlich exponent [-]. The exponent n_f is generally lower than unity for pesticides.

For sorbing solutes, the mass balance [Equation 8](#) must account for the quantity of solute adsorbed onto the soil solid phase, resulting in [Equation 12](#):

$$\frac{\partial(\theta \cdot C_l + \rho_b \cdot C_s)}{\partial t} = -\mathbf{div}\mathbf{J}_s \quad (12)$$

where ρ_b is the soil bulk density [$M \cdot L^{-3}$], i.e., the mass of dry soil per unit of bulk soil volume. For steady-state water flow and linear-sorbing solutes, the CDE ([Equation 9](#)) is written by [Equation 13](#):

$$\frac{\partial C_l}{\partial t} = \frac{D_h \partial^2 C_l}{R \partial z^2} - \frac{V_w \partial C_l}{R \partial z}, \quad (13)$$

with $R = 1 + \rho_b \cdot K_d/\theta$ [-]. The CDE for linear-sorbing solutes ([Equation 13](#)) has a similar form to that for inert solutes ([Equation 9](#)), which means that the transport of linear-sorbing solutes in soils happens R times more slowly

than inert solutes. This is why R is also called the *retardation factor*.

If sorption is not instantaneous, one has to account of the rate of the sorption process. *Kinetic sorption* for linear-sorbing solutes may be written by [Equation 14](#):

$$\frac{\partial C_s}{\partial t} = \omega \cdot (K_d C_l - C_s), \quad (14)$$

where ω is the first-order rate constant of the kinetic sorption process [T^{-1}]. [Equation 13](#) is then modified with an additional term accounting for kinetic sorption ([Equation 15](#)):

$$\frac{\partial C_l}{\partial t} = \frac{D_h \partial^2 C_l}{R \partial z^2} - \frac{V_w \partial C_l}{R \partial z} + \omega \frac{\rho_b}{R \cdot \theta} (C_s - K_d C_l). \quad (15)$$

Solute degradation, transformation, or absorption all result in the disappearance of the solute from the soil. These processes are generally accounted for by introducing a sink term, r_s [$M L^{-3} T^{-1}$], in the mass conservation [Equation 8](#) to give [Equation 16](#):

$$\frac{\partial (\theta \cdot C_l)}{\partial t} = -\mathbf{div} \mathbf{J}_s - r_s. \quad (16)$$

When the sink term is due to microbiological degradation, it is generally described as a linear first-order process ([Equation 17](#)):

$$r_s = -\mu \cdot C_l, \quad (17)$$

where μ is the degradation rate constant [T^{-1}]. Rather than using a rate value, degradation is often quantified by the half-life of the solute $t_{1/2} = \ln 2 / \mu$ [T].

When the sink term is due to absorption by plant roots, it may be described by [Equation 18](#):

$$r_s = -\alpha \cdot C_l \cdot r_w, \quad (18)$$

where r_w is the water sink term [T^{-1}], that is the quantity of water removed from the soil by plant roots per unit of time, and α is a parameter [-] varying between 0 (no absorption) to 1 (fully passive absorption).

All the processes that have been described so far can be found in models such as HYDRUS-1D (Simunek et al., 2005; available at www.pc-progress.com). The simulation of transport processes coupled to more complex geochemical processes may be realized by using the HP1 model, which is a coupled version of HYDRUS-1D with PHREEQC (also available at www.pc-progress.com). The HYDRUS-1D model is also capable of simulating preferential flow of solutes in soil.

Preferential flow

In many situations, it has been observed that solutes can be transported more rapidly in the soil than what is expected from the solute transport equation describing the three above-mentioned transport processes: convection, molecular diffusion, and mechanical dispersion. It is as if

solutes were bypassing part of the soil porosity, thereby covering longer distances than they would have done if they would have explored the whole available porosity. This process is named *preferential flow*. The bypass pathways or *preferential pathways* can be many in soils: biopores (earthworm galleries, dead roots), fractures, and fissures. Parts of the soil porosity can also be regions of lower hydraulic conductivities, like dead-end pores, intra-aggregate pores, that are accessible to the solutes only through diffusion process. The result is that a large fraction of the solutes undergoes a higher velocity than the bulk velocity since they are transported through a restricted portion of the available water-filled porosity, resulting in an earlier breakthrough or preferential flow. Preferential flow can thus be a major factor of environmental pollution. Indeed, by this process a fraction of the pollutants can bypass the soil surface horizon where transformation processes (degradation of pollutants by biological activity) and retention processes are the most active.

Different models have been proposed to describe preferential flow (Šimůnek et al., 2003). The mobile-immobile model (MIM) or dual-porosity model assumes that the liquid phase of the soil is partitioned into mobile (flowing) and immobile (stagnant) flow regions (Coats and Smith, 1964), which gives [Equation 19](#):

$$\theta = \theta_m + \theta_{im}, \quad (19)$$

where θ_m and θ_{im} are the volumetric fractions of soil mobile and immobile water, respectively [$L^3 L^{-3}$]. Mobile region corresponds to inter-aggregate pores and macropores while immobile region corresponds to intra-aggregate pores or soil matrix. Water flow is assumed to occur in the mobile region only and solute is transported in the mobile region by both convection and hydrodynamic dispersion. Solute transfer between the dynamic flowing region and the stagnant region is described by a first-order mass transfer process. The general governing transport equations are thus written in vertical monodimensional form as [Equations 20](#) and [21](#):

$$\frac{\partial(\theta_m C_m)}{\partial t} + \frac{\partial(\theta_{im} C_{im})}{\partial t} = \frac{\partial}{\partial z} \left(\theta_m D_h \frac{\partial C_m}{\partial z} \right) - \frac{\partial J_w C_m}{\partial z} \quad (20)$$

$$\frac{\partial \theta_{im} C_{im}}{\partial t} = \alpha_{ph} (C_m - C_{im}), \quad (21)$$

where C_m and C_{im} are the solute concentrations in the soil solution of the mobile and immobile regions, respectively [$M \cdot L^{-3}$], and α_{ph} is the mass transfer coefficient [T^{-1}].

The dual-permeability model (DP) differs from the MIM model in that water flow is also assumed to move in the intra-aggregate pores (matrix) as well, but with a lower permeability than in the inter-aggregate pores (macropores). Water content and flow velocity are defined for each system as [Equations 22](#) and [23](#):

$$\theta = w \theta_f + (1 - w) \theta_{ma} \quad (22)$$

$$J_w = wJ_f + (1 - w)J_{ma}, \quad (23)$$

where $w = V_f/V$ [–] is the ratio of the volume of the macropores, V_f [L^3], to the volume of the total porosity, V [L^3], θ_f and θ_{ma} are the volumetric water contents of the macropores and matrix systems, respectively, and J_f and J_{ma} are the water density flux in both systems. Note that θ_f and θ_{ma} are different from θ_m and θ_{im} of the MIM model since they represent the water contents of each pore system and not absolute values of water content referred to the total soil volume.

Thus, mass conservation is calculated for each system such that the transport of solutes is described using two coupled convection–dispersion Equations 24 and 25:

$$\frac{\partial(\theta_f C_f)}{\partial t} = \frac{\partial}{\partial z} \left(\theta_f D_f \frac{\partial C_f}{\partial z} \right) - \frac{\partial J_f C_f}{\partial z} - \frac{\Gamma_s}{w} \quad (24)$$

$$\frac{\partial(\theta_{ma} C_{ma})}{\partial t} = \frac{\partial}{\partial z} \left(\theta_{ma} D_{ma} \frac{\partial C_{ma}}{\partial z} \right) - \frac{\partial J_{ma} C_{ma}}{\partial z} + \frac{\Gamma_s}{w}, \quad (25)$$

where Γ_s is the solute mass transfer term [$\text{ML}^{-3} \text{T}^{-1}$] defined as the sum of the diffusive mass transfer due to the solute concentration difference between the two pore systems and a convective mass transfer due to water mass exchange, Γ_w [T^{-1}], between the two pore systems (Equation 26):

$$\Gamma_s = \alpha_{ph}(1 - w)\theta_{ma}(C_f - C_{ma}) + \Gamma_w C_i, \quad (26)$$

where C_i is equal to C_f if $\Gamma_w \geq 0$ and to C_{ma} if $\Gamma_w < 0$.

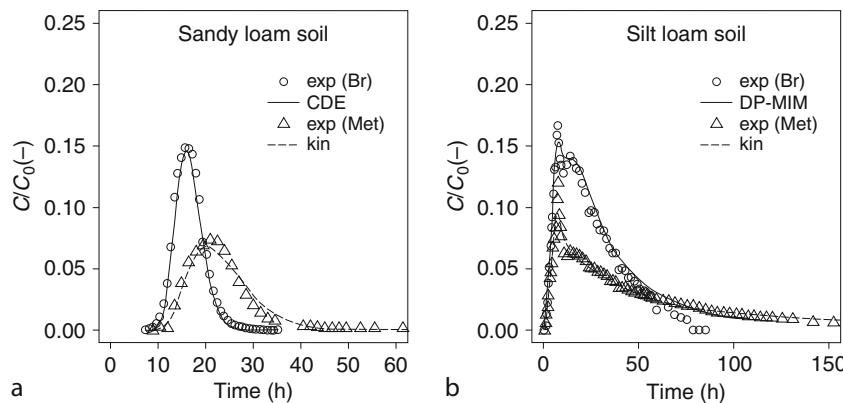

Other approaches consider only gravitational flow in the macropore systems (Jarvis, 1994). Based on the same

approaches, the division of the soil water phase can be further complicated by creating additional pore regions (Gwo et al., 1995).

Many studies of solute transport in the field and in the laboratory have shown evidence of preferential flow. When a pulse of solute is transported under equilibrium conditions, the distribution of the solute concentration in the soil outflow exhibits a Gaussian shape. When preferential flow occurs, the peak position is markedly advanced together with a long elution tail corresponding to diffusion process of solutes from and to regions of low permeability. In some cases, the solute concentration distribution can show a double peak which is indicative of dual-permeability flow. Figure 3 shows examples of an inert conservative solute (bromide) undergoing classical convection–dispersion transport at equilibrium conditions in a sandy loam soil column (Figure 3a) and the same solute undergoing preferential flow in a silt loam soil column (Figure 3b). In these examples, a pesticide was simultaneously injected in the soil columns together with bromide: for equilibrium conditions (Figure 3a), the pesticide exhibited delay due to sorption processes, while in the second case (Figure 3b) the pesticide arrived simultaneously as the tracer because of preferential flow.

Summary

Solute transport processes in soils are at the basis of plant nutrition and environmental contamination. Three main processes are governing solute transport in soil: convection, molecular diffusion, and mechanical dispersion. As most solutes are subjected to physicochemical interactions with the soil solid surfaces and/or physicochemical or biological transformation, models of solute transport in soil

Solute Transport in Soils, Figure 3 Breakthrough curves of bromide and the herbicide metribuzin in a sandy loam soil column (a) and in a silt loam soil column (b), measured under constant near-saturated flow conditions. The convection–dispersion equation (CDE) describes correctly bromide transport through the sandy loam soil column (a), while the model DP-MIM (three porosity domains, dual-permeability model) describing preferential transport must be used to correctly describe the double peaks and long elution tail of the bromide breakthrough curve in the silt loam soil. Metribuzin exhibits delay compared to bromide, due to sorption process in the sandy loam soil. In the silt loam soil, metribuzin is not delayed compared to bromide as it is rapidly transported through preferential pathways (macropores) at the same speed as that of bromide. In these examples, kinetic sorption processes were needed to correctly describe metribuzin transport in both soils.

need to account for these processes. However, such representations of solute transport in soil may still be found unsuitable when solutes are transported by preferential flow processes. Preferential flow results in solutes being transported more rapidly than expected through a limited fraction of soil porosity. As such, it is regarded as a major factor of groundwater contamination.

SORPTIVITY OF SOILS

Budiman Minasny¹, Freeman Cook²

¹Food & Natural Resources, The University of Sydney, Sydney, NSW, Australia

²CSIRO Land and Water, CSIRO Long Pocket Laboratories - Indooroopilly, Indooroopilly, QLD, Australia

Definition

Sorptivity is a measure of the capacity of the medium to absorb or desorb liquid by capillarity.

Theory

When water is applied into a dry soil, initially, most of the water is absorbed by the capillary potential of the soil matrix. The capillary force dominates the initial water infiltration process, however, as infiltration proceeds, the gravitational force dominates. Sorptivity is related to the infiltration that is driven by the capillary forces alone. Cumulative absorption or desorption of water into or out of a horizontal (minimal gravity effects) column of soil with uniform properties and moisture content is proportional to the square root of time and has been termed sorptivity (S [$L T^{-1/2}$]) by Philip (1957). He also defined the intrinsic sorptivity (ζ [$L^{1/2}$]) (that associated with the porous material) from the S and the fluid properties, by Philip (1969):

$$\zeta = (\mu/\sigma)S, \quad (1)$$

where μ is the dynamic viscosity ($ML^{-1} T^{-1}$) and σ (MT^{-2}) is the surface tension of the fluid. Sorptivity depends on initial uniform water content (θ_n) or potential (ψ_n) of the soil and the water content (θ_0) or potential (ψ_0) on the intake surface, so that strictly we should write sorptivity as $S(\theta_n, \theta_0)$ or $S(\psi_n, \psi_0)$. The latter form is needed when the potential at the intake surface is positive.

Sorptivity can be defined analytically as a function of soil water content and diffusivity (Philip and Knight, 1974). The calculation of the sorptivity involves iterative numerical procedures, and because of technical difficulties, several approximations have been proposed (Elrick and Robin, 1981; Kutílek and Valentová, 1986). The approximation by Parlange (1975) has been found to give good results (Elrick and Robin, 1981):

$$S_0^2 = 2\sqrt{\theta_0 - \theta_n} \int_{\theta_n}^{\theta_0} \sqrt{\theta - \theta_n} D(\theta) d\theta, \quad (2)$$

where θ_0 is the water content at applied potential ψ_0 , θ_n is the initial water content of the soil, and D is the soil diffusivity.

Measurement

In practice, Philip (1969) showed that sorptivity can be measured relatively easily from horizontal infiltration,

where water flow is only controlled by capillary absorption:

$$I = S_0 \sqrt{t}, \quad (3)$$

where I is the cumulative infiltration at time t . Talsma (1969) proposed measurement of sorptivity in the field from short-time ring infiltrometer data. Cook (2008) presented methods for measuring it in the laboratory for the early time vertical infiltration into soil cores.

Algebraic models for infiltration, which satisfy the condition that cumulative infiltration is proportional to the square root of time at short times and reaches a steady state rate at long times (Collis-George, 1977; Philip, 1987), have been developed. From these, the sorptivity component of the infiltration can be estimated.

For vertical three-dimensional (3D) infiltration from the infiltrometers or disk permeameters, sorptivity can be determined from early stages of flow where capillary force dominates (White et al., 1992; Cook and Broeren, 1994; Cook, 2002):

$$\lim_{t \rightarrow 0} \frac{dI}{d\sqrt{t}} \approx S_0. \quad (4)$$

In 3D infiltration, sorptivity does not only affects the early stage of infiltration but also the whole infiltration process.

Smith (1999) proposed a simple field method, which consists of inserting a 100-mm-diameter steel tube into the soil, pouring a volume of water equivalent to 1 cm depth (I_v) into the tube, and recording the time needed for water to imbibe until half of the soil surface is not ponded (t_v). Sorptivity is calculated from $S_0 = I_v/t_v^{1/2}$. This is a rough estimate and only measures sorptivity at saturation.

Values of sorptivity are quite variable, with standard deviations of the same order as those found for hydraulic conductivity (Talsma, 1969).

Applications

White and Perroux (1989) showed how sorptivity measured at different intake potentials could be used to estimate hydraulic conductivity, and this was tested by Cook and Broeren (1994) and was found to give good results. Minasny and McBratney (2000) showed the overestimation of sorptivity when contact sand materials were used with a disk permeameter for estimating sorptivity. Other disk permeameter methods such as those of Vandervaere et al. (2000a, b) also rely on the estimation of sorptivity to obtain the hydraulic conductivity.

Philip (1984) used the sorptivity in deriving travel times from buried and surface point sources which was later used by Cook et al. (2003a, b) for predicting wetting patterns for trickle irrigation. Broadbridge and White (1987) used sorptivity in the estimation of the time-to-ponding which has applications in the design of spray irrigation systems and erosion control. Leeds-Harrison and

Youngs (1997) described a measurement procedure for obtaining hydraulic conductivity of soil aggregates from measurements of water uptake at negative potential (sorptivity). This procedure was employed by Hallett and Young (1999) for quantifying water repellency, which was determined from the sorptivity measurements of soil aggregates using two wetting liquids with different soil–liquid contact angles.

Summary

Sorptivity is a component of the flow processes and needs to be incorporated in any application where adsorption or desorption of a fluid from a porous media is occurring due to a potential change at a surface boundary.

Microgravity soil physics

Definition

Space Soil Physics is the study of physical properties of soils, and more generally porous media, and its relations to water- and air-distribution and transport under reduced gravity conditions experienced during spaceflight and on extraterrestrial habitats.

Space soil physics is a subsection of soil physics that aims to identify, characterize, and predict critical physical phenomena that are affected by, or play a more pronounced role in, reduced gravity necessitated by practical questions of fluid management in partially saturated media, and dust behavior on extraterrestrial bodies. As the gravitational

level is reduced below that of Earth, phenomena relating to competing forces are altered as body forces become less significant compared to surface forces. The influence of such a shift in competing phenomena can be difficult to predict, and poses challenges for engineered systems addressed by Space Soil Physics (National Research Council (U.S.). Committee on Microgravity Research, 2000).

The main focus of Space Soil Physics is on multiphase flow and liquid behavior in porous media in the absence of gravity, where capillarity is the dominant mechanism for fluid management applications ranging from plant-based bioregenerative life support to power generating systems, the design and management of gas and liquid separation and recovery technology, and numerous other functions such as wastewater storage and treatment, and fuel management that operate in the near absence of gravity in terrestrial orbit or on spaceflight missions. Recent evidence suggests that fluid displacement patterns become unstable and enhance phase entrapment in the absence of gravity, thereby modifying macroscopic transport properties essential for fluid management decisions (Or et al., 2009).

Space soil physics plays a critical role in space agriculture for research and design of root-zone hydraulic processes for plant growth in reduced gravity (Bingham et al., 2000). The shift to capillary-dominated fluid distributions provides physical constraints that require novel considerations for growth-media selection, plant hydration (i.e., watering), and aeration (i.e., gas exchange) designs to maintain adequate supplies of water and gas exchange to plant roots (Scovazzo et al., 2001; Steinberg and Poritz, 2005).

Definition

Autocovariance. A measure of association between neighboring observations taken in space or time (Equation 2), manifested in the autocovariance function, which describes the autocovariance behavior versus separation or lag distance between observations. The normalized version of autocovariance is autocorrelation (Equation 1) (Shumway and Stoffer, 2000).

Power spectrum. A graph depicting the decomposition of cyclic variance components of different frequency, wavelength, or period based on the integration of the autocorrelation function (Shumway and Stoffer, 2000).

Spatial process. The change of a variable, or a state vector consisting of several variables, across a spatial domain caused by underlying effects. The spatial process of soil water content across a landscape can be influenced by spatial changes in soil type, topography, vegetation, rainfall, evapotranspiration, management, etc. (Wendoroth et al., 2011).

Introduction

The spatial variability of soil properties generally determines the change of a soil property's magnitude in space. This change is observed at different spatial locations on the land surface, or at some soil depths. The change can be considered across a spatial domain of any size, at any separation distance and for any sample volume. According to Blöschl and Sivapalan (1995), synonyms for domain, separation distance, and sample volume are extent, spacing, and support, respectively. We distinguish between structured and random spatial variability.

A change in a soil property observed across a domain, when observations taken close to each other are more similar than those sampled farther apart, manifests structured variability. If, on the other hand, the magnitude of change or fluctuation remains constant regardless of the separation distance between observations, the spatial variability is random. The structure of variability is usually quantified with a semivariogram (Journel and Huijbregts, 1991) or with the autocorrelation function (Shumway, 1988). Only if spatial variability exhibits structure can values at locations between the observation locations be interpolated by using, e.g., kriging or cokriging (Isaaks and Srivastava, 1989; Goovaerts, 1997; Deutsch and Journel, 1997) and autoregressive state-space models (Morkoc et al., 1985; Shumway and Stoffer, 2000; Nielsen and Wendoroth, 2003). Analysis of variance (ANOVA) applied to observations in randomized treatment experiments assumes random variability, i.e., spatial independence of observations. With structured variability, a spatial range of representativeness can be derived, i.e., the statistical area, or sphere, of influence. Note that, the statistical range of influence differs from the physical range of influence, the latter being determined by the size of the equipment or sample volume.

The spatial range of dependence not only leads to the opportunity to interpolate between measured locations, it also manifests a spatial process, which is the continuous or nonrandom change of an observed magnitude across a spatial domain (Wendoroth et al., 2011). In order to quantify the relationship between two variables measured in a spatial domain, their individual range of representativeness needs to be known, as well as their common range of dependence, manifested by the cross-semivariogram (Deutsch and Journel, 1997; Nielsen and Wendoroth, 2003) or the crosscorrelation function (Shumway, 1988). This consideration is especially relevant for cases in which observations cannot be taken at exactly the same location or are based on a different support size, and the investigator asks, "Although measurements of two variables were not taken exactly at the same location or their individual support volume differs, can I still statistically relate them?" Examples would be (a) the relation of a soil textural observation taken as a bulk composite of four auger samples within an area of 1 m² with a grain yield measurement taken over an area of 100 m² by a combine harvester; (b) the field measurement of a soil water retention curve where the soil water content sensor cannot be installed at exactly the same location but only in close proximity to a tensiometer (Greminger et al., 1985; Nielsen and Wendoroth, 2003).

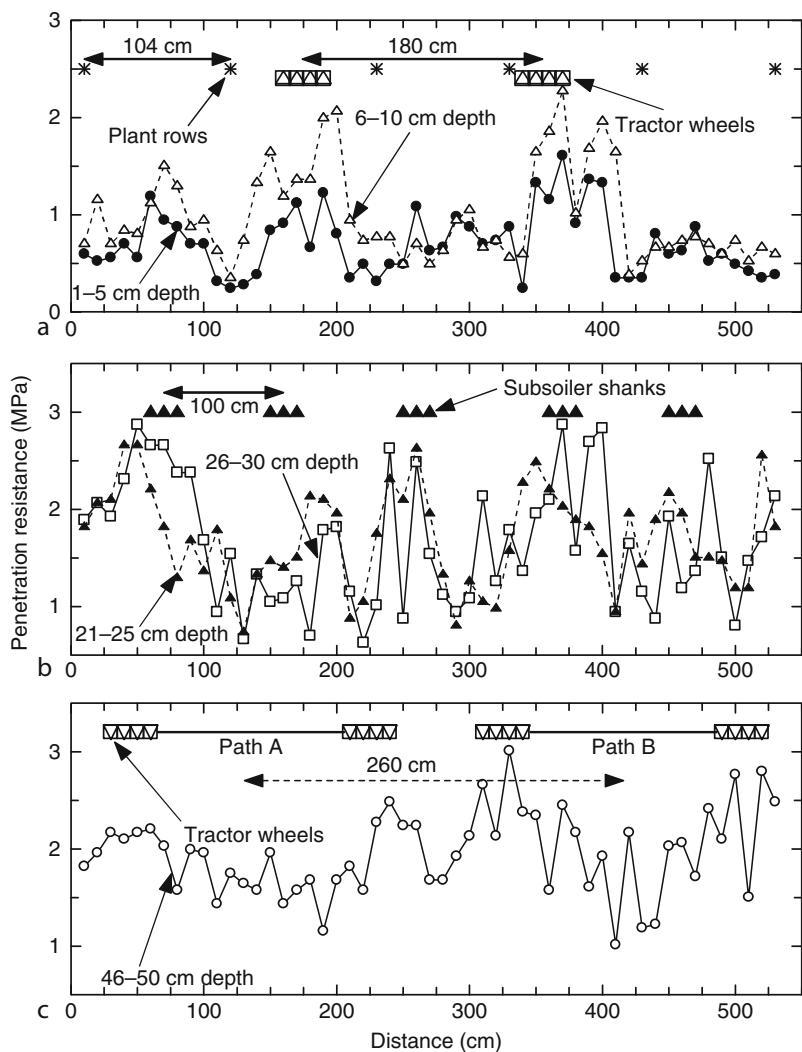

Autocovariance and frequency-domain variability analysis of soil penetration resistance and its relation to vehicle traffic patterns

In many agrophysical investigations of soil properties, management influences on soil state variables, e.g., quantitative measures of soil structure, are studied. Typically,

intensively managed soils exhibit a variability of soil physical properties that reflects the repetitive patterns of field management. These patterns are often times related to the pattern of surface topography, e.g., in furrow irrigation systems or row crops (Nielsen et al., 1983), or to field traffic and soil tillage operations (Domsch and Wendroth, 1997; House et al., 2001; Perfect and Caron, 2002; Wendroth and Nielsen, 2002). Investigations of soil structure carried out perpendicular to the main direction of tillage exhibit a repetitive or sinusoidal variability pattern. To detect these patterns would be impossible with random sampling, but instead requires systematic and equally spaced sampling along a transect.

In a study at the Kentucky Agricultural Station (Spindletop) near Lexington, tobacco was grown at a row spacing of 104 cm. Along a transect laid out

perpendicular to the tobacco rows, vertical cone penetrometer resistance (*PR*) was measured every 10 cm, giving 53 locations. Measurements of *PR* were recorded in units of MPa at every centimeter of depth and averaged over depth intervals of 5 cm. In Figure 1a, *PR* results are shown for the two upper depths, i.e., 1–5 and 6–10 cm, together with the location of the six plant rows perpendicular to the transect. Moreover, the locations of the left and right wheels (180 cm apart) of a heavy tractor that pulled a subsoiler through the plot in one direction prior to tobacco planting are shown. It is obvious that in close vicinity to plant rows *PR* yields relatively small values, whereas between plant rows *PR* values are relatively higher, and they reach the largest levels in zones of tractor wheel traffic during the subsoiling operation. The *PR* values proceed relatively synchronous, spatially, in the

Spatial Variability of Soil Physical Properties, Figure 1 Soil cone penetration resistance along a transect at five depths (a, 1–5, 6–10 cm; b, 21–25, 26–30 cm; c, 46–50 cm) in an intensively tilled tobacco plot. Location of one tractor wheel path with a wheel distance of 180 cm (a) pulling a subsoiler with five shanks separated by 100 cm (b), and of bidirectional tractor paths (A and B, separated by 260 cm) (c) for disk tillage are indicated.

upper two measured layers. The impact of tractor wheel tracks at distances of around 180 and 360 cm, causing larger *PR* values, is more pronounced in the 6–10 cm depth than 1–5 cm depth (Figure 1a).

A different spatial *PR* behavior is observed for the 21–25 and 26–30 cm depth compartments (Figure 1b). Measurements in the 21–25 cm layer proceed more continuously than those at 26–30 cm, which exhibit larger fluctuations from one location to the next. These larger local fluctuations may be ascribed to the paths of subsoiler shanks pulled through soil zones whose locations are also indicated in Figure 1b.

In general, *PR* values proceed higher in the 46–50 cm layer than in the layers above (Figure 1c). Moreover, the spatial *PR* series measured at this depth fluctuates more gradually than in the layers above. However, locally higher *PR* levels are found in those zones that correspond to the back-(path A) and-forth (path B) wheel paths of a tractor pulling a disk after subsoiling and prior to planting. The locations of the four wheels are shown in Figure 1c. The disking operation was repeated three times in both paths and at the locations of the wheels, an effect on *PR* was apparent at the 46–50 cm depth.

For the following analysis, the spatial autocorrelation function $r(h)$ of each series is calculated by Shumway (1988)

$$r(h) = \frac{\text{cov}[A_i(x), A_i(x + h)]}{\sqrt{\text{var}[A_i(x)]} \sqrt{\text{var}[A_i(x + h)]}} \quad (1)$$

where the sample autocovariance is

$$\begin{aligned} \text{cov}[A_i(x), A_i(x + h)] \\ = \frac{1}{N} \sum_{i=1}^{N-h} [A_i(x_i) - \bar{A}] [A_i(x_i + h) - \bar{A}], \end{aligned} \quad (2)$$

and the sample variance is

$$\text{var}[A_i(x)] = \frac{1}{N} \sum_{i=1}^N (A_i(x_i) - \bar{A})^2. \quad (3)$$

In Equations 1–3, A_i denotes observations being taken at locations x_i , \bar{A} denotes the arithmetic mean of A_i , and N the total number of observations.

Typically, a series of soil observations that is autocorrelated or structured exhibits large values of $r(h)$ at short lag distances and $r(h)$ decays with increasing lag distance h and equals zero at some distance, manifesting the fact that at and beyond this distance observations vary randomly. However, the resulting autocorrelation functions for the *PR* measurements at the five soil depth compartments are depicted in Figure 2, and they behave different from a regularly declining $r(h)$ behavior. In the layer 1–5 cm, $r(h)$ obviously oscillates and peaks of $r(h)$ occur regularly at every 100 cm of lag distance, or at every tenth observation. Regardless of where an observation is taken within the 530 cm transect, at 100, 200, 300, and

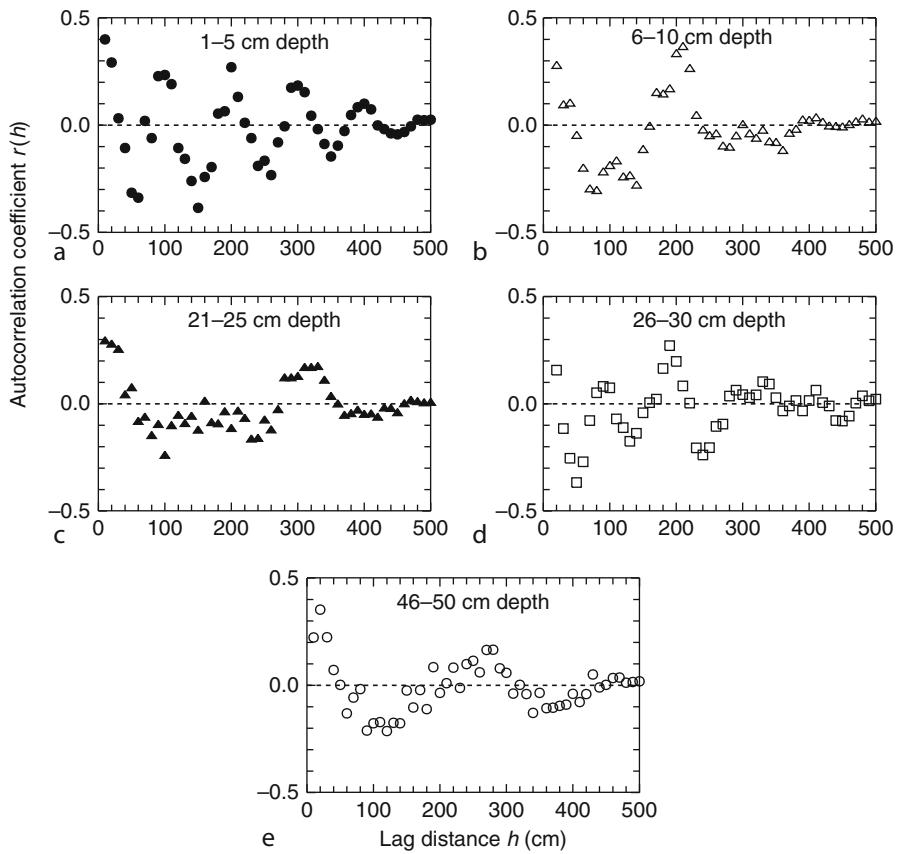

400 cm away from it, the magnitude of the observation is very similar. Notice the minimum magnitude of $r(h)$ at distances separated from the current location at $h = 50, 150, 250, 350$, and 450 cm, manifesting the opposite or inverse behavior of *PR*. Why does the amplitude of oscillations in the autocorrelation function decrease with increasing lag distance? Because in the sample autocovariance and sample variance, the sums of deviations are divided by N , regardless of the number of pairs of observations considered for a particular lag class. Since the sum term in the covariance equation (Equation 2) declines with increasing lag distance due to a decreasing number of differences in the particular lag class, the autocovariance and the variance decrease as well.

For the autocorrelation function of the 6–10 cm depth, a drop of $r(h)$ can be observed over the first lag intervals to $h = 60$ cm, from where $r(h)$ only slightly increases for the following lag distances but remains negative (Figure 2b). Only up to distances of around $h = 210$ cm, $r(h)$ increases again, implying a repetitive behavior at every 210 cm. The shape of the autocorrelogram for 21–25 cm depth (Figure 2c) is similar to the one at 6–10 cm, but the range of lag intervals at which $r(h)$ represents a repetitive pattern is approximately 320 cm. An autocorrelation behavior similar to that for 1–5 cm (Figure 2a) can be observed for *PR* measurements at 26–30 cm (Figure 2d). However, the cyclic autocorrelation is pronounced only at lag distances between 180 and 200 cm, and to some extent at $h = 100$ cm. This result may be caused by the compaction of tractor wheels that are spaced 180 cm apart from each other (Figure 1c). The signal at approximately 100 cm being less pronounced than the one at 180–200 cm may relate to the distance of subsoiler shanks being approximately 100 cm apart from each other. Their soil loosening effect every 100 cm is diminished by wheel compaction caused by the disking operations that followed.

Upon learning that the autocorrelation function reflects repetitive or periodic patterns of observations, spectral analysis, a specific tool for identifying periodicity- or frequency-based variance components is next applied (Davis, 1986; Shumway, 1988). Spectral analysis builds on Fourier transformation and on the theory that each data series can be considered as a combination of an infinite number of sine and cosine waves with their specific lengths and amplitudes. Hence, as ANOVA is focused on ascribing variance among treatments and their interactions, spectral analysis decomposes variance into cyclic components. Periodic variance components are depicted in the power spectrum $S(f)$ defined as (Shumway, 1988)

$$S(f) = 2 \int_0^\infty r(h) \cos(2\pi f h) dh \quad (4)$$

where f refers to the frequency, the inverse of the period (wavelength), given in length units. The unit for frequency depicted in the abscissa of the power spectrum is the inverse of the basic sampling interval, i.e., in this case $[0.1 \text{ m}]^{-1}$.

Spatial Variability of Soil Physical Properties, Figure 2 Sample autocorrelation functions for penetration resistance data at five depths shown in [Figure 1](#).

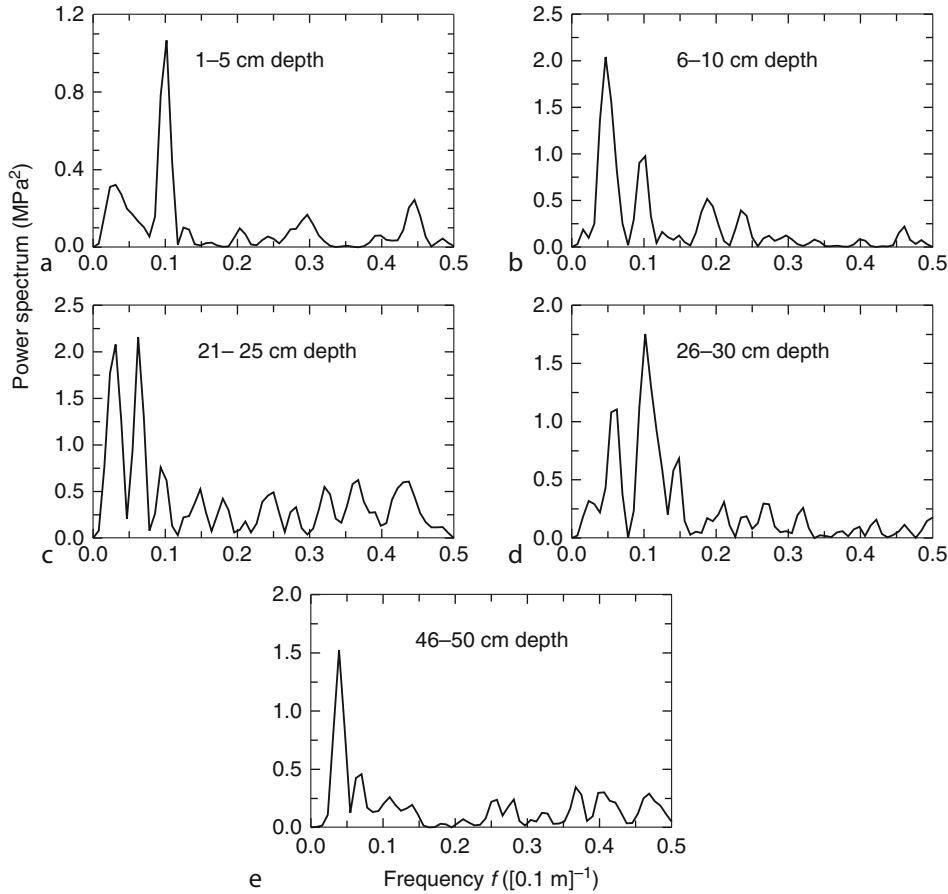

The power spectrum or periodogram derived from *PR* measurements at 1–5 cm depth is shown in [Figure 3a](#). In the graph, the abscissa depicts the frequency of the signal. For example, $f = 0.5$ refers to a period length of 0.5^{-1} , hence a period length of 2 observation intervals, equal to 20 cm for the *PR* data set. This is the minimum length of a period because the shortest fashion of a periodic fluctuation is a series of alternating high and low observed values. Such alternating data behavior would result in a spectral peak at a frequency of 0.5, or a period of 2. The smaller the frequency, the larger is the scale or characteristic wavelength at which cyclic variation occurs. The peak in the power spectrum of the 1–5 cm depth observed at a frequency of 0.1, a wavelength of 0.1^{-1} or 10 basic observation intervals (10 cm each), refers to the peaks in the autocorrelation function ([Figure 2a](#)) occurring periodically at lag distances of approximately 100, 200, 300, and 400 cm. A cyclic variance component at a frequency of 0.1 can also be observed at the 6–10 cm depth ([Figure 3b](#)). However, it is less pronounced than that at the 1–5 cm depth ([Figure 3a](#)). Instead, the strongest variance signal exists at a smaller frequency band around 0.05, corresponding to a wavelength of 200 cm. Notice the

consistency of this result with the peak in the autocorrelation function at $h = 200$ cm ([Figure 2b](#)).

At the 21–25 cm depth, the two strongest variance signals exist at frequencies of around 0.03 and 0.06, corresponding to wavelengths of approximately 320 and 160 cm, respectively ([Figure 3c](#)). In our calculations, the lengths of periods in the neighborhood of 320 cm are 426 and 256 cm, respectively, and in the neighborhood of 160 cm are 183 and 142 cm, respectively, which is determined by the number of spectral estimates being a power of 2. No clearer distinction can be made at the spectral resolution chosen in our calculations. At periods of approximately 160 cm ($f = 0.06$) and at 100 cm ($f = 0.1$) major variance components are detected ([Figure 3d](#)).

As is apparent in the original *PR* data for the 46–50 cm depth ([Figure 1c](#)), its variation is dominated by relatively long periods, manifested in the power spectrum with a distinctive peak at $f = 0.039$, corresponding to a period length of 260 cm ([Figure 3e](#)). This period length corresponds to the distance between the center of wheel paths A and B, the traffic pattern due to disking displayed in [Figure 1c](#).

In the following, analytical procedures for calculating spatial statistical relationships between different variables

Spatial Variability of Soil Physical Properties, Figure 3 Power spectra for penetration resistance data at five depths shown in Figure 1. Respective autocorrelograms are displayed in Figure 2. The frequency units reflect the inverse of the basic sampling interval.

are applied and discussed. First, the crosscorrelation function $r_c(h)$ is calculated with (Shumway, 1988)

$$r_c(h) = \frac{\text{cov}[A_i(x_i), B_i(x_i + h)]}{\sqrt{\text{var}[A_i(x_i)]} \sqrt{\text{var}[B_i(x_i + h)]}} \quad (5)$$

where the numerator term refers to the covariance between variable A_i observed at location x_i and variable B_i observed at separation distance h away from x_i . In the denominator, the individual variance terms of both variables are given.

In the crosscorrelation function, the relationship between two variables is measured when they are not sampled at the same location but at a separation distance h apart from each other. In Figure 4a, the crosscorrelation function for the PR data measured at 1–5 cm versus those at 6–10 cm, is plotted. The crosscorrelation coefficient $r_c(h)$ at $h = 0$ is equal to the classical correlation coefficient. Crosscorrelation coefficients displayed for positive lags h on the right-hand side of the crosscorrelogram manifest the relationship of the current PR values at 1–5 cm depth with PR values at 6–10 cm depth for previous lag distances, h . The left side of the crosscorrelation function

displays the spatial relationships for PR at 6–10 cm versus PR at 1–5 cm for prior distances h . On both sides of the crosscorrelation function, the cyclically proceeding relationship between the two variables is obvious. Although both series vary periodically (Figure 1a) their characteristic wavelengths differ, i.e., the most important periods are 100 and 200 cm for the 1–5 and 6–10 cm depth, respectively (Figure 3a and b). Hence, in the crosscorrelogram, the common wavelength is reflected through relatively large correlation coefficients at $h = \pm 200$ cm.

The crosscorrelation of PR at 1–5 and 26–30 cm depth is shown in Figure 4b, indicating common fluctuations every 100 cm. Interestingly, the maximum crosscorrelation coefficient is not observed at a lag $h = 0$, but at $h = 20$ cm. This phenomenon is often observed for two time series when a fluctuation occurs over the same characteristic wavelength in both series but with a certain spatial or temporal delay, e.g., daily soil temperature series at different soil depths (Rose, 1966). One way of understanding this phenomenon is to identify the causes of PR variation in the two layers considered. In both layers, a significant periodic variation component was observed

for wavelengths of 100 cm. At the 1–5 cm depth, the main cause for periodic fluctuations may have been the position of plant rows at every 104 cm, whereas at the 26–30 cm depth the subsoiler shanks were pulled through the ground at a similar interval, but slightly shifted relative to the plant rows. Note that the subsoiling happened before planting, and both field operations were spatially not coordinated.

The PR series measured at 6–10 and 46–50 cm are inversely crosscorrelated and are not perfectly synchronous, being shifted by 40 cm (Figure 4c). Wherever high PR values are observed at 6–10 cm depth, the 46–50 cm depth exhibits low PR , with a phase shift of 40 cm. Higher PR values occur at the 6–10 cm depth in the wheel path of the tractor pulling the subsoiler (Figure 1a). At 46–50 cm, repeated paths of tractor wheels originating from the above-mentioned post-subsoiling but preplanting disk tillage operations cause relatively higher PR (Figure 1c). Recompaction of the previously loosened subsoil might have occurred during the disking operations and the associated wheeling paths (A and B), which are laterally shifted relative to the subsoil shanks by about 40 cm (Figure 1b and c). Note that lower PR values occur in

the zones of subsoiling (Figure 1b), whereas the tractor wheels cause subsoil compaction with higher PR . This pattern of tillage operations causes the inverse relationship between PR values found at the two different depths.

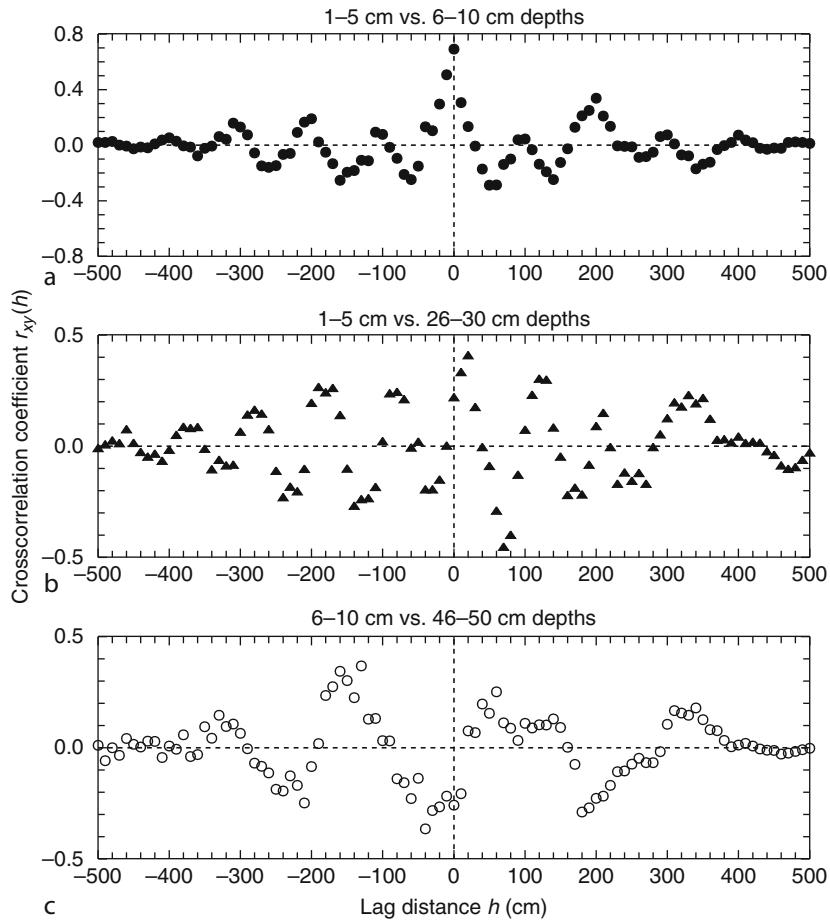

The detection of common frequency-based variance sources is accomplished through cross-spectral analysis consisting of two basic components, i.e., the co-spectrum and the quad-spectrum. Similar to the integration of the autocorrelation function for the power spectrum, the crosscorrelation function needs to be integrated for the co-spectrum $Co(f)$ through (Shumway, 1988)

$$Co(f) = 2 \int_0^\infty r_c(h) \cos(2\pi fh) dh \quad (6)$$

Before the crosscorrelation function can be integrated, both the right-hand side and left-hand side of the correlogram are averaged with

$$r_c(h) = 0.5[r_c(h < 0) + r_c(h > 0)]. \quad (7)$$

Through this averaging, fluctuations described by a cosine function are emphasized, and those described by a sine

Spatial Variability of Soil Physical Properties, Figure 4 Crosscorrelograms for three pairs of layer-specific penetrometer resistance data shown in Figure 1.

function are diminished. The second element, i.e., the quad-spectrum $Q(f)$ is calculated with (Shumway, 1988)

$$Q(f) = 2 \int_0^{\infty} r'_c(h) \sin(2\pi f h) dh. \quad (8)$$

This element of cross-spectral analysis is necessary in order to properly emphasize the fluctuations described by a sine function rather than cosine function by averaging both branches of the crosscorrelogram with

$$r'_c(h) = 0.5[r_c(h > 0) - r_c(h < 0)] \quad (9)$$

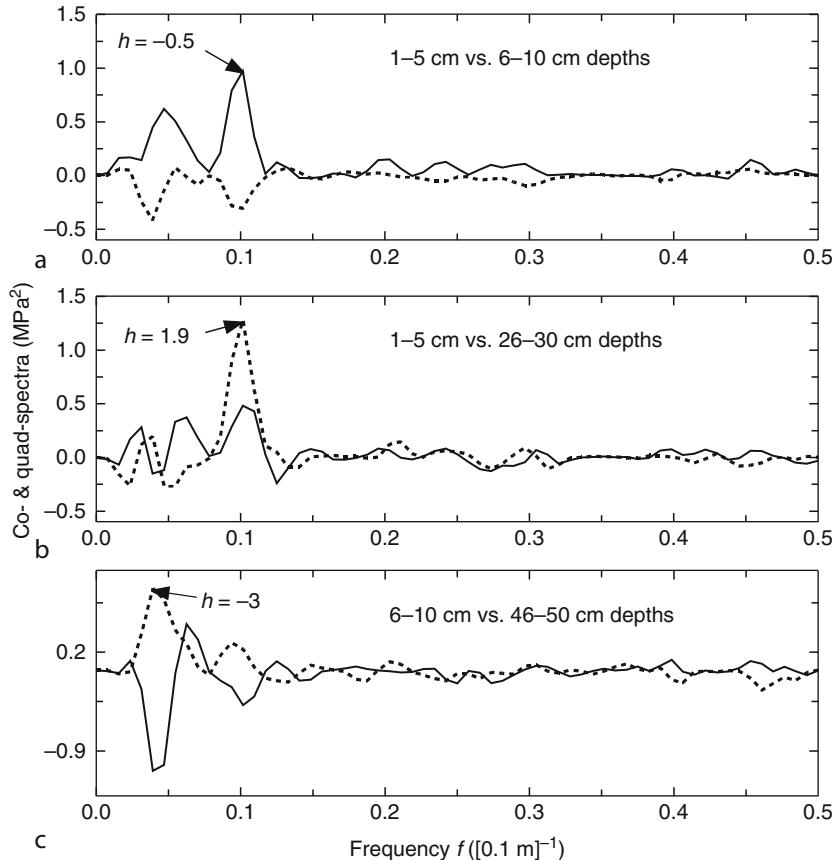

A perfect sine wave is equal to a perfect cosine wave when it is delayed by an angle of 90° . Both the co- and the quad-spectra need to be considered in cross-spectral analysis because two series may exhibit periodic fluctuations at the same wavelengths, but they may be shifted against each other. This shift is quantified for each particular frequency through the so-called phase spectrum defined as (Shumway, 1988)

$$h_{\phi}(f) = \frac{1}{2\pi f} \tan^{-1} \left[\frac{Q(f)}{Co(f)} \right]. \quad (10)$$

In Figure 5, co- and quad-spectra are shown for PR compared for the same pairs of depths for which crosscorrelation functions are depicted in Figure 4. The phase lag $h_{\phi}(f)$ for the peaks for PR at the 1–5 and 6–10 cm depths observed for $f = 0.1$ (Figure 5a) yields a low value of -0.5 sampling intervals, manifesting the almost synchronous behavior of the two series obvious from the corresponding crosscorrelation function (Figure 4a). At the same frequency, the periodic variation between PR in 1–5 and 26–30 cm (Figure 5b) is shifted by $+1.9$, corresponding to the maximum crosscorrelation coefficient observed at $h = 2$ (Figure 4b). For the band of even larger wavelengths ($f = 0.039$), the co- and quad-spectra (Figure 5c) result in a phase of -3 lags, which only approximately corresponds to the lag of -4 in the crosscorrelation (Figure 4c). This slight discrepancy is due to the coarse resolution of frequencies at this scale.

Variance scales of soil water storage, clay content, and corn yield

The spatial variation in soil profile water storage differs with time. Depending on the season, on the magnitude of soil water content or matric potential, and on the

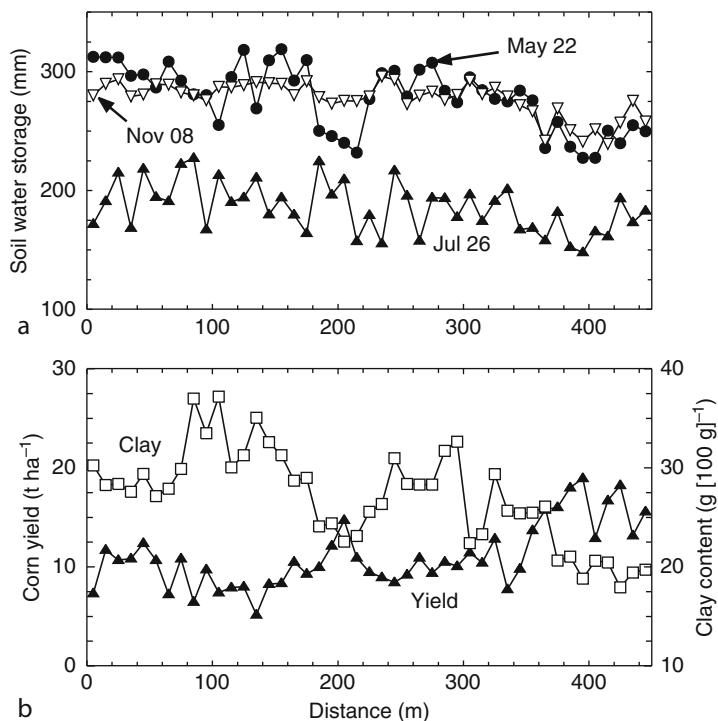

Spatial Variability of Soil Physical Properties, Figure 5 Co-(solid line) and quad-spectra (dashed line) for layer-specific pairs of penetration resistance measurements displayed in Figure 1. Respective crosscorrelograms are shown in Figure 4. The phase lag is denoted with h .

vegetation and its status, different patterns of spatial soil water distribution enunciate processes within the vadose zone whose relevance for soil water storage (SWS) changes throughout the year and, perhaps, over longer time intervals (Nielsen, 1997). In other words, the dominance of a spatial process on soil water storage distribution is not maintained throughout the year, but varies. Hence, for some seasons of the year, the spatial pattern in soil moisture distribution exhibits temporal persistence (Vachaud et al., 1985; Hu et al., 2010), but there are times when the distribution of soil moisture follows a pattern that is not consistent with that observed at other times. There are many ways to characterize the change in variation behavior over time. Roth (1995) derived the variation behavior for soil water status and flux from two-dimensional computer simulations of a Miller-similar medium. Under dry conditions, variance in soil water status is large in general and related to soil textural effects. With increasing soil water content, variance in water status and fluxes may decrease and reaches a minimum at a soil water potential level that is often called field capacity. With further increasing soil water content, variance increase is caused by soil structural effects (Roth, 1995). Field measurements by Wendoroth et al. (1999) confirmed this postulation. For a variety of different soils, Vereecken et al. (2007) reported standard deviation in soil water content versus average soil water content. Besides temporal

changes in the magnitude of the variance, the spatial autocovariance can change with time as a manifestation of cause controlling variance. Kachanoski and De Jong (1988) applied the above-mentioned frequency domain-based analyses to discriminate different spatial scales in field soil water content variation prevailing at particular times during their experimental period.

For deriving the scale of variance for profile soil water storage at different times and its relation to profile-average clay content and yield of corn, soil water content was measured in a farmer's field in Western Kentucky along a transect with 45 regularly spaced locations separated by 10 m. At each location, water content was measured and integrated over the 0–80 cm soil depth with a capacitance probe. In Figure 6a, soil water storage is depicted for three measurement dates in 2007, i.e., May 22, July 26, and November 08. The two series measured in May and November differ substantially from the one measured in July, the latter reflecting a situation of stored water depletion due to dry weather conditions and crop water uptake. The series observed in May and November exhibit a spatial process on a similar average level, and they behave similarly over the domain measured, but they differ in their local fluctuations. The May series exhibits more local noise whereas the November water storage proceeds smoother at the local scale. Neglecting the general water storage level, the July series manifests the

Spatial Variability of Soil Physical Properties, Figure 6 Profile soil water storage (SWS) integrated over a 0–80-cm soil depth at 45 locations separated by a 10-m distance, for 3 days in 2007 (a) and corn yield in 2007 and profile-average soil clay content (b), all in a farmer's field in Western Kentucky.

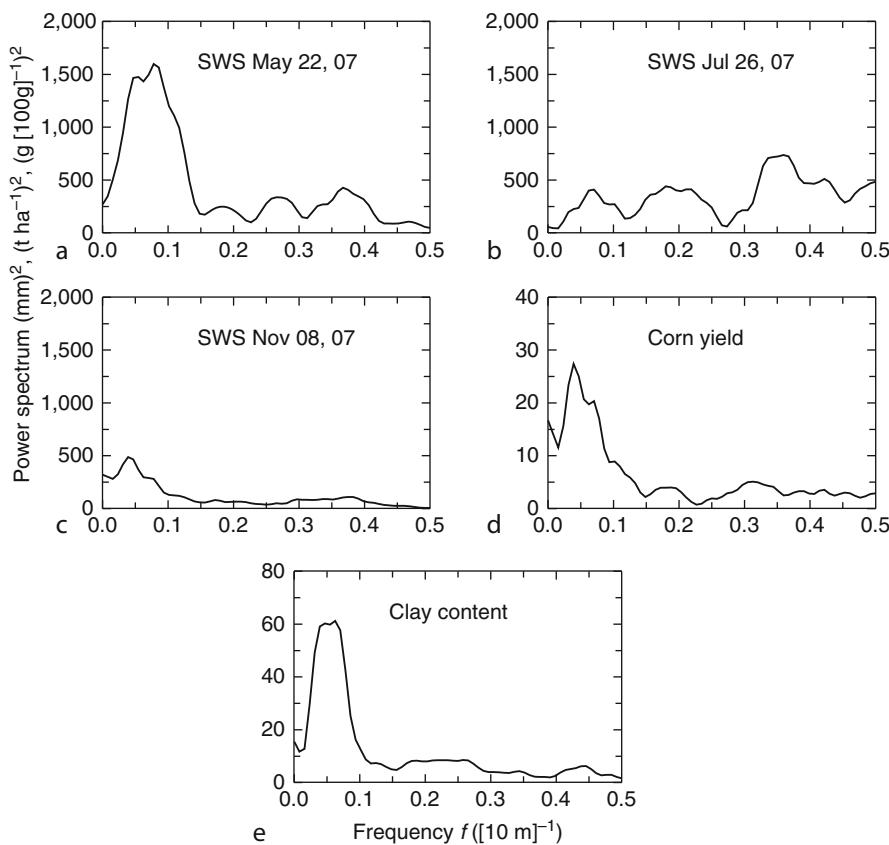

largest local variance, i.e., the storage differences between neighboring profiles are largest on this summer day. For the same transect, corn yield and profile-average soil clay content are illustrated in Figure 6b. In a very general way, clay content and corn yield are negatively related, and clay content and soil water storage in May and November behave spatially similar.

In what follows, the application of spectral analysis illustrates an example unlike the penetration resistance data set discussed above, because these data are not affected by cyclically repeated patterns related to soil management but are influenced by the curvature and characteristics caused by landscape morphology, soil genesis, vegetation, and crop establishment, irrigation, etc. This has been shown in the work of Warrick and Gardner (1983) and Kachanoski and De Jong (1988).

Power spectra for the three spatial series of soil water storage are shown in Figure 7a–c, which are purposely plotted with the same y -axis scale. The spectrum for the May 22 series reflects a strong weight on the large-scale variance for $f < 0.1$, corresponding to substantial variance observed over a distance of 100–200 m in the field. Small-scale peaks indicate variability at frequencies of 0.27 and 0.37, corresponding to every 40–30 m, respectively, but

these are less pronounced than the large-scale variance. Overall, due to similar large-scale behavior, the power spectrum for water storage measured in November (Figure 7c) is consistent with the one obtained for May (Figure 7a), but the overall variance is smaller in November, reflected by a smaller area under the peak profile. Notice that at small scales, the November series is smooth, manifested by the absence of peaks at $f > 0.1$. The spectrum for the July series (Figure 7b) manifests more pronounced small-scale fluctuations every 30–50 m. This small-scale variability contributes to a larger magnitude in total variance of the July series than the barely pronounced large-scale peak at a similar frequency that dominated variance in the May and November series (Figure 7a and c). The two remaining spectra for corn yield and clay content (Figure 7d and e) manifest the same dominating large-scale variance that is observed for the May and November water storage series.

Above, the degree of periodic coincidence in two PR series measured at different depths was illustrated with cross-spectral analysis. An additional statistical measure is the coherency spectrum defined by (Shumway, 1988)

Spatial Variability of Soil Physical Properties, Figure 7 Power spectra for the data depicted in Figure 6, i.e., soil water storage (SWS) on May 22, 2007 (a), July 26 (b), November 08 (c), corn yield (d), and clay content (e), all measured in a farmer's field in Western Kentucky in 2007.

$$Coh(f) = \frac{Co^2(f) + Q^2(f)}{S_A(f) S_B(f)} \quad (11)$$

which – similar to the coefficient of determination in regression analysis – quantifies the relationship between two variables for the spectrum of different frequencies. Coherency spectra for various combinations of the variables presented in Figure 6 are depicted in Figure 8. Common variance scales of 30–50 m dominate the coherency between the May and July water storage series (Figure 8a). However, a broader range of common frequencies is obtained for the May and November series (Figure 8a). While the soil water storage measured in May and yield have many, not extremely pronounced common frequencies, water storage in July is related to corn yield only at scales above 100 m (Figure 8b). Water storage measured in November varies consistently with corn yield over large but also small common scales, and there are a variety of different common scales between clay content and yield (Figure 8c).

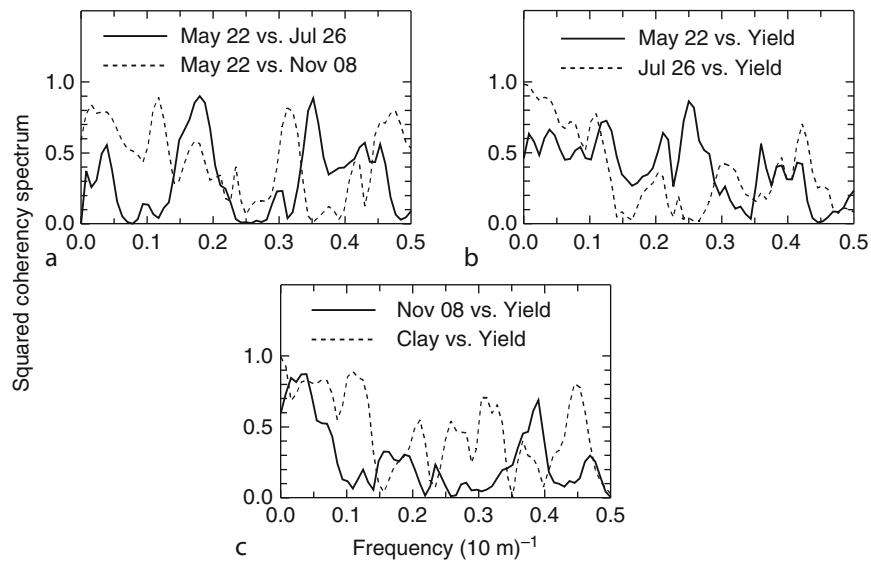

For two series, their common scales of variation are quantified in the coherency spectrum. It is important to note that spatial series separated by a longer time interval can exhibit more common scale variability than those observed over a shorter interval. For example, the water storage series observed in May and November display more common variability scales with corn yield than storage measured in late July, which was close to harvest. The physiological or functional relevance of a state variable and its spatial pattern can prevail over much longer time intervals and periods than is often assumed. Erroneous assumptions about functional relationships can lead to

measurements taken at closer, but functionally rather irrelevant times.

Outlook

Frequency domain-based analysis provides many opportunities to study agrophysical processes in systems even without any imposed treatments. Folorunso and Rolston (1985) discovered soil water content to vary in wavelengths of 4–5 m. Moreover, these periodic fluctuations coincided with the spatial pattern of greenhouse gas emissions. An additional frequency component, caused by water-soluble organic carbon was found in their study. In their investigations of surface topography, horizon thickness and density, Kachanoski et al. (1985a, b) detected common wavelengths between 2 and 10 m length at which variations in surface curvature, slope gradient, and A-horizon mass occurred. When the same relationships were investigated for the B-horizon, characteristic periodicities were found again at 10-m wavelengths, but were barely observable for shorter wavelengths that dominated variability in the A-horizon.

The first two-dimensional application of spectral analysis was performed by Bazza et al. (1988) who investigated variation in soil surface temperature in a 6-ha field that had previously been irrigated with water at different salinity levels. Those prior treatments could not be laid out in a random fashion but had to be arranged in a regular repetitive pattern. Perpendicular to the direction of different treatments, soil temperature and salinity level exhibited a close inverse relationship whose periodic coincidence was obvious. On the other hand, along the differently treated strips, soil temperature showed only minor and

Spatial Variability of Soil Physical Properties, Figure 8 Coherency spectra for pairs of data depicted in Figure 6, i.e., soil water storage series measured on May 22, July 26, and November 08, respectively (a), May and July storage series versus corn yield (b), and November storage and clay content versus yield (c), all measured in a farmer's field in Western Kentucky in 2007.

rather random variation. This was one of the first studies in soil science in which treatments were laid out non-randomly but in a cyclic spatial pattern.

Spectral analysis has also been applied to study crop competition (Samra et al., 1993) and two-dimensional vegetation patterns (Renshaw, 1997). Samra et al. (1993) investigated the competing interactions between Bhabbar grass planted in between rows of Eucalyptus trees. Growth performance of Bhabbar significantly differed depending on plant position relative to the tree row. Moreover, little difference was observed in the ecological impact of the trees on the grass in a dry year. It is extremely hard, if not impossible, to imagine a study in which these findings could have been derived from samples taken randomly in a randomized treatment experiment. Similar to ANOVA, Samra et al. (1993) applied F statistics for the identification of significant frequency-based variation components in their analysis of power (ANOPO).

In a pine stand forest ecosystem, Böttcher et al. (1997) investigated the spatial variation in solute input into the ground water, i.e., sulfate concentration of canopy throughfall. Their analysis revealed that the spatial pattern of solute input proceeded in a spatially synchronous fashion with the distributional pattern of pine canopy coverage of the ground. Maximum sulfate concentrations were found at the locations corresponding to the edges of the canopies, minima in zones of maximum canopy coverage. Note that the sulfate concentrations in the uppermost ground water sampled in 1989 were stronger related to the canopy coverage pattern than in 1993 due to more pronounced canopy variation in younger trees.

Management-induced variation in crop growth is often times an unintended effect that can be discovered by frequency-domain analysis of integrative crop state variables. In their investigation, Wendoroth et al. (1997) found that the position of sprinklers in an almond orchard caused systematic differences in almond tree growth, reflected in trunk circumference. One-year yield observations would not have obviously shown this cyclic and systematic effect.

Tillage-induced horizontal variability has been analyzed with spectral techniques (Petersen et al., 1997; Wendoroth and Nielsen, 2002). In their study, Petersen et al. (1997) detected periodic variation in dye patterns as an indicator of flow at a frequency that corresponded to the furrow width of the plow. The furrow width was also one of the main factors causing horizontal variability in soil chloride concentration and soil water content in the study of Wendoroth and Nielsen (2002). In addition, they discovered that an additional cyclic impact corresponded to the width of the plow.

Interestingly, the topographic curvature index and corn grain yield varied coincidentally in a landscape morphology study of Timlin et al. (1998). While yield maps in subsequent years were temporally unstable, pronounced surface curvature caused yield patterns to vary depending on whether curvatures were convex or concave in shape,

and on whether the year was relatively dry or wet. Moreover, depth to fragipan caused yield fluctuations in dry years.

Decomposition of soil water content variability, along several transects and with depth, using spectral coherency manifested strong relationships between the scale of variation at the surface layer and those at deeper soil layers in a study by Cassel et al. (2000). The same analysis was applied to detect common frequency-based variability components during subsequent sampling dates. Relatively large-scale fluctuations, at a scale of 50 m, dominated common variability behavior in surface soil water content measured at different times.

Recently, R.L. Fox's idea of applying nitrogen not in randomized plots but at continuously varying rates across the landscape was applied in experiments of Shillito et al. (2009) and Wendoroth et al. (2011). The study of Shillito et al. (2009) resulted in systematic differences in nitrogen response of potato yield to the amount of nitrogen applied. The regular and repetitive pattern of applied nitrogen evidently showed nonunique response caused by systematic soil variability. In the study of Wendoroth et al. (2011), less pronounced but still obvious differences in nitrogen response of winter wheat were observed across a field with sinusoidal nitrogen application. Spectral and another frequency-based analysis, i.e., the wavelet spectrum, revealed a strong periodic component at the treatment scale, and in addition a large-scale component based on soil textural differences manifesting a trend in soil quality underlying the field investigated.

Experimentalists who intend to answer a question related to scale and frequency of variation in a soil or crop property, impact of surface topography, soil management, and other sources of variation by using spectral analysis need to remember that observations undergoing frequency-domain analysis must be taken equally spaced. Moreover, a prior assumption or investigation of fundamental wavelengths affecting the variability of observations needs to be seriously considered in the design of the experiment. A process is under sampled if the shortest periodic fluctuation is covered with just three observations over a distance $2\Delta x$ where Δx is the basic sampling interval, which would result in a spectral peak at a frequency $f = 0.5$, the so-called Nyquist frequency (Davis, 1986). The shortest periodic fluctuation needs to be covered by more than three observations. As shown in the examples of penetration resistance analyzed, measurements of different variables do not necessarily need to be taken at exactly the same point. Observations undergoing crosscorrelation and cross-spectral analysis can be taken at the same location, or at locations along a parallel line transect, at the same location but at a different depth, at the same or a parallel location at a different time, etc. Any combination of observations along a space or time axis is possible. Prior to the analysis of the frequency domain, autocovariance analysis needs to be employed to identify the spatial or temporal representativity of observations. The next step is to identify the spatial or

temporal distance over which two variables are still meaningfully related with each other, information that is depicted in the crosscorrelogram. Still, in too many agronomic and soil-related studies these two essential characteristics of observations are disregarded, misleading the investigators to conclusions about the lack of relationships among the two or more variables investigated.

In the original applications of Fourier-transform-based analysis, time series analyses were applied to electric signals, collected using data-logging devices, resulting in significant power spectra that were not affected by data shortage. In many soil science applications, especially in the spatial domain, observed series may cover only a limited number of waves. Nevertheless, new soil sampling and sensor technologies provide increasing opportunities for which frequency domain analysis is the tool of choice (Pringle and Lark, 2007). Experiments with a frequency-based layout of treatments – different treatments should cover different wavelengths – allow studying treatment response while discerning whether underlying soil processes gradually alter the response.

Summary

According to the French mathematician J.B. Fourier (1768–1830), any continuous single-valued function can be represented by an infinite number of sinusoidal waves of different length, amplitude, and phase. If the variance of soil state variables taken across a spatial or temporal domain is not random, it follows some pattern at various scales, manifested as local trends. Managed soils often exhibit a spatially cyclic variation in properties caused by the repetitious pattern of management, e.g., row spacing, wheel traffic, tillage, irrigation, and fertilization. Landscape topography, pedogenesis, hydropedologic conditions, and vegetation cause trends and curvature in the spatial series of data observed over larger scales. The variance in regularly repeating observation patterns and their causal factors can be decomposed in spectral analysis. Typical contributions to the variance are illustrated in the power spectrum, which depicts the main frequencies, periods, wavelengths, or scales over which variance occurs. In a study of intensive soil tillage for tobacco, spatial soil penetration resistance data series, measured perpendicular to the main tillage direction and at different soil depths, exhibited typical variation patterns at different scales. Spectral and cross-spectral analysis quantified cyclic variation components. Their typical wavelengths varied with depth and could be linked to different wheel traffic and soil management patterns. In a landscape-scale study on soil water storage, soil texture and crop yield, spectral analysis was helpful in detecting different spatial patterns in soil water storage throughout the year. Coherency spectra identified the main common scales of variation. Typical variation scales for corn yield, after a relatively dry growing season, were related mainly to those for soil water storage measured when that

storage was relatively high. In order to predict significant spatial patterns for important variates and their spatial processes such as crop yield, optimum times for measuring the distribution pattern of underlying soil state variables can be identified using cross-spectral and coherency analysis.

SPECIFIC SURFACE AREA OF SOILS AND PLANTS

Zofia Sokołowska

Institute of Agrophysics, Polish Academy of Sciences,
Lublin, Poland

Definitions

Different kinds of the surface area may be found in soil. The *geometric surface area* is calculated on the data of shapes and dimension of representative soil particles. The *internal surface area* is the surface of inter walls of the microcapillaries (the term “internal surface” is usually restricted in its application to those cavities, which have an opening to exterior of the grains). The *external surface area* is defined as the sum of geometric and internal surface area. The *interlayer surface area* is the surface of interlayer walls of minerals of the montmorillonite type. The *total surface area* is the sum of the external and internal surface areas, as well as the surface area of organic matter.

The total, external and internal surface areas are the main types of specific surface that can be used to characterize each adsorbent. Sometimes other kinds of surface area are invoked, but all of them are special cases of the definitions given above.

Specific surface area of a soil sample is combined surface area of all the particles in the sample, as determined by some experimental technique and expressed per unit mass of the sample, mostly in $\text{m}^2 \text{ g}^{-1}$. As its definition implies, term “specific surface area” is an operational concept.

Introduction

Surface area is recognized to play a complementary part to porosity in adsorption phenomena for a vast range of solids. Solid phase of a soil is a mixture of different inorganic constituents as nonporous materials of different size and shape, porous materials with microcapillaries or pores, and phyllosilicates with the interlayer structure, as well as organic species, mainly organic matter.

Methods of measurements of specific surface area

Physical methods

Direct physical methods for measuring specific surface area (the crystallographic or geometric surface area) are

based on light or electron microscopy and on X-ray diffraction methods. All these techniques can be used to determine the shape and dimensions of individual soil particles and, additionally to assess crystallographic structure and interlayer spacing of clay minerals. Providing that a characteristic particle size and shape can be determined, the specific surface area can be obtained from mass–volume relationships. To estimate the specific surface area of clay minerals, the structural formula and unit cell dimensions must be known.

Chemical methods

The majority of chemical methods are based on measurement of adsorption of polar and nonpolar gases, vapors or dissolved molecules (Schofield, 1947; Everett and Ottewill, 1970; Tiller and Smith, 1990; Chiou and Rutherford, 1993; Sivapullaiah et al., 2008). The adsorbable compounds used to determine specific surface area are chosen on the basis of their molecular properties. Polar adsorbates include water vapor, ethylene glycol, or ethylene glycol monoethyl and they are employed to measure the total surface area. Typical nonpolar adsorbates are nitrogen, argon, krypton and they are applied to measure the external surface area. Nitrogen is commonly used as the adsorbate because it interacts weakly with a broad array of surface functional groups and therefore permits for the determination of exposed area of soil.

The application of the physical adsorption of gases to the estimation of the specific surface area of soils.

The physical adsorption is also called “the van der Waals adsorption.” The adsorbate molecules are accumulated at a surface in result of their physical interactions with that surface. These interactions include: dispersion forces (which are attractive in nature) and short-range repulsive forces. In addition, there may exist forces due to permanent dipoles within the adsorbed molecules. The process of physical adsorption is reversible, the heat of adsorption is low, and the thickness of adsorbed layers may be a few molecular diameters of a gas molecule.

The amount of gas adsorbed per gram of solid, N , depends on the equilibrium pressure, p , the temperature, T , and also on the nature of the gas and solid. The adsorbed amount at a constant T is called the adsorption isotherm when the measurements were carried out at consecutively increasing pressures, and the desorption isotherm, when the adsorption data were obtained along decreasing pressures branch. The amount of adsorbed, N , may be measured in any suitable units, i.e., grams or milligrams, moles or millimoles, and cubic centimeter under normal temperature and pressure (NTP) conditions. The adsorption isotherm is the most popular way to express the adsorption data.

The isotherms start at the origin of the coordinates and they end is at a nearly of the saturated vapor pressure. No simple interpretation can be given to describe the main part of the curve. The initial part of the isotherm is used

to obtain the surface area, whereas its end-part to evaluate the pore structure of a solid body. A number of different theories have been proposed for the interpretation of adsorption data, but only a few equations have been found to reproduce with a reasonable precision a large number of experimental isotherms. The best known and probably the most frequently used theory is that proposed by Brunauer, Emmett, and Teller (BET). The BET theory not only leads to a simple analytical equation (called the BET equation) for the adsorption isotherm, but also provides the way to classify the isotherm into five distinct categories. The BET theory has proved remarkably successful in the calculation of specific surface area of several isotherms, providing that they belong to an appropriate type (specifically, to the type II), according to the BET classification scheme. Other theory that also can be employed to determine the specific surface area is that proposed by Langmuir. The latter theory is usually applied to calculate the specific surface area for the isotherms of type I according to the BET classification.

The Langmuir equation describes localized monolayer adsorption on a homogeneous surface. It has the form:

$$N = \frac{N_m kp}{1 + kp} \quad (1)$$

In the above, N_m is the monolayer capacity, that is, the amount of adsorbed molecules necessary to cover the surface with a monomolecular film, and k is a constant.

In contrast to the Langmuir isotherm that characterizes monolayer adsorption, the BET equation describes localized multilayer adsorption on a homogeneous surface. It reads:

$$N = \frac{N_m x C_{BET}}{(1 - x)[1 + (C_{BET} - 1)x]}, \quad (2)$$

where $x = p/p_0$ is the relative pressure of a vapor (p_0 is the saturated vapor pressure), and C_{BET} is a constant, usually called “the BET constant.” The range of validity of the BET equation does not always extend to relative pressure higher than 0.5.

Calculation of the specific surface area from adsorption data

The surface area of soil samples is evaluated from adsorption–desorption isotherms as follows. The first step in the application of the Langmuir or BET method is to obtain the monolayer capacity, N_m . The second step is to calculate the specific surface area from the value of N_m .

The monolayer capacity from Langmuir plot

A linear form of the Langmuir equation (the so-called Langmuir plot) has the form:

$$\frac{p}{N} = \frac{1}{N_{mk}} + \frac{1}{N_m} p. \quad (3)$$

The parameters k and N_m can be directly evaluated fitting experimental data by a straight line. If p/N data are plotted against p , the resulting straight line slope, s , gives $s = 1/N_m$ and the intercept $i = 1/k N_m$. From the above quantities, we obtain $N_m = 1/s$ and $k = (1/(N_m)(1/i))$.

The monolayer capacity from BET plot

The linearized form of the BET isotherm has the form:

$$\frac{x}{N(1-x)} = \frac{1}{C_{BET}N_m} + \frac{(C_{BET}-1)}{C_{BET}N_m}x. \quad (4)$$

If $x/N(1-x)$ is plotted against p/p_0 , a straight line should result with the slope $s = (C_{BET}-1)/N_m C_{BET}$ and the intercept $i = 1/N_m C_{BET}$. From the above quantities we obtain N_m and C_{BET} , namely, $N_m = 1/(s+i)$ and $C_{BET} = (s/i) + 1$. Note that the most reliable results are usually obtained if the approximation is carried out within the range of relative pressures of $0 < p/p_0 < 0.35$.

Calculation of the surface area

The second step is to calculate the surface area from the dependence:

$$S = N_m M^{-1} L \omega, \quad (5)$$

where L is the Avogadro number (6.02×10^{23} molecules per mole), M is the molecular weight of gas or vapor (in gram per mole) and ω is the molecule cross-sectional area of an adsorbate molecule, expressed in m^2 per molecule. If N_m is obtained from water vapor isotherm and is expressed in grams of water per gram of solid, ω is $10.8 \times 10^{-20} \text{ m}^2$ for water molecule then the specific surface area $S(\text{m}^2 \text{ g}^{-1})$ is $S = 3,612 \times N_m$. One should note, however, that in the case of porous (or "wiggly") solids, the value of N_m may depend on ω , i.e., on the kind of the adsorbate. This is quite obvious, because large molecules cannot enter pores of a diameter smaller than their dimension, whereas smaller molecules can probe such parts of the adsorbent. Therefore, N_m increases with a decrease of ω in general. If the dependence between N_m and ω has the form of a power law, then the exponent can be interpreted in terms of fractal concepts and the adsorbent may be a surface fractal.

The molecule cross-sectional area

Emmett and Brunauer proposed that ω should be calculated from the density of the adsorbate in the ordinary liquid (or solid) phase. This leads to the formula:

$$\omega = f(M/\rho L)^{2/3} \times 10^{16}, \quad (6)$$

where f is the packing factor and ρ is the mass density of the bulk liquid. With the hexagonal close packing of bulk liquid phase the value of f is 1.091 and if ρ is expressed in kilograms per cubic meter, ω is expressed

in square nanometers. For nitrogen as adsorbate at -195°C $\omega = 0.162 \text{ nm}^2$.

The adsorption of water vapor is a complex process in such sense that it is highly specific and thus it may appear that the application of the BET equation to water vapor isotherms in many cases will have no real validity. Early works indicated that the value of the molecule cross-sectional area is 0.106 nm^2 . McClellan and Harnsberg (1967) given cross section surface areas of different molecules adsorbed on solid surfaces.

Adsorption from solution

The adsorption of dissolved molecules from solution can also be used to estimate the specific surface area of solid. Usually, the adsorption isotherms obtained are classified as the type I in the BET classification scheme and therefore the Langmuir model can be used. Several organic molecules have been used to determine specific surface area from Langmuir equation. Those are: organic dyes (methylene blue, crystal violet), cationic surfactants (cetylpyridinium bromide, CPB) or other compounds, e.g., carbon tetrachloride, ortho-phenanthroline, and so on.

Retention of polar liquids

Retention data of EG (ethylene glycol) and EGME (ethylene glycol monoethyl ether) can be used to estimate the total (i.e., internal and external) surface area of expandable clay minerals and soil organic matter because EG and EGME molecules are able to penetrate the interlayer space of clay minerals. This method also has been applied to natural soil. However, the use of the retention method is complicated because the polar EG/EGME molecules exhibit a tendency to form multilayers around exchangeable cations and, additionally, they undergo partition into soil organic matter.

Other methods

More recently, new methods for soil-specific surface area determination have been proposed. These methods are based, among others, on the measurements of adsorption of polyvinyl alcohol from aqueous suspension (Pagel-Wieder and Fischer, 2001), investigations of the soil-moisture potential (Filgueira et al., 2006), evaluation of hygroscopic water content (Moiseev, 2008), and determination of fractal dimension of particle-size distribution (Ersahin et al., 2006).

Specific surface area of mineral and organic solid (soils and plants)

Specific surface area can be related to various chemical and physical properties of soils (Zawadzki et al., 1971; Gliński et al., 1988; Wilczyński et al., 1993; Petersen et al., 1996; Theng et al., 1999; Stawiński et al., 2000; Ferreiro et al., 2002; Sokołowska, 2004; Pennell, 2005; Dolinar et al., 2007; Sivapullaiah et al., 2008).

The relationships between the specific surface area and some physical and chemical properties of mineral soils are presented in [Table 1](#) (modified from Sokołowska, 2004).

Dobrzański et al. (1977) found for 724 Polish mineral soil samples a wide range of the specific surface areas from a few to several hundreds $\text{m}^2 \text{ g}^{-1}$. The relationships between the specific surface area and the content of soil fractions <0.02 (a), <0.002 mm (b), and the organic matter content (c) for these soils were expressed by:

$$R = x_1a + x_2b + x_3c + w, \quad (7)$$

where x_1 , x_2 and x_3 are the multiple regression coefficients for the values a , b and c and w is a constant.

In particular, for mineral soils there exist a linear relationship between specific surface area and the content of the granulometric fractions. For the clay fraction the correlation coefficient is very high (cf. [Table 1](#) and [Figure 1](#)). Similarly, for several soils, the specific surface area is strongly correlated with the cation exchange capacity and the correlation coefficient is again very high for several soils (see [Table 1](#) and [Figure 2](#)). There also exist exceptions – poor correlations between those quantities were reported (Martel et al., 1979) for very organic-rich soils.

Soil organic matter is one of the import factors determining surface properties of soils and can also change the value of the specific surface area. However, the effect of the soil organic matter on the specific surface area is not unequivocal in general (Sokołowska et al., 2009). No correlation between the content of organic matter and surface area were found (Feller et al., 1992; Sokołowska et al., 2001; Sokołowska et al., 2002). The removal of organic matter from soils may either lead to a decrease of the

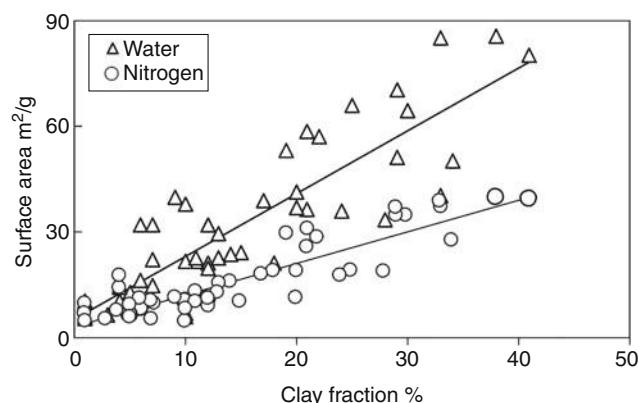

Specific Surface Area of Soils and Plants, Table 1 Correlation coefficients of linear regression between the specific surface area (S) obtained from water vapor and nitrogen adsorption data and selected properties of soils (data for 482 Polish mineral soil samples)

Sorbant	Soil fraction (%)		
	<0.02 mm	<0.002 mm	CEC ($\text{cmol} \cdot \text{kg}^{-1}$)

CEC cation exchange capacity

surface area (Sequi and Aringheri, 1977; Pachepsky et al., 1995) or to its increase (Sokołowska et al., 1993) (see [Figure 3](#)).

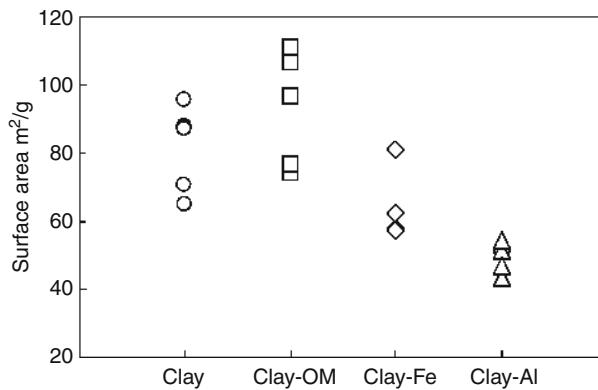

The numerical value of the surface area found for a given soil depends on which experimental method has been used. There are two principal reasons for this very important characteristic. First, the properties of the solid surfaces in soils can often be altered during preparation of the sample for a surface measurement. Second, if a surface reaction is involved in the measurement of the specific surface area, the data obtained reflect only characteristics of the surface functional groups that participate in the reaction, and provide information only about the solid

Specific Surface Area of Soils and Plants, Figure 1 Specific surface area obtained from water vapor and nitrogen sorption data vs. content of the clay fraction.

Specific Surface Area of Soils and Plants, Figure 2 The correlation between the specific surface area (S) obtained from adsorption and desorption data, and the cation exchange capacity (CEC) for vertisol (data taken from Sokołowska et al., 2004a).

Specific Surface Area of Soils and Plants, Figure 3 Specific surface area of clay fractions before and after removal of organic matter, iron, and aluminum.

surfaces that were reactive under the condition of the measurement (Figure 3) (Purin and Murari, 1963; Everett and Ottewill, 1970; Newman, 1983; Churchman et al., 1991; Ferreiro et al., 2002). Frequently the nitrogen surface area has been interpreted as the “external” surface, and the water surface area as the “total” one. In most cases, the total surface area exceeding the external one is measured. For soil minerals the water surface area is higher than the nitrogen surface area: for bentonite and zeolite about 10 times, for vermiculite more than 25 times, whereas for the other minerals around 2–3 times.

For an ideal adsorption, the adsorption and desorption isotherms should coincide (provided no phase transformations, e.g., a two-dimensional condensation within a monolayer, occur in the system). However, in the case of many experimentally measured isotherms one observes that the desorption branch deviates within some range of pressures from the adsorption one. When adsorption and desorption data are plotted together, then the upper curve corresponds to desorption, while the lower branch indicates adsorption. This behavior is called adsorption hysteresis. Adsorption hysteresis is very common. Generally, hysteresis loop is connected with porosity and their shape is determined by the character of adsorbent and adsorbate and by the interactions between them (Gregg and Sing, 1978; Oćik, 1982; Sing, 1982). Generally, the values of the specific surface area obtained from adsorption and desorption data are different (Figure 2) (Sokołowska, 2004).

The term adsorption presently used in the physical chemistry for mineral adsorbents and soils, is not adequate for organic soils, because the accumulation of gaseous molecules occurs not only at surfaces, but they can also enter the interior of organic phase, i.e., they can undergo absorption. In such cases the term *sorption* is more appropriate. The term *sorption* embraces both types of phenomena, adsorption and absorption.

The BET surface areas of the organic soils and other organic materials, evaluated by using polar substances,

usually locate in high ranges of surface areas of mineral soils (Mayer and Xing, 2001; Józefaciuk and Szatanik-Kloc, 2003; Sokołowska et al., 2004b, 2008; Szatanik-Kloc et al., 2009). Polar compounds (like EG) can partition into soil organic matter and this should hamper their use for measuring reliable value of specific surface area (Pennell et al., 1995). For the surface area determined by the EG method, the term “apparent surface area” was proposed, while the surface area determined by N₂-BET method was called “the free surface area” (Chiou et al., 1990). The last term corresponds to the interfacial area of a solid, which exist before the adsorption and can be unequivocally measured by an adsorbate that does not change the structure of the solid.

Conclusion

Two factors, surface area and porosity are recognized to play complementary part in adsorption phenomena for a vast range of solids. Specific surface area is an important feature of soil. It characterizes both quantity and quality of mineral and organic components and also their physical and physicochemical properties. These properties treated separately do not give such exact information about the state of the soil as specific surface area. The idea of estimate of the surface area is to find the number of adsorbate molecules that cover the adsorbing surface as a monolayer, and multiply this number by the area occupied by a single molecule. The specific surface area is usually determined by adsorption methods. Therefore, methods are needed for the rapid determination of the specific surface area, especially in routine analysis. Regression relationships (pedotransfer function) were developed for the approximate estimation of the specific soil surface area.

STABLE ISOTOPES IN EVALUATION OF GREENHOUSE GAS EMISSIONS*

Kurt A. Spokas
United States Department of Agriculture, Agricultural Research Service, St. Paul, MN, USA

Definitions

Isotopes. Atoms of the same element with differing number of neutrons, but with the same number of protons.

Stable isotopes. A particular grouping of isotopes that do not undergo radioactive decay (thereby are stable).

Introduction

Isotopes offer a unique opportunity to have natural tracers present in the ecosystem to track produced greenhouse gasses (GHG; [Climate Change: Environmental Effects](#)) through multiple scales. Isotopes are atoms of the same element with differing number of neutrons, but with the same number of protons. For example, carbon-12 (^{12}C) and carbon-13 (^{13}C) are two naturally occurring isotopes of carbon, both have six protons, except ^{12}C has six neutrons and ^{13}C has seven neutrons. This differing number of neutrons leads to differences in the atomic masses of the elements. There are two basic types of isotopes, which are grouped by their stability. The first group of isotopes that do not decay are referred to as stable isotopes and those that do decay are called radioactive isotopes. Radioactive isotopes undergo radioactive decay by which the unstable atom loses energy (emitting radiation/ionizing particles). Radioactive isotopes are mainly used for energy production (Ferguson, [2007](#)) as well as geological dating of materials (Arnold and Libby, [1949](#)). These radioactive isotopes can also be used in the evaluation of greenhouse gas emissions, particularly in mechanistic studies (e.g., Turnbull et al., [2006](#)). However, the main focus here is on the stable isotopes.

Isotopic compositions at or near natural abundance levels are reported in delta notation (δ), a value which is in parts per 1,000 or per million ("‰"). Delta values are not absolute isotope measurements but rather differences between sample readings and a reference material ([Table 1](#)).

These reference materials are considered to have a delta value of zero ($\delta = 0\text{‰}$). Absolute isotope ratios (R) are measured for both the sample and reference standard, and then delta is calculated by the following equation:

$$\delta X \text{ per mil versus standard} = \left(\frac{R_{\text{sample}} - R_{\text{std}}}{R_{\text{std}}} \right) \times [1,000 \text{ ‰}],$$

where X is the particular element and R is the ratio of the atomic percentages of the heavier isotope to the lighter isotope, e.g., for nitrogen this would be

$$R = \left(\frac{\text{Atomic \% } ^{15}\text{N}}{\text{Atomic \% } ^{14}\text{N}} \right)$$

The major benefit to stable isotopes as opposed to radioactive isotopes is that stable isotopes do not decay. Since stable isotopes do not decay, their abundance is not a function of time, which improves the use of the stable isotopes as tracers of GHG emissions. For many biological (microbial reactions, enzyme reactions, plant respiration, etc.) and abiotic processes (diffusion, photolysis, solution equilibrium, phase transitions, etc.), there are differences in the reaction rates for different isotopes (Galimov, [1985](#)). These differences in reaction rates lead to differences in the distribution of the isotopes in the end products compared to the starting material, which is referred to as fractionation (Hayes, [1982](#)). However, this fractionation can be a function of several variables (e.g., microbial species, temperature, substrate availability) and presents a potential source of error in isotopic interpretations (e.g., Morris et al., [2005](#)). Recent observations have also revealed the potential for water vapor flux fractionation in addition to thermal and gravitational fractionation in soil gas transport (Severinghaus et al., [1996](#)).

Different sources of trace gasses often show characteristic variations in their isotopic signatures, which allow one to distinguish the sources of the GHG. However, atmospheric sink reactions cause kinetic isotope fractionations which contribute to the naturally occurring variations of isotopic composition and need to be accounted for in global estimates (Kohen and Limbach, [2005](#)). There are approximately 250 known stable isotopes (Lajtha and Michener, [1994](#)). However, for GHG emission research, the focus is predominately on isotopes of carbon, nitrogen, hydrogen, oxygen, and sulfur ([Table 1](#)). In general, lighter isotopes react faster than heavier isotopes (Kohen and Limbach, [2005](#)), although exceptions exist such as gravitational fractionation where the heavier isotope is preferentially settled by gravity (Gibbs, [1970](#)). This small difference in reaction rates (fractionation) between isotopes leads to differences in the isotopic signature of the products as compared to the reactants. Provided the amount of fractionation is known along with the reactant and product isotopic distribution, the relative contribution of different processes can be calculated from the changes in the isotopic distribution.

The use of stable isotopes for mechanistic studies falls into two different categories. The first are those that utilize the natural abundance distribution ([Table 1](#)) to track processes, which is referred to as natural abundance isotope techniques. On the other hand, there are methods that add amounts of the rarer isotope (typically the heavier isotope) to the system under investigation to track the flow of the element through the system, which is referred to as isotope tracer techniques.

Stable Isotopes in Evaluation of Greenhouse Gas Emissions, Table 1 Abundances of stable isotopes of the major elements for greenhouse gas studies. (Data taken from Rundel et al. (1989).) Incidentally, all original supplies of both SMOW and PDB have been used up and replaced by secondary standards (U.S. National Bureau of Standards and International Atomic Energy Agency)

Element	Isotope	Abundance (%)	Reference material
Hydrogen	¹ H	99.985	Standard mean ocean water (SMOW)
	² H	0.015	
Carbon	¹² C	98.890	Peedee Belemnite (PDB)
	¹³ C	1.110	(Belemnitella Americana—Peedee formation of South Carolina, USA)
Nitrogen	¹⁴ N	99.63	Atmospheric air
	¹⁵ N	0.37	
Oxygen	¹⁶ O	99.759	SMOW or PDB
	¹⁷ O	0.037	
Sulfur	¹⁸ O	0.204	
	³² S	95.00	Canyon Diablo meteorite
	³³ S	0.76	
	³⁴ S	4.22	
	³⁶ S	0.014	

Background

Presented is a very brief history of isotopic studies; for further background on isotopes the reader is encouraged to consult Clark and Fritz (1997), Kendall and Caldwell (1998), and Kohen and Limbach (2005). As summarized recently by Kaiser (2002), isotopes have a fairly recent history. The initial research on stable isotopes was first conducted about 50 years ago (nitrogen metabolism using ¹⁵N [Dugdale et al., 1959]). The first measurements of the ¹⁵N content of atmospheric nitrous oxide (N_2O) were carried out in the early 1970s (Moore, 1974) and it was observed that stratospheric N_2O was enriched in ¹⁵N relative to troposphere N_2O , an observation that is still confirmed today (Yoshida and Matsuo, 1983; Crutzen, 2001). These large-scale measurements were soon followed by mechanistic studies utilizing isotopes for N mineral cycling (e.g., Dugdale et al., 1959; Garber and Hollocher, 1982). For C, the initial stable isotope work utilizing ¹³C was not conducted until the late 1970s (e.g., Slawyk et al., 1977), partly due to the previous focus on the radioactive ¹⁴C isotope (Kamen, 1963). The major contribution of this early research was confirmation that GHG (particularly N_2O , methane [CH_4] and carbon dioxide [CO_2]) produced from different processes have differing isotopic compositions. These differences are the foundation for the use of isotopes as tracers and results in isotopic analyses being pivotal to numerous research areas. Since we can quantify the differences in these stable isotopes, they have an immense utility to act as tracers for various biogeochemical applications to study both small as well as large global source–sink relationships (Rundel et al., 1989).

The use of stable isotopes in research has paralleled instrumentation improvements. Within the last 10 years,

new analytical techniques for determining intra-molecular ¹⁵N-site preference in the asymmetric N_2O molecule have been created (Toyoda and Yoshida, 1999), which has contributed to substantial new insights into fundamental nitrogen cycling quantification (Mariotti et al., 1981; Baggs, 2008). Intra-molecular preferences have been made possible by instrumentation improvements such as the first dual-isotope measurements (¹⁵N and ¹⁸O) (Wahlen and Yoshinari, 1985; Kim and Craig, 1990; Kim and Craig, 1993; Röckmann et al., 2001). Isotopic measurements typically have required expensive and dedicated stable isotope mass spectrometer systems in order to quantify the isotopic compositions. Recent instrumentation advances have eliminated this requirement with the use of tunable diode and quantum cascade lasers in the early 2000s (Petrov et al., 1998; Kosterev et al., 1999). These lasers can be located in the laboratory or field setting. These advancements have allowed coupling of isotopic data along with eddy covariance data to allow real-time calculation of various isotope fluxes across diverse ecosystems (e.g., Bowling et al., 2003; Schaeffer et al., 2008). Furthermore, these new analytical techniques allow isotopic ratios to be monitored in real-time and without the periodic sampling (in gas flasks or other containers) that was the high-labor burden of initial work with isotope research.

When we refer to isotopes in the evaluation of greenhouse gas emissions, there are two different scales of processes. The first is large-scale emissions (global) and the other is mechanistic determination of soil microbial processes (small scale). These two approaches will be discussed separately. However, these processes are not separate since the mechanistic studies feed into the global-scale studies.

Global-scale studies

As first noted back in the 1970s, isotope measurements provide a means to constrain the global budgets of GHG since different sources typically have different isotopic signatures. Isotopes initially were utilized in global circulation models in the 1980s focusing on the isotopes of water with very coarse spatial resolution (Joussaume et al., 1984; Grew et al., 1987; [Stable Isotopes, Their Use in Soil Hydrology](#)). However, more recently isotopes have been utilized in global top-down modeling approaches to constrain the global GHG budgets, since isotope measurements provide additional data to constrain these budgets. A couple of examples of this are given below.

Isotopic signatures of atmospheric CH_4 ($\delta^{13}\text{C}$) were recently used to more accurately constrain the contribution of atmospheric CH_4 from vegetation. Back in 2006, Keppler et al. (2006) presented results of a combination laboratory and bottom-up modeling that feasibly showed terrestrial vegetation as a yet unknown major contributor to global CH_4 budgets. From this research, they estimated that this discovered source from terrestrial plants would result in 62–236 Tg CH_4 year⁻¹ contribution to the global CH_4 budget (10–40% of total global CH_4 sources).

However, Ferretti et al. (2007) utilized $\delta^{13}\text{C}$ data to illustrate through a top-down modeling approach that this source of CH_4 was significantly lower than Keppler et al.'s (2006) estimates. From the isotopic data, both from atmospheric sampling and ice core data, they restricted this source down in the range of 0–42 Tg $\text{CH}_4 \text{ year}^{-1}$. Still the CH_4 from terrestrial plants is a source, but not to the degree that was suggested by the upscale modeling (bottom-up) of Keppler et al. (2006).

The isotopic signatures of N_2O have advanced the understanding of the contribution of various sources to the global N_2O budget (Baggs, 2008). However, major complications exist in the ability to differentiate a true isotopic signal due to the variety of production/consumption reactions that are possible in soils with the fractionation factor being dependent on the rate of N_2O reduction (Vieten et al., 2007). There is also uncertainty in the size of the global source for N_2O from oceans (Bange, 2006) as well as soils (Pérez et al., 2001; Conen and Neftel, 2007). Despite all the uncertainties, current estimates have established closure of the N_2O budget within an error of 10% (Houghton et al., 1994). Recent developments in the isotopologues of N_2O (or site preference for isotopic substitution) have provided new insights in potential differences between reaction pathways (Well et al., 2008). Röckmann et al. (2001) have utilized this new research data in the development of a refined model for the reconstruction of the global isotopic average N_2O source for present and preindustrial atmospheres.

Mechanism level research

Soil is a complex system. Recent advancements in DNA and RNA extractions from soils have improved our estimates on the diversity and abundance of microbes in the soil system. It has been estimated that up to 1,000,000 genomes exist per gram of soil (Chatzinotas et al., 1998; Gans et al., 2005). Putting this into a more tangible analogy, there are more than 10^{16} microbes in a ton of soil compared to a mere 10^{11} stars in our total galaxy (Curtis and Sloan, 2005). This makes it clear, that the soil is a very diverse and complicated system. Given these vast populations, a daunting task is to assess soil microbial processes. Further complicating matters, fewer than 1% of soil microorganisms can be cultured in the laboratory (Torsvik et al., 1990), leading to significant gaps in the fundamental understanding of microbial mechanisms and assessments of microbial functionality in the soil. However, soil microbial communities are instrumental in the emissions of GHG from the soils (Conrad, 1996; [Greenhouse Gases Sink in Soils](#)). A useful tool for the tracking and detection of microbial functionality is the use of stable isotopes in the assessment of microbial processes.

One particular application of stable C isotopes is in the determination of the percent of CH_4 being oxidized as the gas migrates through the cover soils at a landfill site. Stable carbon isotopic methods, which rely on the difference between the $\delta^{13}\text{C}$ of emitted CH_4 compared to the $\delta^{13}\text{C}$ of

un-oxidized CH_4 in the anaerobic zone (landfill), provide an estimate of the fractional CH_4 oxidation. In other words, the percentage of CH_4 that is oxidized during transport through the landfill cover soil materials. Isotopic methods have been developed over the last decade and rely on the preference of methanotrophs for the isotope of smaller mass (^{12}C rather than ^{13}C) (Liptay et al., 1998; Chanton and Liptay, 2000). In general, $\delta^{13}\text{C}$ values for un-oxidized CH_4 in the anaerobic zone are from about –57 to –60. However, when the CH_4 undergoes oxidation, these values undergo a positive shift to –35 or more, due to the microbial preference for the lighter isotope. This methodology has been pivotal in the improved estimation of the percent oxidation within landfill covers (Chanton et al., 2009). Additional improvements in the methodology are underway with the combined use of $\delta^{13}\text{C}$ and $\delta^2\text{H}$ methods since the hydrogen isotope has a larger relative fractionation factor in microbial processes (e.g., Hackley et al., 1996). This is analogous to the use of ^{18}O in the N_2O studies mentioned above and should provide additional insights into the active microbial mechanisms.

The most vital development in recent years in N_2O has been the research on isotopologues and ^{15}N site preference for the elucidation of major microbial pathways of N_2O production/consumption in soils (Baggs, 2008). N_2O is produced by a series of biogeochemical reactions. The most important are nitrification and denitrification (Firestone and Davidson, 1989). Since these processes are linked and use the same substrates, it is difficult to separate the contribution of each. Initially, it was assumed that a high $\delta^{15}\text{N}$ indicated a denitrification dominated system and a lower delta value indicated that nitrification dominated (Boontanon et al., 2000). However, this approach is problematic due to the wide isotopic variations (^{15}N) in the precursors of N_2O (nitrate or ammonia), which directly affects the distribution in N_2O (Pérez et al., 2000). Recent advantages in the dual-isotope methodology and site preference measurements have aided our understanding (e.g., Johnston et al., 1995). Pérez et al. (2006) have observed different site preferences in resulting N_2O for nitrifying versus denitrifying bacteria in incubations of Amazon forest soils. Sutka et al. (2006) utilized site preference differences to demonstrate the existence of two different nitrifying enzymatic pathways for N_2O production as well as the ability to detect denitrification. Baggs (2008) presents a good review on the current state of stable isotope research with N_2O . Site preference will be a useful tool in separating the microbial influences on N_2O production/consumption and potentially aid to the determination of the overall N_2O source strength of soils. The advantage to site preference is the lack of isotopic fractionation effects (Sutka et al., 2006) that has complicated the straight stable isotope approaches (Pérez et al., 2000). However, additional research is needed to fully evaluate these initial observations and results to be fed into the global-scale modeling effort to ascertain the contributions of the various sources.

Conclusions

The use of stable isotopes in tracking environmental processes is a very powerful tool across multiple disciplines, particularly in the quantification and tracking of GHG emissions. Some of the most important advancements in environmental research have utilized stable isotopic data. This overview provided a brief introduction, but by no means an exhaustive description, particularly in light of the growth of the research in this field. Stable isotopes offer a unique means of assessing GHG emissions from a variety of sources. However, as recent research has demonstrated, the complexity of the soil system and the number of simultaneous processes occurring limit the straightforward application of stable isotopes (e.g., Hayatsu et al., 2008), and the newer methods of dual-isotope and position specific isotope preference appear to be the future key into unlocking some the complexity of the natural system. With these new-found keys, we are gaining an increased knowledge of the global GHG cycles. This knowledge is vital not only for determining global GHG sources and sinks, but also for the potential mitigation of GHG emissions, particularly from soils. In other words, once we know the dominant processes we can alter management decisions to minimize sources.

Stable nuclides in the soil–plant–water system

Definitions

Isotopes. One of two or more atoms having the same atomic number (same chemical element) but different mass numbers due to different numbers of neutrons in their nucleus.

Stable isotopes. An isotope of an element that does not undergo radioactive breakdown. Stable isotopes are nonradioactive.

Stable isotopes in soil hydrology. Stable isotopes used to investigate soil–water interactions with the biological, hydrological, and atmospheric spheres.

Introduction

The Greek term “isotope” was coined in 1913 by Margaret Todd, a Scottish doctor and the British chemist Frederick Soddy to describe elements occupying the same place in the periodic table but with different atomic weights. In 1912, Joseph John Thomson proved the existence of stable isotopes: measuring the deflection of a stream of ionized neon gas, induced by magnetic and electrical fields, on a photographic plate. His assistant Francis William Aston pursued these discoveries developing mass spectrometry techniques to separate isotopes. Research has since continued on isotope properties and their characteristics; however, it is the application of isotope techniques and the information they can yield that has led to the most revolutionary advances in many fields of science. Using isotopes it is possible to trace the origin and pathway of different entities or to characterize complex natural phenomena, these techniques have been developed in a range of disciplines from medicine, to cure disease to earth sciences, using hydrology-based studies to solve environmental problems. Recent advances have been made using stable isotopes as high precision tools to explore the complex soil–plant–water continuum responding to the problems facing modern society such as water scarcity and resource management by improving water use efficiency (see *Water Use Efficiency in Agriculture: Opportunities for Improvement*), assuring food security, and reducing environmental impacts such as diffuse pollution and soil salinization (see *Salinity, Physical Effects on Soils*).

Natural abundance of stable isotopes

A number of elements in the periodic table have one or more stable isotopes with distinct concentrations in nature or natural abundance. In soil water studies the isotopes of interest are the isotopes of water itself (isotopes of oxygen and hydrogen) or those of associated elements that are dissolved in water (e.g., isotopes of nitrogen and carbon). Oxygen has three stable isotopes: oxygen-16 (^{16}O), oxygen-17 (^{17}O), and oxygen-18 (^{18}O), and their respective natural abundance on earth is 99.76%, 0.035%, and 0.2%. Oxygen-18 is usually preferred to oxygen-17 in environmental studies, because it is more abundant and therefore easier to measure.

Hydrogen has two stable isotopes: hydrogen (^1H) and deuterium (^2H or D) with natural abundances of 99.985% and 0.015%, respectively. ^{18}O and ^2H are extremely useful in hydrological studies, as they allow the direct tracing of water pathways.

Nitrogen has two stable isotopes: ^{14}N and ^{15}N with natural abundances of 99.634% and 0.366%, respectively. Carbon also has two stable isotopes: ^{12}C and ^{13}C with natural abundances of 98.9% and 1.1%, respectively.

Expression mode of stable isotope

Stable isotopes of an element are expressed as a ratio of the rarer isotope to the abundant isotope (e.g., $^{18}\text{O}/^{16}\text{O}$, $^{15}\text{N}/^{14}\text{N}$, $^2\text{H}/^1\text{H}$) as it is easier to measure isotopic ratios, rather than absolute values. Isotope ratio analysis is traditionally undertaken using isotope ratio mass spectrometry (IRMS), recently other successful spectroscopic techniques have been developed. In natural abundance studies, where there are minute differences, isotope ratios are reported, referenced against international standards, in delta (δ) units, parts per thousand ‰. This is also called the “isotopic signature” (Equation 1). The accepted reference for water is VSMOW (Vienna Standard Mean Ocean Water) (Clark and Fritz, 1997; Hoefs, 1997).

$$\delta^{18}\text{O}_{\text{sample}} = \left(\frac{(^{18}\text{O}/^{16}\text{O})_{\text{sample}}}{(^{18}\text{O}/^{16}\text{O})_{\text{VSMOW}}} - 1 \right) 1000 \text{ ‰ VSMOW} \quad (1)$$

In environmental studies it is sometimes useful to trace an artificially isotopically enriched source (e.g., fertilizer, irrigation water), especially if there is no natural isotopic variation in the different natural sources. Enrichments of the isotopes are then expressed as atom% enrichments (Equation 2 example for ^{15}N) (Knowles and Blackburn, 1993).

$$\%^{15}\text{N}/\text{N}_{\text{tot}} = 100 \frac{^{15}\text{N}}{^{15}\text{N} + ^{14}\text{N}} \quad (2)$$

If there is sufficient isotopic distinction of one element (natural abundances or enrichment) between sources it is possible to follow the pathways of the individual sources in the environment, as the isotopic signature of the mixed pool will be the result of the isotopic signature and contribution of each component to the final pool, based on mass balance equations. If there are only two sources and the isotope values of all pools are known then it is possible to quantify the contribution of each individual source to the final pool, from the isotope values alone, using an isotope mixing model. If there are three possible sources, an additional isotope signature is required to resolve the mixing model using this approach.

Specific properties of stable isotopes useful for environmental studies

Small differences in physical and chemical reaction rates caused by kinetic and equilibrium effects induce minute variations in the isotopic ratios of both substrates and products. The alteration in isotopic ratio between substrate and product is called fractionation. The specific sensitivity of isotopes during phase changes or reactions can be exploited to track changes in the environment. For example, during the process of water evaporation, the liquid phase becomes preferentially enriched in ^{18}O isotopes compared to the vapor phase.

There are two main phenomena that lead to isotopic fractionation: (i) isotope exchange reactions occurring at equilibrium and (ii) kinetic processes.

For reactions at equilibrium, modifications of the isotopic signature are quantified by the fractionation factor α , which is expressed as the ratio between the substrate and the product (Equation 3).

$$\alpha = \frac{R_{\text{substrate}}}{R_{\text{product}}} \quad (3)$$

For example, for oxygen isotopes in the liquid water (substrate) and vapor phase (product), the fractionation factor α at equilibrium during the process of evaporation (Majoube, 1970) is expressed as follow (Equation 4):

$$\alpha^{18}\text{O}_{\text{water-vapor}} = \frac{(^{18}\text{O}/^{16}\text{O})_{\text{water}}}{(^{18}\text{O}/^{16}\text{O})_{\text{vapor}}} \quad (4)$$

The fractionation factor between the liquid and vapor phases during evaporation of water is temperature dependent (Majoube, 1971). During evaporation of liquid water, the isotopic ratio $^{18}\text{O}/^{16}\text{O}$ increases in the liquid phase simultaneously inducing a depleted ratio in the vapor phase of the atmosphere. This is of practical importance when measuring isotopes in the Earth's atmosphere as the size of a cloud during rainfall is continuously diminishing. This type of reaction is well described by the Rayleigh equations (Clark and Fritz, 1997; Kendall and Caldwell, 2000). Kinetic processes also occur in nature due to incomplete and unidirectional reactions such as evaporation, dissociation reactions, biological mediation, and diffusion (Hoefs, 1997), contributing to slight global differences in isotopic signatures as predicted by the fractionation factors at equilibrium.

Numerous natural phenomena induce the modification of the isotopic signature of a considered element, allowing further interpretations and quantifications of natural processes and environmental tracing.

Factors influencing the isotopic signature of rainfalls, a source for soil water

Precipitation is a major input to the soil–plant–water system. It is therefore important to understand the natural processes influencing the isotopic signature of precipitation. Several factors have an impact on the isotopic signature of precipitation at the moment of its formation, such as temperature latitude/annual temperature, season, distance to coast, altitude, amount of rainfall leading to interannual variation, and small-scale variations (Clark and Fritz, 1997; Mook, 2006). Precipitation events can be individually traced in the Soil–Plant–Atmosphere Continuum (qv) of a specific field provided it has a distinct isotopic signature, which is the result of the environmental effects described above. Therefore, prior to starting any isotopic measurements, it is recommended to be aware of impact of such site-specific factors on isotope ratios, especially temperature.

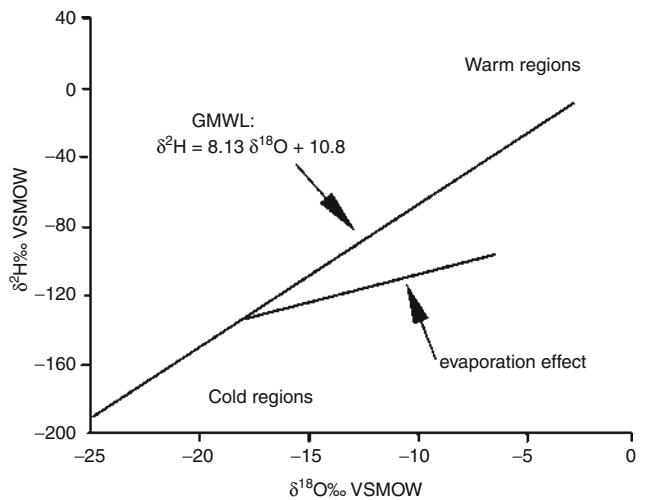

A clear relationship has been established between $\delta^{18}\text{O}$ and $\delta^2\text{H}$ in rainfall collected at different locations on Earth, known as the Global Meteoric Water Line (GMWL, Craig (1961)). It is also possible to establish a local

relationship (LMWL) at the site of measurement by collecting precipitations. Comparing the isotopic signature of collected soil water samples to the GMWL or the established LMWL allows determining the occurrence of evaporation (see Figure 1).

The use of stable isotopes in soil hydrology

Soil hydrology is a vast and complex domain, where water acts as the vector to transport dissolved nutrients, chemical compounds, and pollutants (see *Solute Transport in Soils*) in a medium interacting with the biological, hydrological, and atmospheric spheres (see *Soil Water Flow*). Water is also essential for assuring plant growth and facilitates the absorption of nutrients.

In the soil–plant–water system hydrological mass balance, the water inputs (qv *Water Budget in Soil*) are precipitation and/or irrigation, while the outputs are runoff, downward percolation and *Evapotranspiration* (qv), the combination of both soil evaporation and plant transpiration. Improving *Soil Water Management* (qv) by optimizing the hydrologic mass balance (qv *Water Budget in Soil*) in the soil–plant–water system is the key to solving many pressing environmental problems related to soils such as: (i) reducing diffuse pollution due to diluted nutrients or pollutants (qv *Leaching of Chemicals in Relation to Soil Structure*), (ii) improving *Water Use Efficiency in Agriculture: Opportunities for Improvement* (qv) and nutrient uptake by plants in cropped area to assure food security, (iii) reducing the water erosion, and (iv) reducing soil salinization (qv *Salinity, Physical Effects on Soils*). Therefore, there is a need to improve the knowledge of the driving processes associated to water such as *Evapotranspiration*, leaching, and plant water and nutrient uptake.

Stable Isotopes, Their Use in Soil Hydrology,

Figure 1 The GMWL established by Rozanski et al. (1993) and a schematic representation of the evaporation effect on the $\delta^2\text{H}$ versus $\delta^{18}\text{O}$ ratio of collected water. Evaporation induces a relative enrichment in $\delta^{18}\text{O}$ versus $\delta^2\text{H}$ compared to the original rainfall sample. The slope value of the trend decreases with increasing aridity.

Stable isotopes of water (^{18}O and ^2H) are tools that can be used in association with conventional methods to explore (i) water movement in the [Soil–Plant–Atmosphere Continuum](#) (qv), which includes impacts of management on downward percolation, runoff, soil evaporation, and plant transpiration; and (ii) the origins of soil water coming from precipitation, irrigation, groundwater capillary rise, river, and marine intrusion.

Previous research studies have specifically used isotopes of water (^{18}O and ^2H) to investigate water mechanisms, origins, and pathways within the soil–plant–water system.

Some studies have used the isotopic signature of soil water of bare soils to model soil water flux: percolation (see [Layered Soils, Water and Solute Transport](#)) and evaporation (see [Laminar and Turbulent Flow in Soils](#)) as shown on [Figure 2](#) (Allison et al., 1983; Barnes and Allison, 1984, 1988; Barnes et al., 1989; Barnes and Turner, 2000). Based on these models, it is possible to understand complex problems driven by water flux such as soil salinization (qv [Salinity, Physical Effects on Soils](#)), for example, Grunberger et al. (2008).

The percolation of precipitation through soil can be traced by comparing the isotopic signature of soil water with the signature of collected precipitation, for example, Gazis et al. (2004). This approach is useful to determine risky periods for diluted nutrient leaching in cropped area, for example, Macaigne (2007).

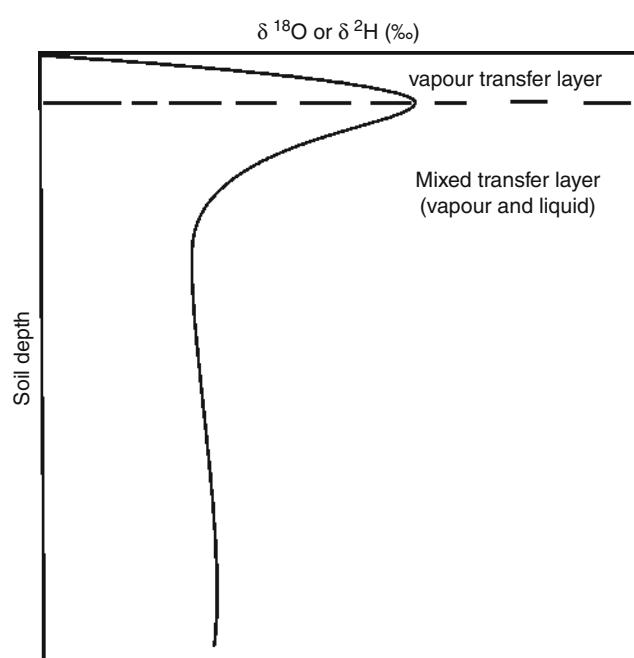

The isotopic signature of ^{18}O and ^2H in water extracted from soils and plants helps in characterizing plant water use and determining the influence of plants at a catchment scale perspective, especially the impact of deeply rooted trees on the hydrological cycle (Dawson and Ehleringer, 2000).

Specific studies have investigated plant transpiration from plant tissue as reviewed by Barbour (2007). Gas exchanges in ecosystems such as transpiration and CO_2 flux can also be studied with ^{18}O and ^{13}C (Yakir and Sternberg, 2000). Furthermore, soil evaporation (E) can be separated from plant transpiration (T) in the evapotranspiration flux (ET) based on isotopic measurement of ^{18}O and ^2H in soil water associated with soil water mass balance (Hsieh et al., 1998); or with more complex transport models integrated heat (see [Coupled Heat and Water Transfer in Soil](#)) and kinetic effects on the isotopic fractionation factor (Braud, 1995; Braud et al., 2005a, b); or with measurements of the ET flux (Wang, 2000; Yakir and Sternberg, 2000; Williams, 2004; Yepez et al., 2007) (see also [Stomatal Conductance, Photosynthesis, and Transpiration, Modeling](#)). Since transpiration reflects the true plant water use, separating E from T can help developing knowledge-based management strategies for improving water use efficiency in cropping systems.

In conjunction with ^{18}O and ^2H , other stable isotopes are used to characterize specific problems such as nitrate leaching and plant resistance to drought (qv [Drought Stress, Effect on Soil Mechanical Impedance and Root \(Crop\) Growth](#)). Movements of nutrients such as nitrate in the soil–plant–water system can be explored with nitrogen 15 (^{15}N) (Knowles and Blackburn, 1993). A slight enrichment in ^{15}N in the fertilizer allows investigating the fraction of fertilizer recovered by the plant (IAEA-TCS-29/CD, 2008). These and similar techniques have been widely used to test the efficiency of agricultural practices and biological nitrogen fixation (BNF) (Hardarson and Broughton, 2003). It is also possible to investigate NO_x gas emissions and nitrate removal from agricultural catchments to improve land management, for example, Zaman et al. (2008). Since ^{18}O is also present in phosphates (PO_4), it can be used to identify phosphate sources in aquatic systems coming from waste water, fertilizer, or plant effluent (Young et al., 2009). [Drought Stress, Effect on Soil Mechanical Impedance and Root \(Crop\) Growth](#) (qv) has also been well explored by using a methodology based on the isotopic ^{13}C signature also called carbon isotopic discrimination (CID) (Farquhar et al., 1988; Condon et al., 1993; Dercon et al., 2006).

Summary

Specific properties of stable isotopes can be exploited in soil hydrology to investigate and understand complex mechanisms and to identify the origins of water. The isotopic signature of individual precipitation events determined by temperature and other natural effects allows tracing its pathways in the soil–plant–atmosphere system. The use of stable isotopes (^{18}O and ^2H , ^{15}N , ^{13}C) associated to models

STANDARDIZATION IN AGROPHYSICS

Andrzej Bieganowski, Magdalena Ryżak
 Institute of Agrophysics, Polish Academy of Sciences,
 Lublin, Poland

Definition

According to EN 45020:2006 (EN – European Standard), *standardization* is an activity of establishing, with regard to actual or potential problems, provisions for common and repeated use, aimed at the achievement of the optimum degree of order in given context.

There are two notes that complete the definition and explain the aim of standardization in the same standard:

- (a) *Note 1.* In particular, the activity consists of the processes of formulating, issuing, and implementing standards.
- (b) *Note 2.* Important benefits of standardization are improvement of suitability of products, processes, and services for their intended purposes, prevention of barriers to trade and facilitation of technological cooperation.

Standardization in agrophysics is realized on three levels:

- International level – ISO standards (ISO – International Organization for Standardization)
- Continental level – for instance EN – standards in Europe
- National level – for instance DIN (German Standards), BS (British Standards), or PN (Polish Standards)

Because agrophysics is an interdisciplinary science, the agrophysical standards are published by different

STEADY FLOW

The condition in which flow velocity do not vary with time.

STICKY

Having the property of adhering or sticking to a surface.

STOCHASTIC MODEL

Models based upon the concept that the variable of interest is represented by variability or uncertainty in the input values and the output represents probability distributions functions.

Law that defines the settling velocity of a particle based on its density and size.

STOMATAL CONDUCTANCE, PHOTOSYNTHESIS, AND TRANSPERSION, MODELING

Andrée J. Tuzet

Unité Mixte de Recherche, Environnement et Grandes Cultures, Institut National de la Recherche Agronomique (INRA), Thiverval Grignon, France

Definition

Stoma. Stomata are small pores on the epidermis of plant leaves. The aperture of the pore is controlled by the conformation of the two guard cells surrounding the pore. When the guard cells are relatively flaccid, the stomatal pore is nearly closed, and when they are turgid, it is open. **Stomatal conductance.** Stomatal conductance expresses the aptitude of stomatal aperture to control gas exchanges from or into the leaf.

Photosynthesis. Photosynthesis is a plant process that converts atmospheric carbon dioxide into more complex organic compounds, especially sugars, using energy from sunlight.

Transpiration. Transpiration is water taken up from the soil and lost through the stomata in the leaves. This loss of water as vapor through stomata is directly related to the degree of stomatal opening, the supply of water to the leaves, and the evaporative demand of the atmosphere surrounding the leaf.

Introduction

Modeling, like scientific observation and experimentation, is a method for increasing our understanding of cause-and-effect relationships. It requires classifying the processes involved according to importance, which results in the creation of a simplified reality. The modeling approach selected for a given problem depends on implied objectives, which can be expressed as a combination of precision, generality, and reality (Levins, 1966).

In order to utilize water resources effectively, and to quantitatively evaluate plant production and interaction between the vegetation and the environment, we need to model mass and energy-exchange processes within the soil–plant–atmosphere system through stomatal conductance, photosynthesis, and transpiration. The processes of transpiration and photosynthesis are closely related since they are regulated by the same stomatal feedback control mechanism. This feedback mechanism constantly modifies the conductance to water vapor and carbon dioxide exchanges in response to changing environmental conditions. The use of mechanistic models is ideally suited for gaining a better insight into the integrative behavior of the soil–plant–atmosphere system.

Stomatal conductance

Stomata have evolved physiological control mechanisms to satisfy the conflicting demands of allowing a net carbon gain by leaves while restricting water loss to acceptable

levels, under a range of environmental conditions. Therefore, it is very important to understand responses of stomata to environmental factors and to simulate stomatal conductance. In these aspects, numerous researchers have contributed to the study, and important advances have been achieved in understanding and mathematically modeling the physiology of stomatal movement (Jarvis, 1976; Cowan, 1977, 1982; Ball et al., 1987).

Jarvis (1976) presents an early empirical model in which stomatal resistance is estimated as multiplicative response functions of environmental variables (solar radiation, leaf temperature, water vapor pressure deficit) and soil or leaf moisture status. The environmental dependences are assumed to be separable, so that the dependence on each environmental variable is described by an individual response function which varies between 0 and 1. Predicted values of stomatal conductance are derived as the product of the maximum stomatal conductance and each of these functions. This approach is often employed in various forms for different vegetation surfaces; it is mainly guided by the concern to keep the number of physical variables low, while preserving the main mechanisms controlling the opening and closing movement of the stomata. The general problem arising with this approach is its specificity to particular vegetation–climate systems and parameters, such as the maximal stomatal conductance, or the sensitivity of stomatal conductance to environmental variables, and it must be therefore constantly readjusted to fit a particular vegetation type or prevailing condition.

Cowan (1977) is one of the first to analyze the role of stomatal conductance in regulating the balance between transpiration and net uptake of CO₂ for photosynthesis, in order to assess the transpiration-use efficiency (amount of C gained per water used). He considers functional and theoretical constraints that are presumably major factors in the evolution of the regulatory mechanisms of stomata, and he proposes to link stomatal control to an optimization between changes in assimilation and transpiration (Cowan, 1982). The mechanistic basis of this theory remains unresolved. The reason for this is that while diffusion is a well-defined physical process, and photosynthesis is essentially a reaction involving identifiable molecular components including CO₂, stomatal function is a control process depending on numerous feedbacks between poorly defined physiological and biochemical processes. Numerous empirical models of stomata behavior are developed on the basis of these experimental and observational studies. The model proposed by Ball et al. (1987) and later extended by Leuning et al. (1995) which links conductance to photosynthesis received wide attention and applications. This model expresses the dependence of stomatal conductance on net carbon assimilation, relative humidity or vapor pressure deficit, and leaf CO₂ concentration. The great interest in this approach relies on the opportunity to integrate it in general circulation models by coupling stomatal conductance transpiration and CO₂ concentration for predicting

greenhouse gas-induced climate change. It is also advantageous because the dependence of stomatal conductance on various factors can be achieved indirectly through their effects on photosynthesis since the model operates as a function of carbon assimilation. Correct parameterization of the model provides close agreement between simulated and observed stomatal conductance values and carbon assimilation rates. However, the empirical nature of this model makes it difficult to extrapolate it into different environmental conditions. For example, the effect of soil water stress on stomatal conductance is not explicitly included in this model.

To account for the dynamic response of stomata to the competing atmospheric demand and supply of water to leaves Tuzet et al. (2003) developed a model which fully couples stomatal conductance, water transport through the plant and soil, CO₂ assimilation, and the leaf energy balance. In this model, the parametrization of stomatal conductance is a variant of the Ball–Berry model which includes the responses of stomata to leaf water status. This stomatal feedback control mechanism is activated by the level of leaf water potential. It is expressed in terms of stomatal sensing of the soil water uptake, via changes in the gradient of water potential between the leaves and roots. An empirical logistic function is used to describe the sensitivity of stomata to leaf water potential. In this approach, water uptake by the roots is calculated dynamically to get the detailed distribution of water near the roots. This precise description is particularly important as the soil dries out because of the strongly nonlinear relationship between the moisture content and the hydraulic conductivity, which affects the water transport from the bulk soil to the root surfaces. This new scheme calculates directly the effects of supply and loss of water by leaves on stomatal conductance, an approach also adopted by Williams et al. (1996) and Grant et al. (1999).

Photosynthesis

Photosynthesis is the process of converting light energy to chemical energy and storing it as carbohydrates. This process occurs in plants and some algae. Plants need light energy, CO₂, and H₂O to make sugars. Photosynthesis takes place in the chloroplasts and involves the interception of light energy and its conversion to chemical energy in the intermediates of high chemical potential, which are then used to drive the catalytic fixation of CO₂ into sugars and others compounds. Photosynthesis is not a single reaction; rather, it is composed of many individual steps that work together with remarkably high overall efficiency. Despite this complexity, there are several key biochemical processes that allow simplification in photosynthesis modeling.

Over the past 25 years, models of photosynthesis integrated to the leaf level have progressed from a collection of partial process models to an integrated mathematical form, with an undeniable dominance of Farquhar, von Caemmerer, and collaborators in the process. Today almost

all mechanistic models of leaf photosynthesis are based on the kinetic properties of the enzyme Ribulose-1,5-bisphosphate (RuBP) carboxylase/oxygenase (RuBisCO). This enzyme is used in a dark reaction to catalyze the first major step of carbon fixation and the competing reaction of RuBP oxygenation. This reaction does not directly need light to occur, but it does need the products of the light reaction: ATP (Adenosine Triphosphate) and NADPH (Nicotinamide adénine dinucléotide phosphate). The dark reaction involves a cycle called the Calvin cycle in which CO₂ and energy from ATP are used to form sugars.

According to the model (Farquhar et al., 1980; Farquhar and von Caemmerer, 1982), the net rate of carbon assimilation is the carbon fixed by the rate of RuBisCO carboxylation minus the carbon released by the photorespiratory cycle (half the rate of RuBisCO oxygenation) and minus day respiration (CO₂ release occurring in the light other than that of photorespiration). Farquhar's model assumes that for C3 plants, the rate of RuBisCO carboxylation is limited by the slower of the two processes: (1) the maximum rate of Rubisco-catalyzed carboxylation (Rubisco-limited) or (2) the regeneration of RuBP controlled by the electron transport rate (RuBP-limited). The rate of regeneration of RuBP is dependent upon the concentration of the high-energy nucleotides ATP and reduced NADPH, both of which dependent on photochemical energy supply, which is controlled by Photosynthetic Photon Flux.

At the level of the individual C3 leaf, Farquhar's model enjoys general acceptance, and it is widely used to interpret leaf-scale photosynthesis data. However, considerable skill is needed in using it for a plant canopy. Although the big-leaf approximation is successful for modeling evapotranspiration for plant canopies, the same approximation may be erroneous for photosynthesis because of the additional leaf internal control on carbon assimilation. From this perspective, the big-leaf methodology needs to be further examined using experimental data. Many studies demonstrate successful use of Farquhar's model at the canopy level using other approaches such as vertical integration against radiation gradient (Baldocchi, 1993) and separation of a canopy into sunlit and shaded portions (Norman, 1993; De Pury and Farquhar, 1997).

Transpiration

Transpiration is the process by which water is taken up from the soil and lost through the stomata in the leaves. It is only a part of the total evaporation that may occur from vegetation. In transpiration, water flows through the plant in response to physical forces. There is a decreasing water potential from the soil to the roots, up through the xylem and leaves, and out into the atmosphere. Therefore, water moves by bulk flow in response to water potential gradients, pulling water from regions of high water potential toward areas of lower water potential. The atmosphere, even with only small humidity

deficits, is a large sink for water vapor and draws water away from the leaves through the stomata, thus allowing cooling of the leaf surface in the evaporating process.

The driving force of water through the plant is determined by factors such as solar and atmospheric radiations, wind speed, temperature, and air humidity. In the air spaces within the leaf, the liquid water becomes vapor. If the stomata are open, water vapor will usually diffuse into the atmosphere because of the relative dryness of the atmosphere compared to the near saturation inside the leaf.

The flow of water through the transpiration stream can be thought of in terms of supply and demand. Most of the time, water lost through transpiration is replaced by water absorbed from the soil by the roots. Short-term water deficits can occur in plants even when there is adequate soil water available. This can occur if the atmospheric demand exceeds the capacity of the roots to meet it. These deficits can be partly made up for by the closure of stomata. We can say that transpiration processes depend on biologically mediated responses to aerial and soil environments that can, in turn, exercise feedback effects via the plant on the energy balance, turbulent exchanges, and air characteristics (temperature and humidity), thereby determining the state of the environment itself. Therefore, the prediction of transpiration fluxes under changing climates involves suitable models describing the complex interaction of plant and environmental variables.

For many decades, transpiration models based on the energy balance were mostly derived from the Penman equation (Penman, 1948). Priestley and Taylor (1972) show that transpiration is a rather conservative variable, which can be determined primarily by the available energy. Combined with temperature and vapor pressure deficit, they obtain good results for well-watered vegetation. Monteith (1965) enlarges the Penman model with a stomatal conductance model. However, the use of simplistic approaches often fails to account for a number of interacting effects such as energy balance and soil water availability. More sophisticated approaches are proposed to account for interactive effects and to view the water transfer system in the three domains of soil, plant, and atmosphere as a whole. This need for a soil–plant–atmosphere continuum (SPAC) approach was first recognized by Philip (1966) and Cowan (1977) and by many other authors later. In these models, root water uptake is determined by a potential transpiration calculated from atmospheric conditions and a reducing function, which depends on the mean soil water content. Use of mean soil moisture content, rather than the value near to the roots, may lead to incorrect values for the resistance to water flow in the soil. Furthermore, the spatial distribution in moisture content also changes through the day, and hence the dynamics of water flow to the roots will not be captured when mean soil moisture content is used to calculate soil hydraulic resistance. To overcome this deficiency, the model of Tuzet et al. (2003, 2008) uses Richards' equation for water flow from the soil to the roots, rather than using soil hydraulic resistances. Plant water relations are

modeled as an analog to a simple electrical circuit including plant hydraulic resistances and plant capacitance. This approach ensures a complete coupling between stomatal conductance, plant energy balance, transpiration, and water transport in the soil–plant–atmosphere continuum and describes the dynamics of the different water fluxes.

Summary and conclusions

To survive and grow, plants must take up carbon dioxide through the stomata while avoiding desiccation and death. Stomata play a pivotal role in regulating water loss and CO₂ uptake by plant leaves. The degree of regulation varies continually in response to changing environmental factors such as light intensity, leaf temperature, water vapor pressure deficit, CO₂ concentration, and soil or leaf water status. Therefore, understanding stomatal behavior must involve a description of the *coupled* processes of leaf energy balance, transpiration, photosynthesis, and the dynamics of water transport within the soil and plant.

The development of such models is important not only in improving water use efficiency of cropland but also in studying the interactions between the vegetation and the atmosphere under variable climatic environmental conditions.

environment, and an environmental buffer in the formation, attenuation, and degradation of natural and xenobiotic compounds. A favorable balance between solids and voids in soil is needed to optimize air exchange, to allow plants to extract water, and for soil to store water in pores. In addition, the organic contents of soil are vitally important in providing energy, substrates, and the biological diversity necessary to sustain many important ecosystem functions.

The soil surface is the vital interface that (1) receives much of the fertilizers and pesticides applied to cropland, (2) receives the intense impact of rainfall, and (3) partitions the flux of gases into and out of soil. Optimizing porosity and organic matter content of surface soil is necessary to optimize soil functioning, since characteristics at the soil surface oftentimes control functions deeper in the soil. As well, the soil surface is the most dynamic portion of soil that can be manipulated by management, and therefore, is the most sensitive to damaging or enhancing activities.

As soil organic matter increases, soil porosity also increases (Figure 1), in response to the positive effect of organic matter on soil aggregation, tilth, and biopore development (Kay and VandenBygaart, 2002). The degree of soil organic matter stratification can be viewed as an indicator of soil quality or soil ecosystem functioning, because surface soil organic matter is essential for erosion control, water infiltration, and conservation of nutrients (Franzluebbers, 2002).

Surface enrichment in soil organic matter and an improvement in soil porosity are dependent on (1) continuous surface residue cover and (2) minimal traffic, especially under wet conditions. Lack of residue cover and exposure of soil to high-intensity rainfall leads to poor aggregation, reduced plant-water availability, erosion,

STRATIFICATION OF SOIL POROSITY AND ORGANIC MATTER

Alan J. Franzluebbers

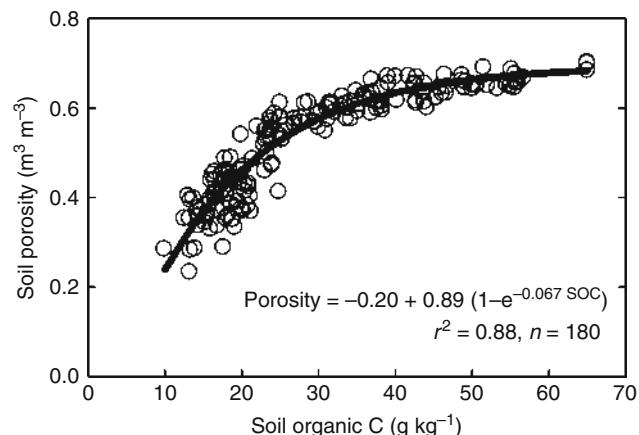

United States Department of Agriculture, Agricultural Research Service, Watkinsville, GA, USA

Definition

Soil porosity is the volume of soil not occupied by solids and can be filled with air or water. Volume of soil pores and concentration of organic matter are greatest nearest the soil surface and decline with depth. This characteristic is typical of undisturbed soils under grassland, forest, and conservation-tilled cropland. Soil porosity is strongly linked to soil organic matter concentration.

Soil organic matter and soil porosity stratification

Soil is an essential natural resource that provides several important ecosystem functions, e.g., medium for plant growth, regulation, and partitioning of water flow in the

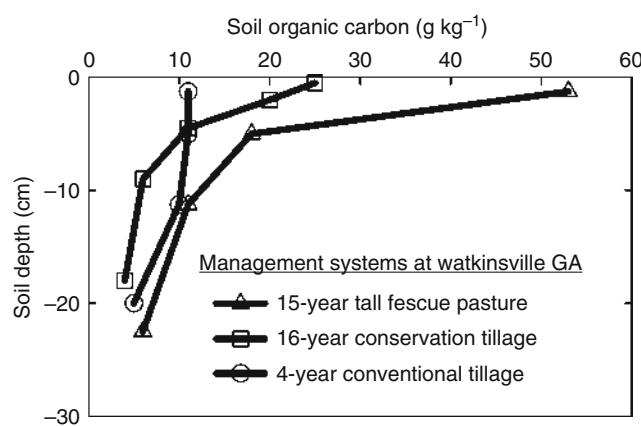

Stratification of Soil Porosity and Organic Matter

off-site sedimentation, and poor water quality, of which, all are characteristics of poor soil quality.

On cropland, soil organic C is uniform with depth when using traditional, inversion tillage systems (Figure 2). However, with conservation-tillage management (systems that leave >30% residue cover on the surface with minimum tillage, reduced tillage, mulch tillage, ridge tillage, or no tillage), soil organic C becomes concentrated at the soil surface and declines with depth (Figure 2). Pastures in a warm, humid climate are capable of increasing surface-soil organic C even more than under cropland (Figure 2). Perennial pastures encourage surface-soil

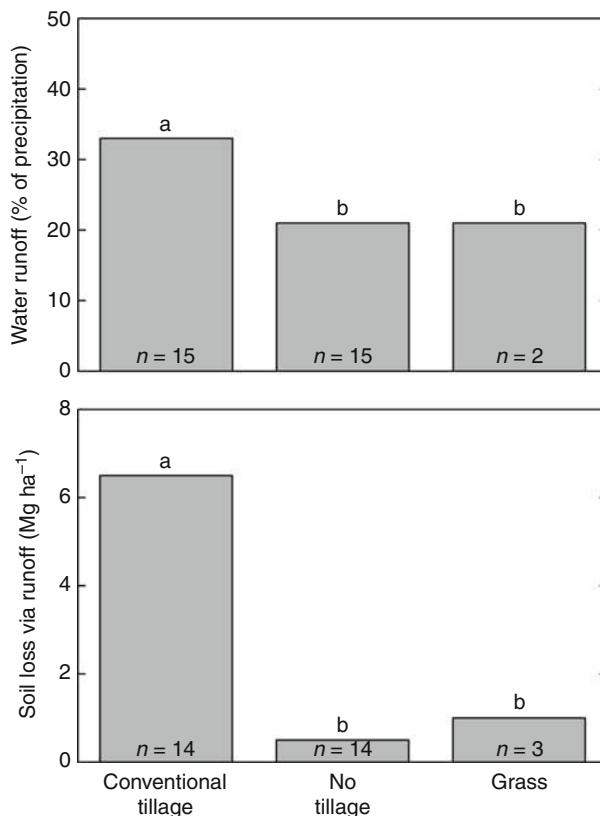

Stratification of Soil Porosity and Organic Matter,
Figure 2 Soil organic carbon as a function of depth and management on a Typic Kanhapludult in Georgia. (Data from Schnabel et al., 2001.)

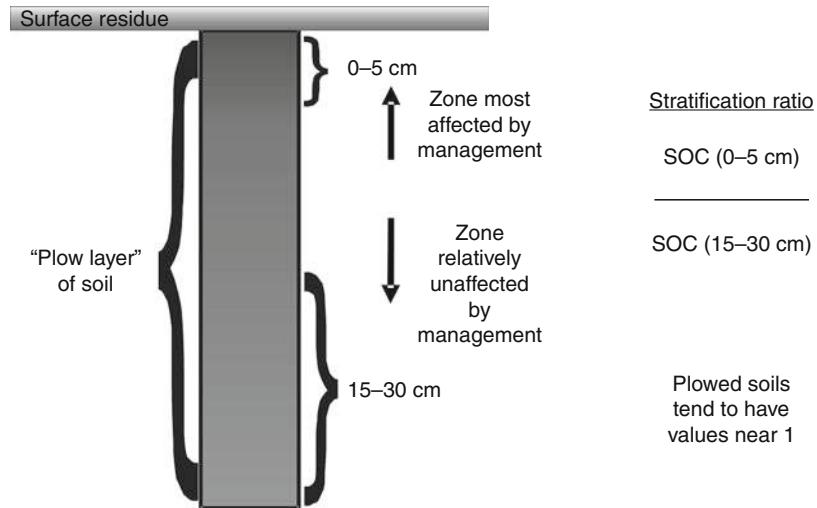

Stratification of Soil Porosity and Organic Matter,
Figure 3 Soil bulk density (inversely related to soil porosity) as a function of depth and management on a Typic Kanhapludult in Georgia. (Data from Franzluebbers and Stuedemann, 2008). Note: Bulk density of 1.1, 1.3, and 1.5 Mg m⁻³ would correspond to porosity of 0.58, 0.51, and 0.43 m³ m⁻³, respectively.

organic matter accumulation due to increases in C input (a longer growing period than most annual crops that fix C in plant biomass and greater transfer of C to an extensive root system) and decreases in C output (reduced decomposition due to lack of soil disturbance, more thorough soil drying, and large proportion of substrates at the soil surface).

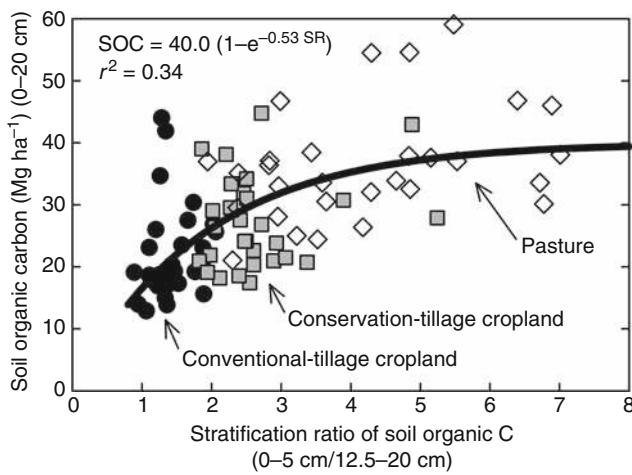

Soils under conservation-tillage cropland generally have lower soil porosity (conversely higher bulk density) in much of the previous “plow layer” than under conventionally tilled cropland (Figure 3), except at the soil surface with very high organic C concentration and consequently high soil porosity. Loss of porosity at depths below the soil surface with conservation tillage is often associated with changes in pore size distribution (Kay and VandenBygaart, 2002). Volume of macropores (>30 µm) usually decreases with conservation tillage (such pores are temporarily built through the loosening action of inversion tillage implements). However, biopores (rounded pores >500 µm) often increase with increasing number of years under conservation tillage.

Stratification of Soil Porosity and Organic Matter,

Different letters above bars within a panel indicate significant differences ($p < 0.05$). n number of observations.

Stratification of Soil Porosity and Organic Matter, Figure 5 Illustration of sampling zones and calculation of stratification ratio of soil organic matter.

Stratification of Soil Porosity and Organic Matter, Figure 6 Stock of soil organic C as a function of stratification ratio of soil organic C across 87 sites in the Piedmont and coastal plain regions of Alabama, Georgia, South Carolina, North Carolina, and Virginia. (Data from Causarano et al., 2008.)

Kay and VandenBygaart (2002) suggested that stabilized pore size distribution can only be expected with at least 15 years of conservation tillage.

Stratification ratio of soil organic matter has been calculated in several soils as an indicator of soil ecosystem functioning. Soils with high stratification ratio under long-term conservation-tillage cropland or under grassland often have greater water infiltration, lower soil loss from erosion, and lower nutrient loss in runoff than soil with low stratification ratio under conventional, inversion tillage (Franzluebbers, 2008). From a compilation of

water catchments with relevant data in the USA, water runoff and soil loss were lower in conservation-tillage cropland and grasslands than in conventionally tilled cropland (Figure 4). The effect of stratified organic matter is often greater on soil erosion control than on water runoff, since water can fill pores and runoff, but soil is stabilized with high organic matter even with excess rainfall.

Stratification ratio is calculated from the concentration of soil organic C at a sampling depth near the soil surface divided by the concentration of soil organic C at a sampling depth near the bottom of the “plow layer” (Figure 5). The depth increments for sampling are somewhat arbitrary at this point, until greater definition can be established as to what the impact of different sampling depths might be on predicting soil ecosystem functioning. Various numerator-depth increments sampled have been 0–3, 0–5, and 0–6 cm, while denominator-depth increments have been 12.5–20, 15–30, and 20–30 cm.

Stratification ratio of soil organic C (0–5/12.5–20 cm) has been related to the potential of conservation agricultural systems to sequester soil organic C in the southeastern USA (Franzluebbers, 2010). In a land-use survey, stratification ratio of soil organic C explained 34% of the variation in the stock of soil organic C under a diversity of management and soil conditions (Piedmont and coastal plain regions of Alabama, Georgia, South Carolina, North Carolina, and Virginia) (Figure 6). This relationship indicates that the majority of C stored with conservation management in Ultisols and Alfisols of the region occurred within the surface 5 cm. However, when stratification ratio of soil organic C was calculated as concentration at 0–2.5 cm divided by concentration at 7.5–15 cm, there was little relationship with soil organic C stock of conservation-tilled coastal plain soils in Virginia (Spargo et al., 2008). The surface 2.5 cm was

not adequately deep enough to represent the accumulation of soil organic C in these soils.

Conclusions

Quantity of soil organic matter is important to ecosystem functioning. However, stratification of soil organic matter appears to be even more important to ecosystem functioning. Soil quality and ecosystem functioning could be assessed with calculation of stratification ratio.

Stratification ratio increases the most on soils with low native organic matter. Such soils can be found in extreme environments with coarse texture and low precipitation or high temperature. Conservation management of these soils low in native organic matter are therefore, most improved in soil quality with the accumulation of organic matter at the soil surface.

STRENGTH

The capacity of a body to withstand stresses without experiencing failure, whether by rupture, fragmentation, collapse, or flow. In quantitative terms, it is the maximal stress a given body can bear without undergoing failure, or the minimal stress that will cause the body to fail.

Synopsis

The quantification of stress propagation and associated deformation processes in soils requires a detailed analysis of stress-strain relationships due to the nonlinear elastoplastic soil behavior. Deformation responses to loads are stress-strain path dependent, where deformation by compression and shear in turn controls stress distribution in the soil profile. Stress-strain relationships and resulting alterations of physical soil properties like hydraulic, gas, and thermal conductivity, as well as rooting need to be considered as an interactive process.

Introduction

It is well known that soils as three-phase systems can always mobilize internal tensile strength and shear forces over depth, which may attenuate applied external stresses. If, however, the external forces exceed the internal soil strength, a further deformation will occur until a new equilibrium will be reached and the rearrangement of particles as well as of soil aggregates has led to an equilibrated new, more rigid, denser volume orientation with the applied forces (Kezdi, 1969; McCarthy, 2007; Hartge Horn, 1999; Fredlund and Rahardjo, 1993; Horn et al., 2006). Within the last 4 decades, the mechanical stresses applied by agricultural (also forestry) machinery as well as the frequency of wheeling throughout the year have quadrupled and “final (=highest) maximum” values are still not to be seen (Hakansson, 2005).

Stress theory

The extent of soil deformation can be predicted by stress-strain processes and by their relative proportions. In the absence of gravitational and other applied forces, stresses in three-phase soil systems are subdivided into three normal stresses (σ) and six shear stresses (τ) acting on a cube; at equilibrium, the shearing forces reduce to three

components. Therefore, three normal-stress ($\sigma_x, \sigma_y, \sigma_z$) and three shear-stress ($\tau_{xy}, \tau_{xz}, \tau_{yz}$) components must be determined to fully define the stress state at a point (Nichols et al., 1987; Horn et al., 1992). This stress state can be then described completely by a symmetric matrix:

$$\begin{bmatrix} \sigma_x & \tau_{xy} & \tau_{xz} \\ \tau_{xy} & \sigma_y & \tau_{yz} \\ \tau_{xz} & \tau_{yz} & \sigma_z \end{bmatrix}. \quad (1)$$

For a single-valued characterization of the stress state, two invariants of the stress matrix are often used, the mean normal stress (MNS) and the octahedral shear stress (OCTSS) (Koolen and Kuipers, 1983):

$$MNS = \frac{1}{3}(\sigma_1 + \sigma_2 + \sigma_3) \quad (2)$$

$$OCTSS = \frac{2}{3}\sqrt{(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2}. \quad (3)$$

Strain theory

All stresses exceeding the internal soil strength initiate a plastic (irreversible) deformation. The latter is a process more complex than a volume reduction which is same as the volumetric strain, expressing only one degree of freedom, whereas deformation at constant volume (shearing) summarizes five degrees of freedom. Although it is useful to distinguish between shear and compaction/decompaction processes as they typically exhibit very different effects, all deformations in soils are combinations of both, utilizing the full range of six degrees of freedom. Analogous to the stress theory, strain can be described by normal ($\varepsilon_x, \varepsilon_y, \varepsilon_z$) and shear strain ($\varepsilon_{xy}, \varepsilon_{xz}, \varepsilon_{yz}$) components, being described completely by the symmetric strain matrix:

$$\begin{bmatrix} \varepsilon_x & \varepsilon_{xy} & \varepsilon_{xz} \\ \varepsilon_{xy} & \varepsilon_y & \varepsilon_{yz} \\ \varepsilon_{xz} & \varepsilon_{yz} & \varepsilon_z \end{bmatrix}. \quad (4)$$

In the corresponding principal axis system, the strain matrix reduces to:

$$\begin{bmatrix} \varepsilon_1 & 0 & 0 \\ 0 & \varepsilon_2 & 0 \\ 0 & 0 & \varepsilon_3 \end{bmatrix}. \quad (5)$$

The strain matrix completely describes the local soil deformation. For example, the volumetric strain (ε_{vol}) can be calculated as:

$$\varepsilon_{vol} = \varepsilon_1 + \varepsilon_2 + \varepsilon_3 = \varepsilon_x + \varepsilon_y + \varepsilon_z. \quad (6)$$

Note that the trace of a matrix is invariant under coordinate transformations. Furthermore, the strain components

and their proportions depend on internal and external parameters and require the determination of all components in a three-dimensional volume.

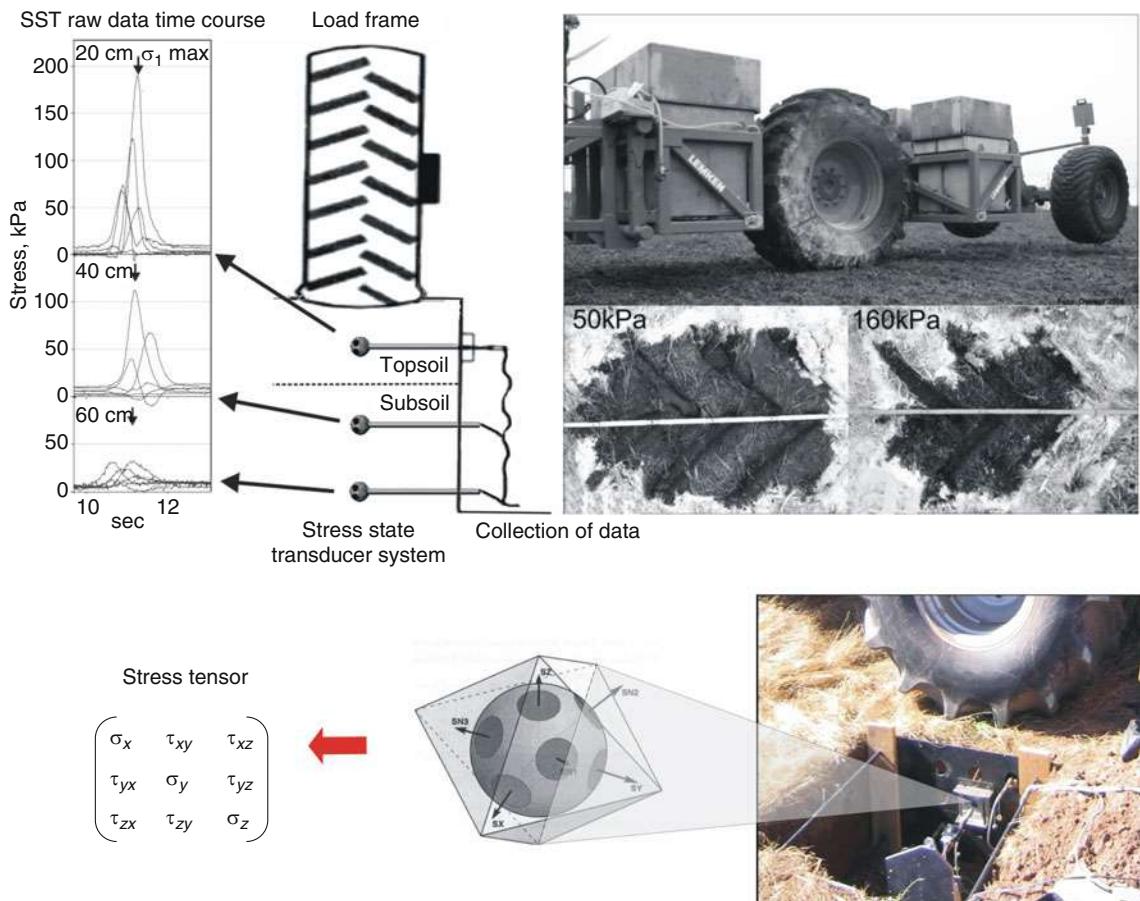

Stress propagation

Each applied stress is transmitted into the soil in three dimensions and can alter the physical, chemical, and biological properties if the internal mechanical strength ([Pre-Compression Stress](#)) is exceeded. The type of external force applied, time dependency, and number of compaction events can either change properties to depths by divergent processes or destroy a given structure by shear forces known as kneading. The latter case may result in complete homogenization and reversal to normal shrinkage behavior (Horn, 1988). [Figure 1](#) shows some general measurement techniques for in situ stress registration and analysis.

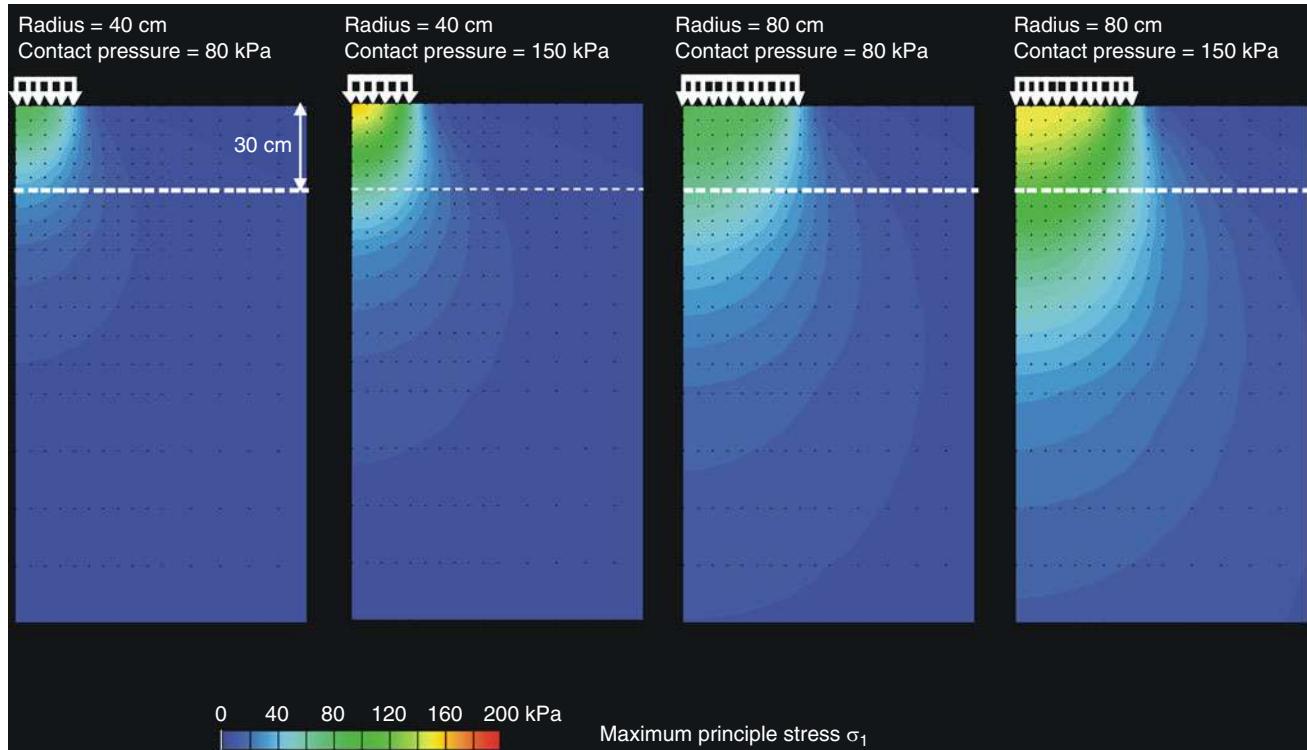

Stress propagation theories are rather old and have been often modified and adapted to in situ situations.

The fundamental theories introduced by Boussinesq (1885) are only valid for completely elastic material. Fröhlich (1934) and Soehne (1958) included elastoplastic properties through the introduction of concentration factor values (v_k) which allowed a more realistic description of the deeper stress penetration in soft soils. More comprehensive descriptions of these models are obtained by finally introducing pre-compression stress (P_v)—dependent values of the concentration factor, which are smaller in the recompression stress range, while they increase within the virgin compression stress range ([Pre-Compression Stress](#)). The latter can be explained by the plastic deformation behavior which causes a deeper stress transmission with a stress concentration more close to the perpendicular line of the load center.

The stress distribution in soils obeys the following physical laws: At a given contact area (defined as radius in [Figure 2](#)), the stress penetration is the stronger the greater the contact pressure. However, at a given contact

Stress–Strain Relations, Figure 1 (a) Experimental setup of a stress state transducer system (SST) and ballasted field load frame to simulate different wheel loads (in this case 3.3 Mg) and tyre inflation pressures. Tyre inflation pressures influence the distribution of the load on the soil surface resulting in different ground contact pressures which is demonstrated by the two footprint areas. (b) Detailed sketch of the stress measurement device showing the geometrical arrangements of stress transducers on the sensor head. From the various orientations of the stress transducers the full stress tensor can be calculated.

Stress–Strain Relations, Figure 2 Simulated distribution of the maximum principle stress (σ_1) for different tyre sizes and ground contact pressures. The dashed horizontal line indicates the depth of the plowed topsoil. Simulation was done with a finite element model (FEM) with a rotational symmetry of the elastoplastic half-space. The left border of the half-space corresponds to the centre of the load surface.

pressure, stresses are transmitted the deeper the greater the contact area (Figure 2).

Additionally, wheeling always induces shear stresses resulting in shear deformation. Shear stress and shear displacement are shown in Figure 3 for the case of a static wheel load with different ground contact pressures. Shear stresses significantly increase when traction forces are considered (not shown), which are generated when the vehicle is moving. In the case where shear stresses exceed the shear strength of a soil, both soil compression and shear deformation will increase and consequently further deteriorate pore functions down to deeper soil levels.

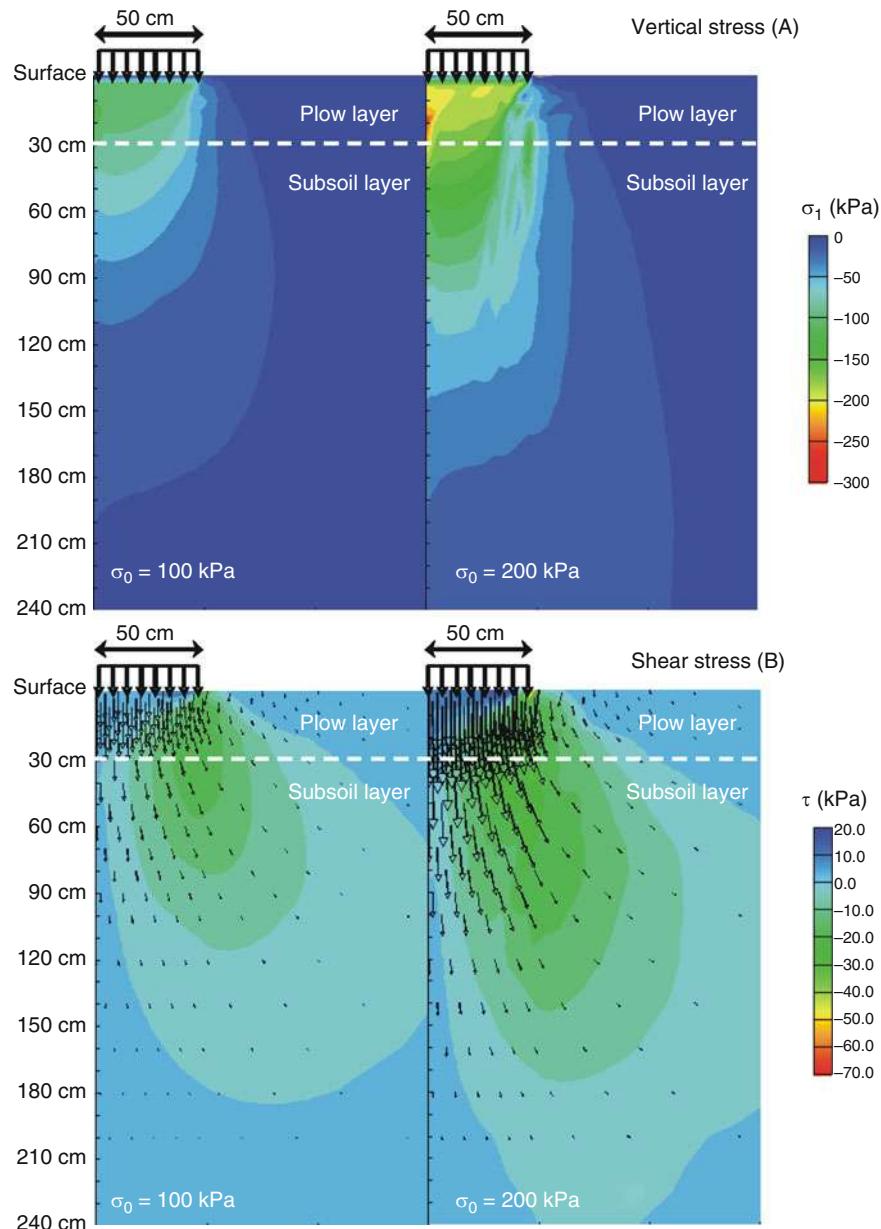

Precompression stress versus load

In order to quantify soil horizon-dependent specific stress attenuation and the consequences for stress-induced changes in physical properties, the combination of P_c of different soil horizons with the stress distribution in the soil profile is required. The concentration factor v_k as a measure of the stress transmission calculated from the Newmark equation (Newmark, 1942) is a function of the equivalent radius of the tire contact area, the effective contact pressure at the top of the respective horizon, and the calculated/measured P_c of each soil horizon. The mechanical strength of a soil can be derived from the

horizon-specific P_c , the actual soil pressure, and the strength-dependent concentration factor v_k of the respective horizon. It can further be deduced up to which depth additional deformation can be expected because the ratio of the applied stress and the strength of each consecutive soil horizon is >1 . The stress propagation theory and the calculation method are described in detail in Horn and Fleige (2003).

An example will elucidate the effect of stress propagation-dependent and internal strength-dependent attenuation for a natural (forest) Luvisol derived from loess and an arable site (Figure 4). If we assume natural properties of a Luvisol derived from loess (under forest) and compare the theoretical stress distribution for various agricultural machinery with depth, it becomes obvious that all stresses applied down to a depth of 60 cm exceed by far the internal soil strength of the Ah horizon with a crumbly structure and that of the clay derived Al horizon with a coherent (=weak) structure. Only the Bt horizon with a more rigid polyhedral and prismatic structure attenuates the remaining stresses more completely apart from the stresses exerted by the heavier sugar beet harvester.

The chosen arable site with an identical Luvisol derived from loess had been wheeled not only over decades with various agricultural machines and had a pronounced platy structure but also by the sugar beet harvester that had

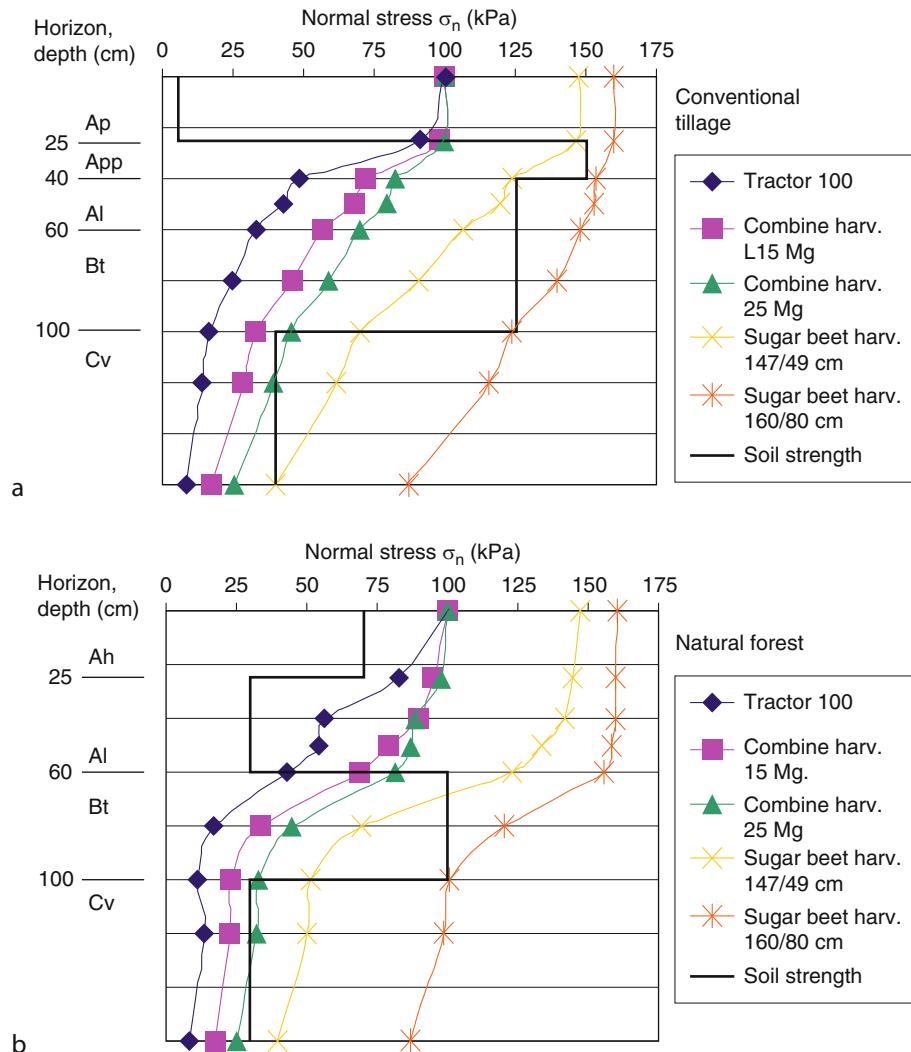

Stress–Strain Relations, Figure 3 Simulated (FEM) distribution of vertical normal σ_z (a) and shear stress τ (b) associated with different ground contact pressures. Arrows indicate corresponding shear displacements. Wheel loads in this case were considered static (no traction force).

passed the site for the first time. Thus, the soil was more rigid, which is expressed by increased actual precompression stresses over depth. Comparable machinery on this site caused the following stress distribution (under consideration of altered concentration factor values): higher values for the precompression stresses in the soil profile as a consequence of the long-term arable land management, including a reduced pore volume and reduced hydraulic functions. The transmitted stresses are attenuated within the soil horizons below the Ap horizon

completely, but stresses associated with heavier machinery (e.g., sugar beet harvesters) still cause additional plastic deformation at greater depth (Figure 4).

Some thoughts on consequences for sustainable land use

Soils are increasingly exposed to mechanical stresses during land use. Knowledge on stress–strain relations in soils and stress distribution within soil profiles is the basis for evaluating soil deformation and to protect soil

Stress–Strain Relations, Figure 4 Comparison between the depth dependent soil strength (pre-compression stress) and vertical stresses under arable land (a) and natural (forest) (b) soil conditions after the first wheeling event with a corresponding sugar beet harvester (35 Mg, 147 kPa contact pressure). The stress distribution was calculated based on strength dependent variation of the concentration factor for the various horizons.

functions. Long-term effects of soil deformation on soil functions include: increased uncertainty of crop yield, reduction in root growth, reduced plant available water and higher sensitivity to drought or stagnic conditions, cooler soils in springtime, enhanced greenhouse gas emission potential, altered nutrient adsorption behavior and retarded accessibility, consequences for microbial activity, retarded drinking water production, and higher sensitivity for overland flow or soil water erosion.

STRESS-STRAIN RELATIONSHIPS: A POSSIBILITY TO QUANTIFY SOIL STRENGTH DEFINED AS THE PRECOMPRESSION STRESS

Rainer Horn, Stephan Peth
Institute for Plant Nutrition and Soil Science, Christian-Albrechts-University zu Kiel, Kiel, Germany

Definition

Concerning their mechanical properties, soils are defined neither by a complete elasticity nor by a complete plastic deformation behavior but as elastoplastic if the relationship between stress and strain is defined.

Precompression stress

Each stress applied to a completely homogenized substrate (e.g., seedbed) will result in a proportional strain or settlement (if plotted as semilog relation) and will define the virgin compression, that is, the normal compression curve. Thus, after stress release the deformation remains preserved. During a following restressing with a new but smaller stress, nearly any additional substantial strain occurs until the former, that is, the maximal mechanical stress applied is reached again. Now, this stress range, smaller than the original one, causes mostly elastic strain behavior and only minor additional volume changes. Exceeding, however, the former maximum stress results in an intense strain (= soil deformation, settlement, and volume decline) in the mostly texture and hydraulic

conductivity (= drainage off the excess pore water) dependent virgin (= normal) compression range.

Synopsis

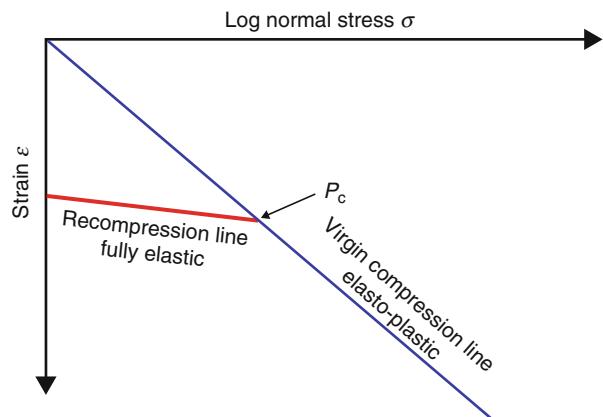

The quantification of the precompression stress of soils and soil horizons allows the overall determination of the internal soil strength and the transition from the elastic, that is, mostly reversible from the plastic deformation in the virgin compression load range.

Introduction

The compression of a soil means a change not only in total pore volume but is generally accompanied by a change in pore size distribution including related soil functions (e.g., permeability, storage of water, and aeration). Hence, the determination of the soils' resistance to compaction (i.e., its stability) and the magnitude of volume changes in soils exposed to external mechanical stresses are of primary importance for preserving soil physical quality.

The precompression stress (P_c) (often also defined as preconsolidation load, precompaction stress) is determined as the transition of elastic to plastic deformation if plotted as a semi-logarithmic stress-settlement (strain, void ratio) behavior. It can be quantified by the semiquantitative method of Casagrande (1936). In soil science, the P_c value and the corresponding graphical method (Figure 1) was introduced and validated for soil profile properties as a threshold value for internal soil strength by Horn (1981).

It is proofed to be a sufficiently good approximation of the stress and strain state of the various soil horizons for a given predrying intensity in numerous research papers (e.g., see Drescher et al. 1988; Horn et al., 2000; Pagliai and Jones, 2002). For more than 500 soil profiles under various land use systems and climates, this method was

Stress-Strain Relationships: A Possibility to Quantify Soil Strength Defined as the Precompression Stress,
Figure 1 Schematic diagram of a stress-strain relation and the definition of the precompression stress P_c (= internal soil strength).

applied to quantify not only the genetic soil processes, but also anthropogenic and climatic site effects (Horn and Fleige, 2003). Thus, the pre-compression stress values give three observations: (1) they are an indicator for the mechanical stability of a soil with respect to compressive deformation (compaction), (2) they record the maximum value of former stresses applied to the soil as long as there has no homogenization taken place since then, and (3) within the virgin compression stress range, each stress applied results in a plastic = irreversible deformation and consequently also reduces the pore volume, pore continuity, the hydraulic, gas, heat conductivity, and the corresponding diffusivity values.

The origins of this strengthening can range from pure mechanical stress application, biological activity (like the strength of earthworm casts or burrow (created by lateral stress application of up to 290 kPa by the worms), to chemical bindings' and also precipitation, hydraulic stresses, that is, shrinkage and swelling-induced aggregate formation.

Besides this Casagrande approach, additional methods were defined mostly by civil engineers like Hvorslev, van Zelst, and Ohde (all cited in Bölling, 1971). Their approaches include the rebound curve after the highest stress was applied in order to derive the precompression stress value. Thus, the latter ones all include the uncertainty of the rebound curve pattern caused by the wall friction effects, which is excluded by the Casagrande method and therefore more defined.

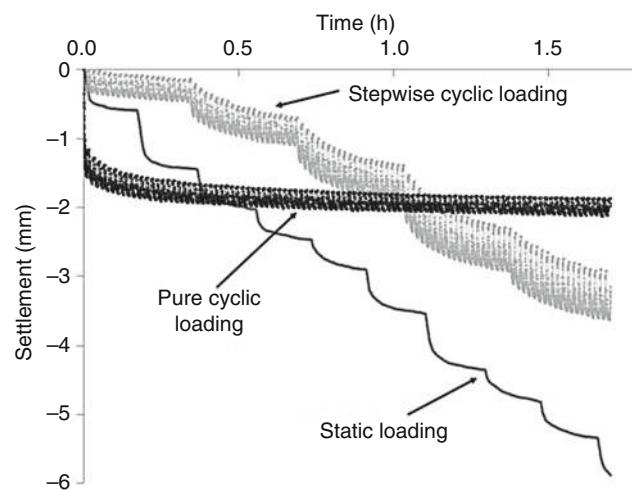

Comparison of various test approaches

Usually this compressive deformation is measured under laboratory conditions using undisturbed soil samples in a confined compression test (cf. Peth and Horn, 2006) whereby stresses in the σ_2 and σ_3 direction are undefined (rigid wall of the soil cylinder).

Three different tests can be carried out to define the internal soil strength (= precompression stress).

1. The stress-strain curve will be defined as a function of loading time and results especially in finer-textured soil samples in a flatter pattern and higher precompression stress values (time-controlled test).
2. The incremental changes in soil strain for a given stress applied can be defined as a criterion before the next stress is applied (height-controlled test).
3. The simultaneous control of the stress-and strain-induced changes of the pore water pressure during the test is used as a measure to define the application of the next stress (= pore water pressure-controlled test). The smaller the hydraulic conductivity due to loading and/or with increasing bulk density, the longer lasts each step – especially after exceeding the precompression stress the re-equilibration to the initial pore water pressure will not occur even after weeks.

Each of these tests can be furthermore prepared as (see Figure 2)

Stress–Strain Relationships: A Possibility to Quantify Soil Strength Defined as the Precompression Stress,

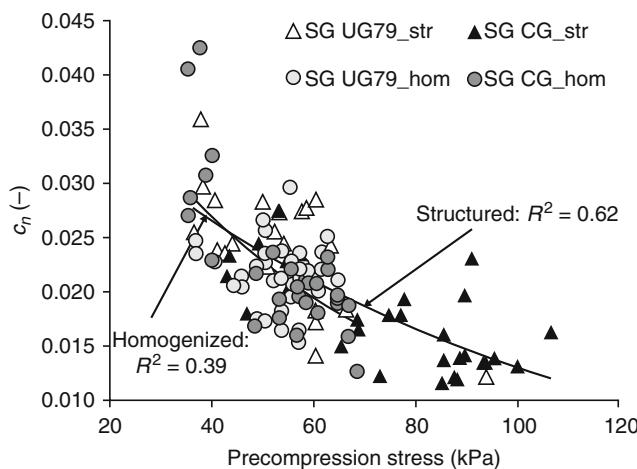

Figure 2 Examples of time–displacement curves during static, pure cyclic, and stepwise cyclic loading tests (taken from Reszkowska et al., 2010).

1. Static loading test (The sample will be loaded for a given time, for example, 10 min for each step and numerous defined stresses are applied successively while the height changes are recorded.)
2. Dynamic soil testing
 - (a) Cyclic loading. During this test, the load will be applied cyclically by repeated loading and unloading. This kind imitates the conditions, for example, due to animal movement or trampling with a given stress. The time intervals between loading and unloading can be defined.
 - (b) Stepwise cyclic loading. During this test, both the applied stresses and the number of cycles vary. Each load can be, for example, applied in 20 cycles (and each cycle may consist of 30 s loading and 30 s of unloading), which will result in a total loading and unloading time of 10 min each.

The results of such loading tests quantify the mechanical soil strength, which depends on soil parameters such as particle size distribution, type of clay minerals, nature, and amount of adsorbed cations, content and type of organic matter, aggregation induced by swelling and shrinking, stabilization by roots and humic substances, bulk density, pore size distribution and pore continuity of the bulk soil and single aggregates, water content, and/or water suction (Horn, 1981).

It can be stated that at a given soil type, the precompression stress value, that is, the internal soil strength is

1. the higher the more pronounced is the aggregation (coh<pris<pol<subangular blocky<crumbs<plat).

Stress–Strain Relationships: A Possibility to Quantify Soil Strength Defined as the Precompression Stress,
Figure 3 Correlation between precompression stress determined using 20th loading cycle (P_c') and coefficient of cyclic compressibility (C_n) for structured and homogenized samples of SG UG79 and SG CG for both investigated soil layers (4–8 and 18–22 cm); $n = 30$ (taken from Reszkowska et al., 2010).

2. the drier, that is, the more negative the matric potential is within the soil.
3. the higher is the organic carbon content. At a given amount of C org. strength increases with an higher proportion of humic acids.
4. the smaller the soil disturbance (conservation tillage results in stronger soils than conventional tilled sites).
5. the higher is the biological activity.
6. the more intense was the previous maximum and the duration of previous drying (for more detailed info see Hartge and Horn, 1999; Drescher et al., 1988; Fredlund and Rahardjo, 1993; Parry, 2004; McCarthy, 2007; Horn et al., 2000, 2005, 2006).
7. the higher because there is a significant correlation between the precompression stress and the rigidity of soil structure during cyclic loading expressed as coefficient of cyclic compressibility (C_n) (for more details see Reszkowska et al., 2010 submitted) (Figure 3).

Conclusions

The determination of the precompression stress is the most effective measure to quantify the internal soil strength as a consequence of soil mechanical, hydraulic, chemical, and biological impacts. This value depends also on the actual matric potential, is the basis for small up to large-scale soil mechanical strength maps, and can serve as a decision tool to predict the alteration in physical but also physicochemical and microbial site properties.

SUBSOIL COMPACTION

Rainer Horn, Heiner Fleige

Institute for Plant Nutrition and Soil Science, Christian-Albrechts-University zu Kiel, Kiel, Germany

Definition

Soil compaction and especially subsoil compaction are defined as one out of the ten major threats concerning soil degradation worldwide. The reduction of pore space and especially of coarse pores, the additional formation of finer pores, as well as the consequences for hydraulic, pneumatic, and heat transport processes are all linked to compaction. It can also be defined as increase in soil mass per volume and in combination with the shear induced rearrangement of particles at a given bulk density.

Introduction

According to the German Soil Protection Law (1998) and the European Soil Framework Directive (2006), soil compaction is besides water and wind erosion is one of the main physical reasons and threats of soil degradation. It is estimated, that 32% of the subsoils in Europe are highly degraded and 18% moderately vulnerable to compaction (Fraters, 1996, cited in Van den Akker, 2002). Thus, also the effects of soil deformation on crop yield, ground water recharge, soil loss by water and wind erosion, gas production, and emission (global warming) are to be considered if the mechanical strength in the top- and subsoil are exceeded (e.g., Horn et al., 2000, 2006; Pagliai and Jones, 2002).

Subsoil compaction is regarded as the major problem because it is defined as permanent and the pore functions

are not renewable after their deterioration or at least alteration. In Germany, the problem of compaction was defined in the German Federal Soil Protection Law (1998) by (1) the *obligation of precaution toward soil compaction*, which includes the request that soil compaction should be avoided “as far as possible,” and (2) the *obligation to prevent harmful changes of the soil*. Test and action values have to be defined for soil strength or maximal stress application, which is still on debate but some preliminary values are given in Horn and Fleige (2009). According to the concept “precompression stress P_c ” (Horn and Fleige, 2003, 2009; Horn et al., 2005; Stress-strain Relations by Peth and Horn) the value P_c can be used as precaution value to avoid subsoil compaction in general. The prediction of the change of soil functions/parameters after exceeding the P_c allows an assessment if critical values caused by subsoil compaction are already exceeded. These maps can be created for all scales and at different accuracy. As a general approach, the developed PDF (pedotransfer functions) can be used to derive for the dominant soil types corresponding PC-maps and stress dependent changes in physical functions up to the farm scale with actual controlled values based on a farm soil map (1:5,000).

Examples for PC maps at various scales

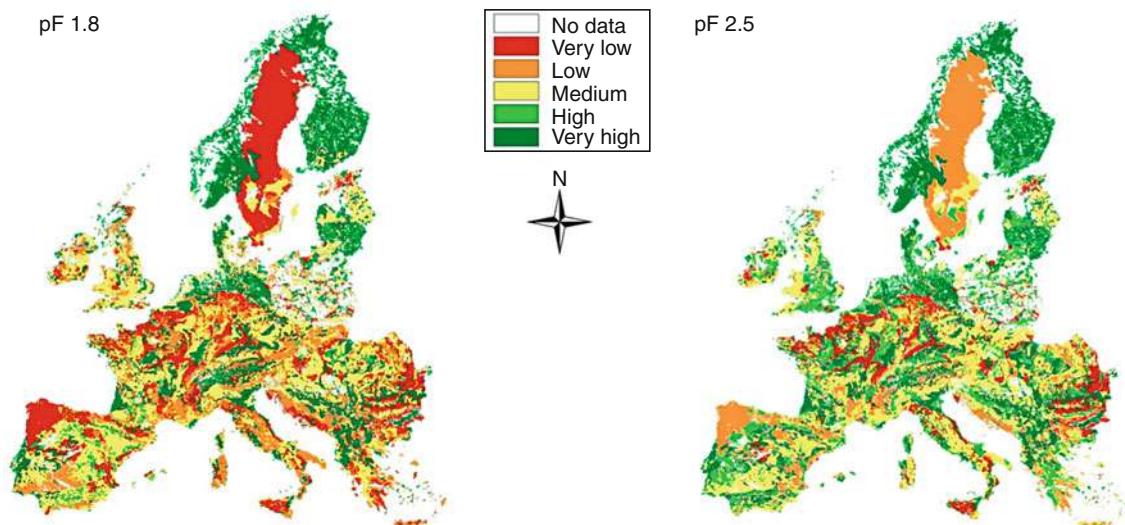

Based on the PDF (for more details see DVWK 1995, 1997, and Horn and Fleige 2003) developed within various projects (e.g., SIDASS, Horn et al., 2005) during the last decades, the map of the internal soil strength for the representative soil types 1/50 km² approximately can be derived (see Figure 1).

It gives a rough overview about the most sensitive soil areas with the most sensitive subsoils but requires further details at large scales if applied for an exact land use planning. A further precision increase is given if a detailed soil map is available, which can be used to derive the corresponding subsoil strength values (Figure 2).

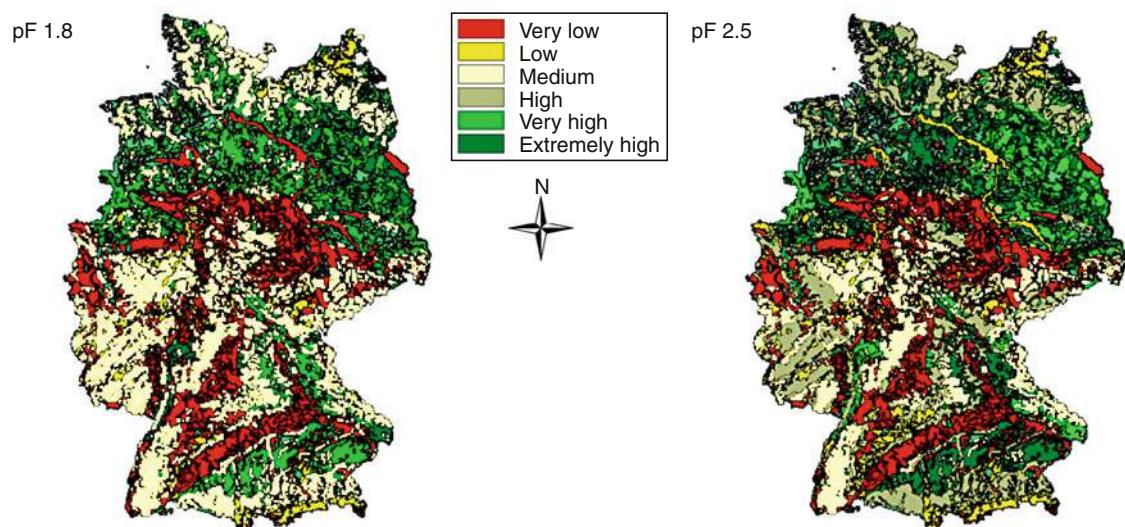

Areas with very weak subsoils can be detected, for example, at a pF value of 1.8 in the loess region while the sandy outwash area (Lower Saxony in Germany) is very rigid. An increase in drying (pF1.8–pF2.5) always results in higher precompression values.

The highest degree of certainty is given in the actual soil regions (e.g., a farm is completely mapped and the precompression stress values for the representative soil types measured (Figure 3).

The farm (155 ha) is located in the hilly weichselian moraine area, which results in a high pedodiversity. The parent material of the soils is derived from glacial till and results in a dominance of sandy loam, loamy sand, and sand. The main soils are partly eroded (Stagnic) Luvisols, associated with Stagnosols, Gleysols, Cambisols, Anthrosols, and in addition Histosols (according to WRB 2006). Areas with low soil strength even within a single field can be detected and consequently also the actual farming processes adjusted to these site properties.

Subsoil Compaction, Figure 1 Mechanical strength (precompression stress) for subsoils (30–60 cm). European scale (1:1,000,000). Classification of the precompression stress (kPa): very low <30, low 30–60, medium 60–90, high 90–120, very high 120–150, extremely high >150.

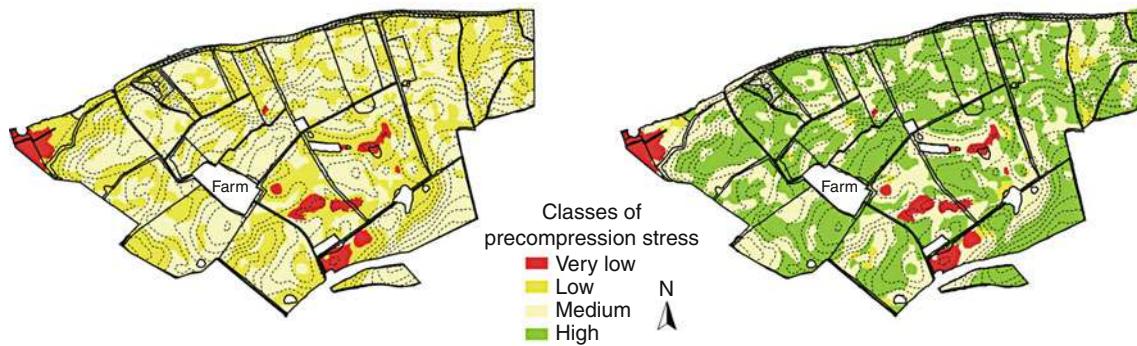

Subsoil Compaction, Figure 2 Precompression stress ranges for subsoils in Germany as a function of predrying: pF 1.8 (−60 hPa) = analog to the springtime, pF 2.5 (−300 hPa) = early summertime = drier (scale: 1:1,000,000). Classification of the precompression stress (kPa): very low <30, low 30–60, medium 60–90, high 90–120, very high 120–150, extremely high >150.

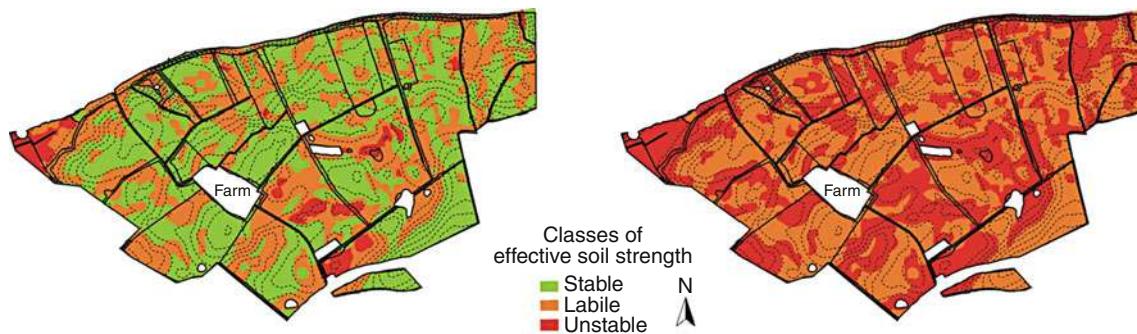

Quantification of the sensitive soils (areas) for defined applied stresses

According to Horn and Fleige (2003, 2009), the relationship of P_c to soil pressure can be determined by considering the stress propagation theory and the ratio $P_c/\text{overburden pressure}$ for classification. If the strength of the soil horizon is lower than the applied stress, the ratio is smaller than 0.8 and the horizon is defined as

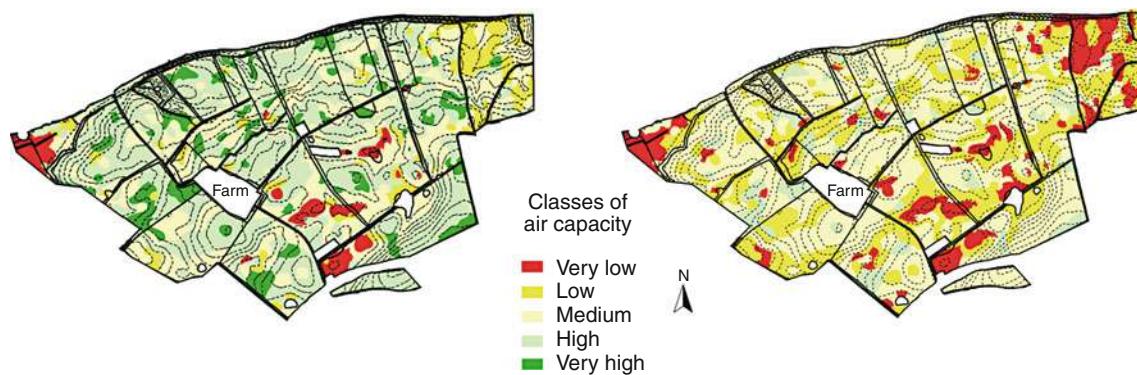

plastic/fluent. If the ratio exceeds 1.2, the soil is defined as rigid (stable and very stable). If the ratio is between 0.8 and 1.2, we classify the applied stress mostly too high (unstable). If the stress distribution under agricultural machinery is now modeled by the method of Newmark 1942 and compared with the actual internal soil strength per horizon, we can quantify the unavoidable consequences for soil functions within the virgin compression

Subsoil Compaction, Figure 3 Modeling of precompression stress P_c at pF 1.8 (-60 hPa) resp. $<\text{pF} 1.8$ (hydromorphic soils) (left) and pF 2.5 (-300 hPa) resp. pF 1.8 (hydromorphic soils) (right) for subsoils (40 cm) at farm scale. Classification of P_c (kPa): very low <30 , low 30–60, medium 60–90, high 90–120.

Subsoil Compaction, Figure 4 Relationship between the precompression stress and actual soil pressure for subsoils (40 cm) at farm scale. Subsoil stress: 60 kPa (left), subsoil stress: 90 kPa (right). Classification of the effective soil strength is defined by the relationship of precompression stress to soil pressure: 1.5–1.2 stable, 1.2–0.8 labile, <0.8 unstable, additional plastic deformation.

Subsoil Compaction, Figure 5 Modeling changes of air capacity at pF 1.8 (-60 hPa), respectively, at $<\text{pF} 1.8$ (stagnic and gleyic horizons) for subsoils (40 cm) at a stress of 90 kPa (right) in comparison to the initial state (left) at farm scale. Classification (Vol. %): very low: <2 , low: 2 to <5 , medium: 5 to <13 , high: >13 .

load range. [Figure 4](#) compares the application of a soil stress of 60 and 90 kPa in the subsoil (40 cm depth) at field capacity. It is obvious that a stress of 90 kPa exceeds the P_c of all subsoils, because the effective soil strength is too small and classified as labile to unstable. At a stress of 60 kPa, about 30% of the subsoils react labile to unstable, whereby there are differences resulting from pedodiversity between the fields.

Consequence of subsoil compaction on the air capacity as a function of stress applied

The analysis stress dependent changes of soil physical properties can again be determined on the basis of corresponding PDF for various texture classes (Horn and Fleige [2003](#)) and results in the differentiation of soil types, regions, landscapes concerning the long-term alterations, and possibly negative effects on soil properties that are responsible not only for crop yield, rooting but also for soil erodibility, filtering, and buffering processes or even gas emission.

A more detailed analysis on the large (farm) scale allows a better and more complete insight also in the irreversible processes and can become the basis for a more site-adjusted land use management ([Figure 5](#)).

It shows the potential effects at a defined stress of 90 kPa at field capacity in comparison to the initial state in the subsoil at the example of the air capacity (macro porosity, pores $>50 \mu\text{m}$). Because the oxygen supply of hydromorphic soils is restricted, a reduction of one air capacity class (e.g., medium to low) is assumed. The P_c of all soils at a stress of 90 kPa is exceeded, but "harmful changes of the soil" by modeling the parameter air capacity exist only for approximately 25% of the soils. On the side, this is attributed to all soils with loamy texture (e.g., eroded Luvisols with Bt-horizon near to the surface) and on the other side furthermore to all loamy sandy hydromorphic soils. Such soils, for example, Gleysols show in many cases medium- to high-air capacity values, but despite a sandy texture a low oxygen supply, because of incomplete air-filled macro pores.

Conclusions

The P_c value and the concept of critical values can be applied for the description of the soil mechanical strength. The P_c value is used as the precaution value to conserve the existing soil structure. P_c -maps of (sub) soils at all scales are a helpful tool for decision makers, agricultural advisers, or farmers for a site-adjusted land use. The decision about the site-adjusted machinery of a farm or a company can be related to the internal soil strength data at the weakest, that is, wettest site conditions in the subsoil and used for the specification of an appropriate agricultural machine. Thus, it will be possible to avoid additional subsoil compaction and define sustainable land use systems.

SURFACE AND SUBSURFACE WATERS

Todd C. Rasmussen

Warnell School of Forestry & Natural Resources, The University of Georgia, Athens, GA, USA

Synonyms

Ground water; Soil water; Streamflow

Definitions

Surface water – liquid water (H_2O , including all isotopic forms) found above the ground surface, including lotic (flowing) water in channels and as overland flow, and lentic (non-flowing) water in lakes, ponds, and wetlands, but does not include water found in plants, animals, or the atmosphere.

Subsurface water – liquid water found below the ground surface, including soil water above the water table and ground water below the water table, but does not include water chemically bound to minerals or organic matter.

Introduction

Water is a chemical compound with three dominant phases on Earth – gas, liquid, and solid. Gaseous water has a high vapor pressure, especially at warm temperatures, making it readily transportable through the atmosphere. Liquid water has a low viscosity, making it highly mobile, and is polar, making it an excellent solvent. Solid water is less dense than its liquid form, making it float.

Accounting for the movement and distribution of water resources is important because water is a vital component of world economic activity, including transportation and commercial, industrial, and energy production (Cech, 2009; Glennon, 2009). It is also important to agriculture, especially in climates where precipitation is insufficient to satisfy crop water requirements (Hillel, 1994).

The vast majority of water on Earth lies within its oceans (Gleick, 1996), while most of the remainder is present in polar icecaps (Table 1). That small residual not found in oceans or icecaps is predominately found in the subsurface, which is more abundant (but generally less accessible) than surface water. The volume of water found

in plant life is only a small fraction of the next larger reservoir, the atmosphere. The residence times (defined as the volume of water, V , in the reservoir divided by the average flux, Q , through the reservoir, $\tau = V/Q$) of water in our oceans and icecaps are much longer than in the soil, atmosphere, and plant life.

Understanding the source of water in streams and groundwater is critical to their management. Water in streams is generated by a range of mechanism, including

- Precipitation on saturated surfaces (e.g., channel surfaces, wetlands, lakes, riparian areas);
- Exfiltration from shallow, perched aquifers and subsurface piping (e.g., root and animal holes);
- Ground-water discharge from aquifers (both unconfined (An unconfined aquifer is a geologic unit capable of transmitting adequate water to wells when pumped, overlain by a water table, that allows gravity drainage from pores when pumped) and confined (A confined aquifer is a geologic unit capable of transmitting adequate water to wells when pumped, overlain by a confining layer that prevents gravity drainage from pores; water released from storage is due to expansion of pore fluids and matrix as the pore fluid pressure declines)).

Subsurface water is found as soil water either above the *water table* (A water table is the water-level elevation in a well completed in an unconfined aquifer), or as ground water below the water table (Figure 1). Recharge to the unconfined aquifers originates as infiltration into soil water, and then percolation through the unsaturated zone to the water table. Recharge is less than infiltration due to plant water uptake in the root zone. Recharge to confined aquifers can occur either in the zone where the aquifer outcrops, or by flow from an adjacent aquifer through a confining layer.

At the local scale, water flow obeys the conservation equation (Hillel, 1998)

$$\nabla \cdot \vec{q} + \frac{d\theta}{dt} \pm r = 0 \quad (1)$$

where \vec{q} (L/T) is the flux vector, θ (L^3 -water/ L^3) is the volumetric water content, and r (L^3 -water/ L^3/T) is the local source/sink term.

At larger, watershed scales, the conservation (or water-budget) equation is

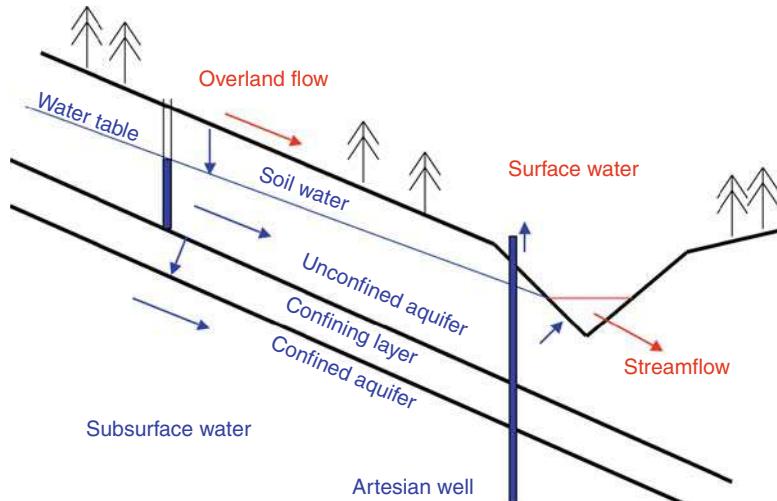

$$P = Q + ET + W \pm \Delta S \quad (2)$$

where P is the precipitation, Q is discharge from the outlet of the watershed, ET is the evapotranspiration, W includes other consumptive water withdrawals, and ΔS is the change in storage per unit time within the watershed. Note that the units of these variables can be or volume per time, (L^3/T), or volume per area per time, which is a depth per time, (L/T).

While water is generally considered to be a renewable resource (i.e., it is replenished by precipitation), the extraction of surface and ground water can exceed the rate

Surface and Subsurface Waters, Table 1 Water volumes and approximate residence times

Reservoir	% of Water		Residence Time
	Global	Fresh	
Oceans and seas	97.5	–	2,643 years
Glaciers	1.75	68.7	12,000 years
Ground water	0.79	30.9	5,400 years
Surface water	0.008	0.3	2.26 years
Soil water			7 weeks
Atmosphere	0.0009	0.04	9 days
Plants	0.00008	0.003	5 days

Surface and Subsurface Waters, Figure 1 Surface and subsurface water schematic.

of natural replenishment (i.e., $W > P$), causing unsustainable declines in local and regional water resources (i.e., $\Delta S < 0$) (Hillel, 1992; Glennon, 2004; Cech, 2009). Even in areas with abundant precipitation, water is often limiting due to asynchronicity between water supply and demand. Increasing water storage using surface and subsurface reservoirs is an important mechanism for synchronizing water supplies with demands.

Modern investments in dams to store surface water have multiple benefits including mitigating floods, augmenting flows for irrigation, and assuring sufficient flows for navigation. Yet the adverse impacts on sediment loads, as well as failure to provide sufficient environmental flows to support endemic fish species, have had grave effects on natural ecologic functions (Ward, 2002). Relying on subsurface water for storage can reduce the ecologic impacts, but these impacts are often difficult to eliminate entirely (Glennon, 2004).

Surface water

Surface water has long been used for agricultural purposes, primarily irrigation and aquaculture (fish production) (Hillel, 1994; Yoo and Boyd, 1994). Most of the earliest agricultural centers were located in subtropical to warm-temperate climates along major waterways, including the Indus, Nile, Tigris/Euphrates, Yellow, and Ganges rivers (Cech, 2009).

Measuring the quantity of flows in streams is important for their allocation and management. Streamflow discharge, Q (L^3/T), is measured using

$$Q = \int_A v(A) dA = \sum_{i=1}^n v_i A_i \quad (3)$$

where v_i (L/T) is the flow velocity determined using a flowmeter at point i within the stream, $A_i = w_i h_i$ is the incremental cross-sectional area surrounding the

measurement point, and where $w_i(L)$ is the distance between velocity measurements, and $h_i(L)$ is the total depth of the stream at the point of measurement. Note that $\bar{v} = Q/A$ is the mean water velocity, where $A = \sum_i A_i (L^2)$ is the total stream cross-sectional area.

Repeated measurements of discharge over a range of stages (water level elevations) are used to construct a rating curve, with the general form

$$Q = a (h - h_o)^b \quad (4)$$

where a and b are fitted coefficients, and h_o is the stage at which $Q = 0$. More accurate measurements of streamflow can be obtained using control structures, such as *flumes* and *weirs*, which provide a uniform cross-section and stable stage-discharge relationships.

For ungaged streams (those without control structures or rating curves), the mean velocity can be estimated using the *Manning formula*

$$\bar{v} = \frac{1}{n} R^{2/3} S^{1/2} \quad (5)$$

where n ($T/L^{1/3}$) is the Manning friction factor, a function of channel characteristics, $R = A/P(L)$ is the hydraulic radius, a function of the stream cross-sectional area, A (L^2), and the wetted perimeter, $P(L)$, which is the length of the streambed interface, and $S(L/L)$ is the channel energy slope, approximately equal to the water surface slope.

Flooding is a major concern along rivers and streams, and occurs when streamflow exceeds the channel flow capacity. The *kinematic velocity*, or *celerity*, (L/T), is used to account for the velocity of the flood wave (McCuen, 2005)

$$c = \frac{dQ}{dA} = \bar{v} + A \frac{d\bar{v}}{dA} \quad (6)$$

The kinematic ratio, k , is a dimensionless number that is the ratio of the celerity to the mean water velocity

$$k = \frac{c}{\bar{v}} = 1 + \frac{A}{\bar{v}} \frac{d\bar{v}}{dA} \quad (7)$$

The kinematic ratio is commonly greater than one because water usually flows faster as the flow area (or depth) increases (i.e., $d\bar{v}/dA > 0$). Yet the marginal velocity may decrease once floods overtop the floodplain (i.e., $d\bar{v}/dA < 0$), introducing additional friction losses, so that $k < 1$. The flood wave velocity can be predicted for a range of stages as a function of the mean water velocity and the kinematic ratio.

A more complete description of the dynamic behavior of flood waves that incorporates the continuity and momentum equations is given by (McCuen, 2005)

$$\frac{\partial h}{\partial x} + \frac{1}{g} \left[v \frac{\partial v}{\partial x} + \frac{\partial v}{\partial t} \right] = S_o - S_f \quad (8)$$

where h is the water surface elevation, v is water velocity, g is the gravitational constant, x and t are distance and time, respectively and S_o and S_f are the bed and friction slopes, respectively.

Subsurface water

Subsurface water is less accessible for exploitation due to the need for mechanical devices (such as pumps) to lift the water to the surface. Early agricultural societies in Central Asia and the Middle East developed the ability to harvest ground water in unconfined aquifers using *qanats*, which are near-horizontal tunnels that intersect the water table and allow the water to flow by gravity to the surface (Hillel, 1994; Cech, 2009). In some areas, vertical boreholes tapped into *confined aquifers* support *artesian* wells, which flow to the surface without pumping.

Modern wells provide access to the ground-water reservoir, but can be limited by the total storage and permeability of the units. Flow through an aquifer is described using *Darcy's law*

$$\vec{q} = -K \nabla h \quad (9)$$

where \vec{q} (L/T) is the three-dimensional flux vector, K (L/T) is the hydraulic conductivity (a measure of permeability), and ∇h is the hydraulic gradient. This formulation is appropriate for flow through an unconfined aquifer.

For a confined aquifer, Darcy's law is written in two dimensions:

$$\vec{q} = -T \nabla h \quad (10)$$

where \vec{q} (L²/T) is the two-dimensional flux vector, and

$$T = \int_b K(b) db = \sum_{i=1}^n K_i b_i \quad (11)$$

is the aquifer transmissivity (L²/T), which represents the integrated hydraulic conductivity across the aquifer thickness, b (L).

Water flow through the soil above the water table is primarily vertical. Because the soil is not fully saturated, an unsaturated flow equation is used

$$\vec{q} = -K(\psi) \nabla h \quad (12)$$

where $K(\psi)$ is the soil-tension-dependent hydraulic conductivity, ψ is the *soil tension* (The soil tension is a negative pressure head that accounts for the cohesive and adhesive forces between water and soil, respectively), and $h = z - \psi$ is the total head, with z being the elevation. Note that

$$\begin{aligned} \nabla h &= [0, 0, 1] - \nabla \psi \\ &= \left[-\frac{\partial \psi}{\partial x}, -\frac{\partial \psi}{\partial y}, 1 - \frac{\partial \psi}{\partial z} \right] \end{aligned} \quad (13)$$

The function $K(\psi)$ can also be written as $K(\theta)$, where θ is the soil water content, and the function $\psi(\theta)$ is the soil characteristic curve that relates the soil tension to the water content.

Modern agriculture relies heavily on ground-water extraction for all or part of their irrigation needs. Declines in water levels due to pumping have resulted in reductions in ground-water flows to streams, causing a reduction in streamflow in these areas (Glennon, 2004). *Subsidence* of the ground surface results when the pore pressure (which partially supports the mineral matrix) is reduced.

Water quality

Water pollution from point and nonpoint sources may compromise the value of water for subsequent use by downstream users. Surface water quality can be compromised by stormwater runoff from agricultural lands, as well as contamination of ground water (Boyd, 2000). Stormwater has been shown to transport a wide diversity of potential contaminants (e.g., nutrients, sediments, pesticides, herbicides, pathogens).

Soil salinization results when flows are insufficient to remove accumulated salts from soils, causing the loss of agricultural productivity. Also, natural sediment transport can be reduced by trapping in reservoirs or by reduced sediment transport capacity, or increased by erosion from land-disturbing activities.

Contaminant migration is commonly represented using the advection-dispersion equation (ADE)

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial x^2} - v \frac{\partial C}{\partial x} \quad (14)$$

where C is the solute concentration, D is the effective dispersion coefficient, v is the velocity, x is distance, and t is time. This equation describes both the advective

component of transport, along with Taylor dispersion. The solution to the ADE for a Heaviside (step) input (release) of a conservative tracer is (Ogata 1970)

$$C(x, t) = \frac{1}{2} \left[\operatorname{erfc} \left(\frac{x - vt}{2\sqrt{Dt}} \right) + \exp \left(\frac{vx}{D} \right) \operatorname{erfc} \left(\frac{x + vt}{2\sqrt{Dt}} \right) \right] \quad (15)$$

Besides advection and dispersion, a wide range of other processes affects the fate and transport of contaminants (e.g., biological uptake and degradation, sorption, volatilization, and settling).

The effects of water quality degradation depend upon the use of the water. Elevated nutrients may be desired for agricultural uses, but not for environmental or drinking water uses. Elevated salinity may be desired for specific forms of aquaculture, but not for others.

Water-quality degradation can be mitigated using a broad array of agricultural practices (e.g., no-till agriculture, riparian buffers, animal exclusion from streams, grass filter strips, terracing, and farm ponds). Efforts to control contamination commonly focus on reducing pollutant loading to levels that do not exceed the *assimilative capacity* of aquatic systems.

Summary

Surface and subsurface waters are a small component of the global water budget, yet are vital for a wide range of economic activities, including agricultural irrigation and aquaculture. Surface and subsurface waters are widely used to augment precipitation, and to carry away salts and other waste materials. Measuring the quantity and flow of surface and subsurface waters is an important component of water management. Adverse environmental and social impacts may occur when water utilization exceeds available supplies, or when contaminant loading exceeds the assimilative capacity of aquatic systems.

SURFACE PROPERTIES AND RELATED PHENOMENA IN SOILS AND PLANTS

Grzegorz Józefaciuk
 Institute of Agrophysics, Polish Academy of Sciences,
 Lublin, Poland

Definition

A *surface phenomenon* is a phenomenon that takes place on or near a surface, that is, in a common boundary among contacting phases (including solid–liquid, solid–gas, and liquid–gas interfaces). The specific properties of surfaces of plant tissues and of mineral and organic surfaces occurring in soils result from their complex chemical buildup, large area and charge, and primarily, from a range of interactions (forces) between the molecules present in the interfaces.

Intermolecular interactions

Chemical forces. The contacting molecules may form a chemical compound at the join. The strongest bonds are where atoms of the two materials swap (ionic bonding) or share (covalent bonding) outer electrons. These attractive forces are effective only over very small distances, less than a nanometer. A weaker bond is formed if an (electron poor) hydrogen atom in one molecule is attracted to a free electron pair of, for example, nitrogen, oxygen, or fluorine atom in another molecule, which is called hydrogen bonding.

Electrostatic (Coulomb) forces. Forces between electric charges of the magnitude (for point charges) directly proportional to the product of the magnitudes of each of the charges and inversely proportional to the square of the total distance between them. Charges of the same sign (like charges) repel and of the opposite signs (unlike charges) attract each other. Linear superposition is applied to calculate the force exerting on one charge by a system of several discrete charges. For a charge distribution in a space (surface) an integral over the region containing the charge is applicable, treating each infinitesimal element of space as a point charge.

Dispersive (van der Waals) forces. These very weak forces compared to chemical bonds forces, also of electrostatic origin, have four major contributions: repulsive forces preventing the collapse of molecules as they move closer to one another due to electronic shells repulsion (Pauli exclusion principle) and three attractive components: the electrostatic (Keesom) force between permanent charges on a molecular ion and permanent multipoles on the other molecule; induction (Debye) forces between a permanent multipole (charge) on one molecule with an induced multipole on the other; and attraction (London) forces between momentary multipole occurring on one molecule due to permanent variation of electrons density around atoms and induced by it momentary multipole on the other molecule. Dispersive forces are generally anisotropic, which means they depend on the relative orientation of the molecules and are effective over very small distances (less than 1 nm).

Diffusive forces. This type of interaction occurs when a mobile part(s) of a molecule penetrate into an adjacent phase while still being bound to the phase of origin.

Steric forces. The sterical join occurs when one molecule locates inside a space within the other molecule to which it fits merely well.

Intermolecular attraction forces between like-molecules in a single phase are called cohesion forces, while these forces between molecules present in two adjacent phases are forces of adhesion.

Adsorption

In a bulk material, all intermolecular forces between the constituent molecules (atoms) are generally neutralized by surrounding neighbors, however, molecules on the surface are not wholly surrounded and therefore they attract

molecules from the adjacent phase that is known as adsorption process. If weak van der Waals forces are responsible for the process, it is classified as physisorption while if chemical bonds are formed in consequence of adsorption, it is called chemisorption. Thus during chemisorption only a single layer (monolayer) of the adsorbed molecules (adsorbate) can form chemical bonds with the surface of the solid (adsorbent) and the process is characterized by high energies ($80\text{--}300\text{ kJ mol}^{-1}$). In chemisorption, the minimum in potential energy occurs at a distance less than 3 Å corresponding to the length of a chemical bond. Physisorption is a general phenomenon and occurs at any surface. Usually the adsorbed molecules (especially from a gas phase) can form several layers on the adsorbent surface (multilayer adsorption). For physisorption, a minimum in potential energy, between 2 kJ mol^{-1} and 15 kJ mol^{-1} , exists at a distance corresponding to the Van der Waals radius (ca. 6 Å) and the quantity of the fluid phase adsorbed decreases with increasing temperature.

Physical adsorption of water vapor on surfaces of soil constituents plays important role in formation of water films under unsaturated soil conditions. Usually adsorption of water vapor on plant root surfaces is more energetically favored than on soil materials (more strongly polar groups on root surfaces) and water films at the same conditions are thicker on the roots. The adsorption of natural organic matter on inorganic particle surfaces such as clay and quartz is an important geochemical process that occurs in soil and aquatic media. Adsorption to mineral phases can stabilize organic matter against microbial decay in soil. Formation of strong bonds that reduce desorbability can explain that effect. With time, the adsorbed organic matter may undergo changes in configuration, migrate into pores, or intraparticle spaces in minerals or rearrange structural configurations of organo-mineral associates so its stability may increase with residence time. Stabilization of low-molecular-weight organic compounds may result from their diffusion and adsorption into pores small enough to prevent hydrolytic exoenzymes from entering.

Catalysis

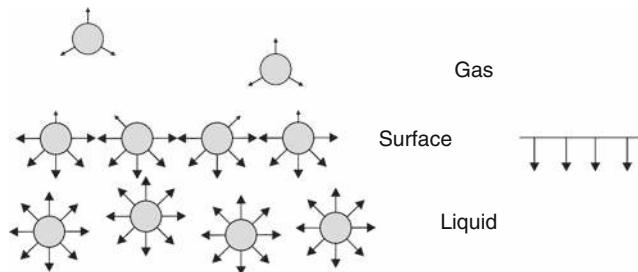

Molecules adsorbed on a surface may react with each other. Usually the rate of the reaction is different than in their own phase due to increase in concentration of the adsorbed reagents, their specific orientation or deformation, weakening intramolecular bonds, dissociation or lysis to reactive forms (new bonds to the surface are favored), or changing the frequency of contact of the reactants. The adsorbent (catalyst) can fasten (positive catalysis) or break the process (inhibition). The adsorbed species are bound to active sites on the catalyst; therefore, the rate of the process is highly related to the total surface area of the adsorbent. In a reaction catalyzed by a solid (heterogeneous catalysis), the diffusion of reagents to the surface and of products out from the surface are frequently

rate-determining steps. Surfaces having acidic character can catalyze many reactions in soils involving water, as hydrolysis and its reverse. Catalytically active are zeolites, alumina, and humic substances. Transition metals catalyze redox reactions (oxidation, hydrogenation).

Surface free energy (surface tension)

A molecule within a bulk phase attracts the surrounding molecules and in turn it is attracted by them (cohesion forces). To create a surface one has to input enough energy to break cohesion bonds. Because at a break two surfaces are formed, the energy given to the surface (surface tension Y , joule per square meter or newton per meter) equals half of the energy of cohesion (ideal case). All surfaces exhibit surface tension that is of most importance for liquid surfaces. The surface of the liquid differs from its bulk. Inside a liquid, all cohesion forces between molecules neutralize each other while on the surface, the molecules are much more attracted by the neighboring liquid molecules, than by the gas molecules outside. As a result, a force directed inside the liquid is formed on the surface and the latter behaves like an elastic membrane, which covers and compresses the liquid tending to diminish the area of its surface ([Figure 1](#)).

The surface tension expresses the force with which the surface molecules attract each other. Surface tension can be modified by other compounds added into the liquid. For example, low-molecular hydrocarbons (e.g., sugar) dissolved in water have little or no effect on the surface tension, as their hydroxyls interact with water molecules via hydrogen bonds, as water molecules bond themselves. Ions of dissociated soluble salts strongly interact with water molecules (hydration); thus, they can further increase the surface tension. Dissolved alcohols decrease water surface tensions, as their nonpolar (hydrocarbon) chains interact with water molecules only by weak dispersion forces. Special molecules having strongly polar hydrophilic head and a long nonpolar hydrophobic tail can markedly diminish water surface tension. Such compounds, called surfactants reduce the surface tension of water by accumulating at the liquid–gas interface, with the head remaining in water and a tail directing outside. Many surfactants can also assemble in the bulk solution

Surface Properties and Related Phenomena in Soils and Plants, Figure 1 Intermolecular forces at liquid–gas interface.

into aggregates (micelles). Examples of such aggregates are phospholipid membranes in plants (e.g., cell vacuoles used for osmotic control and nutrient storage). Soil humic acids have an amphiphilic nature because of the presence of both hydrophilic and hydrophobic fragments in their structure; thus, they are able to reduce water surface tension as well, and can form micelle-like aggregates. In soil environments, such surface activities of humic acids can play an important role in the transport, bioavailability, and biodegradability of hydrophobic organic pollutants (a pollutant is bound to a hydrophobic part of humic acid and so follows its pathway). Usually the surface activity of humic acids is facilitated at lower pH of soil solution. Similarly, hydrophobic fragments of bacterial cell walls can adsorb hydrophobic molecules affecting contaminant mobility.

Evaporation and condensation

The number of bulk neighbors interacting with a molecule located on the liquid surface depends on the surface curvature. If it is convex, fewer neighbors and if concave, more neighbors are in close contact with surface molecule than for flat surface. The cross section of the space containing direct members of the surface molecule (interaction sphere) on various menisci is imagined in [Figure 2](#).

Therefore less energy is needed to move a molecule to the gas phase (evaporate the liquid) from a convex surface than from flat surface and than from concave surface. So the vapor pressure p over convex surface is higher and over concave surface is lower than the pressure over flat surface, p_0 (saturated vapor pressure). Obvious is that the greater surface curvature, that is, the smaller the curvature radius r , the effects are more pronounced (small liquid droplets evaporate much faster than bigger ones), which is described by a Kelvin equation

$$\log(p/p_0) \sim Y/r \quad (1)$$

As an environmental process, evaporation and transpiration of water are collectively termed evapotranspiration. Transpiration is the evaporation of water from the aerial parts of plants, mostly leaves. Transpiration cools plants and enables mass flow of water (and mineral nutrients) through the xylem from roots to shoots that is caused by the increase in water potential in the upper parts of the plants due to the evaporation of water out of stomata into the atmosphere. Plants can regulate transpiration by changing water–atmosphere contact area, that is, by closing or opening stomata depending on external air and soil

Surface Properties and Related Phenomena in Soils and Plants, Figure 2 Surface molecule interaction sphere on convex, flat, and concave surface.

conditions or they adapt their tissue structures to permanent unfavorable conditions (e.g., thick cuticles, reduced leaf areas, sunken stomata, and hairs to reduce transpiration and conserve water).

When vapor of a liquid is adsorbed on a wall of a thin tube (capillary) or on pore walls of a porous body, the film of adsorbed liquid forms a concave meniscus over which the equilibrium liquid vapor pressure is lower than over a liquid flat surface. Therefore, water vapor may condense in capillaries under lower pressure than under the saturated water pressure. The thinner the capillary, the lower water vapor pressure is needed to condense water and after this process is started, the whole volume of the capillary becomes instantaneously filled by the liquid because the radius of liquid meniscus in the tube decreases with the amount of condensed vapor, which is called capillary condensation. As the vapor pressure decreases, the liquid evaporates from the capillary to the atmosphere as vapor molecules. Various pore geometries (different types of menisci curvature) often lead to differences in condensation and evaporation pathways (liquid menisci are different at the same vapor pressure if the pore is empty or filled) that is called a hysteresis. In naturally occurring porous structures (soils), the geometry of pores is very complicated. Soils and their constituents form networks of pores, much like spaces between spherical granules with large voids connected by smaller necks and "snake-like" capillaries. In such structures, the concept of capillary condensation is used to determine pore-size distribution using adsorption-desorption isotherms.

For water vapor, the relation of equilibrium vapor pressure to the saturation vapor pressure can be considered as a relative humidity of the atmosphere, so capillary condensation is an important factor in soil water retention and transport (via gaseous phase). Due to adsorption and capillary condensation, soil stores water even in dry atmospheric conditions.

Capillary condensation is responsible for bridging between mineral and organic grains in soils at low moistures. The condensed layer of water in the pore formed at a contact point between grains adheres the grains. This consolidation mechanism is particularly important in soils poor in structure-stabilizing organic matter and amorphous mineral materials.

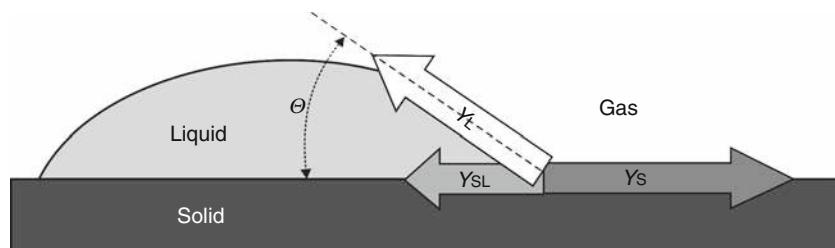

Wettability

The ability of a liquid to maintain contact with a solid surface results from a balance between adhesion and cohesion forces. The cohesive forces tend to keep liquid molecules together, and the adhesive forces tend to bind them to the surface and to spread the liquid upon it (wetting). When the forces of adhesion are greater than the forces of cohesion, the liquid tends to spread on (to wet) the surface, while in the opposite situation, the liquid tends to refuse the surface. Solids in which cohesion forces are very strong (covalent, ionic, or metallic bonds) have thus surfaces of high free energy (high-energy solids) and they are well wettable by most liquids. If cohesion forces are weak (e.g., van der Waals or hydrogen bonds) the solid has low surface free energy (low-energy solids) so it is consequently wetted only by liquids of low surface tension. Depending on wettability, a drop of a liquid placed on a solid surface forms a truncated sphere of which the angle at the solid surface contact point (contact angle) ranges from 0 for completely wettable to 180° for totally nonwettable solids. The contact angle θ results from a tendency of surface tensions to reduce the area of their own surfaces. The surface tension of the solid Y_S (solid-air interface) tends to reduce solid area by covering it with the liquid and consequently to enlarge the area of the liquid; in opposition, the surface tension of the liquid Y_L (liquid-air interface) tends to reduce liquid area by shrinking a drop and the surface tension of the solid-liquid interface Y_{SL} tends to reduce its area by repelling liquid from the contact surface. An equilibrium of interfacial surface tensions at the contact point for homogeneous flat surface is presented in Figure 3.

The force balance at the contact point can be described by the Young equation

$$Y_S = Y_L \cos\theta + Y_{SL} \quad (2)$$

Natural surfaces are usually chemically and geometrically heterogeneous and the wettability of such surfaces is a complex function of heterogeneity. The contact angle observed on rough surface is higher than the (intrinsic) contact angle on the respective flat surface and depends on the ratio of the true area of the solid surface to the apparent contact area (roughness ratio). For example, the lotus petal has uniformly spread hydrophobic

Surface Properties and Related Phenomena in Soils and Plants, Figure 3 Surface tensions balance at solid–liquid–gas contact point.

micropapillae on the surface and a water contact angle on such rough surface increases almost to 180° so water on the petal forms droplets of a spherical shape (superhydrophobicity), which roll out easily (self-cleaning effect). The contact angle observed on a surface build from different patches of various wettabilities (contact angles) relates to the input of the areas of these patches into the whole surface, which is of great importance for water movement in soils. By reducing liquid surface tension, surfactants in general should enhance wettability. However if strong interactions with the surfactant polar head and the polar surface of wettable material occur, the effect can be opposite due to decrease in solid surface free energy by adsorbed surfactant layer. Such effect is important in soils. Polar heads of humic compounds may be bound to mineral surfaces (or to each other) by ion-dipole or dipole-dipole interactions. Under water-saturated conditions, the stability of such associates is not high because weak electrostatic bonds are destabilized by water molecules; however, in undersaturated conditions they become increasingly important. Drying leaves organo-mineral and organic-organic associates with hydrophobic parts directed outward and (if enough organic matter is present) the soil becomes strongly hydrophobic, requiring a long time of watering to restore its original hydrophilic properties.

Capillary rise

When one end of a capillary is immersed in a liquid, it adheres to the surface of the tube with definite contact angle, forming a concave meniscus inside the tube if adhesion interactions overcome the cohesion ones (wettable solids), and a convex meniscus in opposite situation. The tendency to minimize area of the highest energy surface causes that the liquid tends to cover the solid surface and in consequence the liquid column in the tube is pulled up in the case of wettable solids and down in the case of nonwettable solids (here the highest energetic is liquid-air surface). The above phenomenon is called capillary action. Surface tension forces proportional to the curvature of the liquid meniscus surface r (equal practically to the capillary radius) act until they are balanced by weight of the liquid column (proportional to liquid density ρ , the area of the column cross section, and the height of the column H):

$$rY_L \cos\theta \sim \rho r^2 H \quad (3)$$

Thus, the height of the capillary rise is higher in thinner tubes. This phenomenon is important in movement of water in soil and transpirational pull in plants as it allows water to move up without the need for special transport mechanism. Capillary rise pulls water in soil up to the surface of the ground, where from it evaporates. This loss of soil water is minimized by plowing – mechanical disruption of upper soil layer enlarges diameter of capillaries and breaks capillary rise.

Osmosis

When a bulk liquid is separated by a membrane having pores permeable to liquid molecules, statistically the same amount of molecules will pass through the membrane from one side to another and vice versa. If into one part of the separated liquid a soluble substance is added, which molecules are too large to pass through the membrane pores (semipermeable membrane), statistically more liquid molecules passes the membrane from the side of pure liquid than from the side of solution (instead of some liquid molecules that should pass through, molecules of the dissolved substance collide with the membrane being reversed), and as a result the solution is diluted. This dilution may be stopped by exerting an external pressure on the solution thus forcing the liquid molecules to move in opposite direction (to counteract the osmotic pressure). The osmotic pressure Π is directly proportional to the concentration of the dissolved substance c :

$$\Pi \sim c \quad (4)$$

If the other side of the membrane is in contact not with pure solvent but with other solution, the total pressure on the membrane is the difference between osmotic pressures on its two sides. In isotonic situation when the osmotic pressures on both sides of the membrane are the same, no solvent movement occurs. Similar to capillary rise, osmosis is a physical process in which water moves, without input of energy. Seeds use osmotic pressure to crush rocks. Net movement of solvent from the less-concentrated (hypotonic) to the more-concentrated (hypertonic) solution is a frequent phenomenon responsible for water transport into and out of plant cells as many biological membranes are semipermeable (permeability may depend on solute charge and size). Osmosis is responsible for the ability of plant roots to uptake soil water, for the turgor pressure of a cell and for regulating an aperture of stomata. When a plant cell is placed in a hypertonic solution, the water in the cells moves out and the cell shrinks, which finally can lead to plasmolysis, while in the opposite situation the cell expands and can finally explode. To reach a balance in osmotic pressure, plants developed a homeostasis mechanism known as osmoregulation.

Solubility

Solubility is the property of a solid, liquid, or gas (solute) to dissolve in a liquid forming a homogeneous solution. The opposing process to dissolution is precipitation (or crystallization) of a solid. The solubility prolongs until these two processes reach the same rate (saturated solution). Temperature, presence of other species that can react with solute molecules, or pressure (especially for gases) can alter these rates and can thus influence the solubility. Solubility results from prevalence of intermolecular interactions between molecules of the solvent with that of the solute

over those among the molecules of the solute itself and is supported by the entropy factor (dissolved molecules are more dissipated). The solute dissolves better in a solvent having similar polarity to itself (like dissolves like). The solute molecules may form several species in the solution by dissociation, hydrolysis, and polymerization.

Solubility depends on the size (surface area) of the (solid or liquid) solute (similarly as evaporation). So smaller crystals are better soluble than larger ones that results in precipitate aging (the crystal size spontaneously increases in time). Therefore in soils, the solubility of amorphous phases of silicon, aluminum, and iron oxides rather than their more crystalline forms govern the concentration of respective ions in soil solution. Solubility depends also on the polymorphic form of the crystal solid; thus, weathering rates of different rocks of the same chemical composition may significantly differ. Contrary to most solids, the solubility of gases in water decreases with temperature, which may cause root oxygen stress in soils at warm seasons.

Many solids dissolve congruently, which means that the composition of the solid and the dissolved solute are identical. However, some substances dissolve incongruently, that is, the composition of the solute in solution differs from that of the solid. This process is accompanied by alteration of the solid being dissolved and formation of a secondary solid phase. Formation of metamorphic rocks results from incongruent dissolution. Most soil clay minerals dissolve incongruently.

Different soils have diverse solutions depending on soil composition and environmental conditions. Its composition is determined by weathering of parent rock, mineralization of plant residues, dissolution of primary minerals by carbonic acid that liberates calcium, magnesium, and potassium ions, and exchange of gases with the soil atmosphere. Soil solutions can contain dissolved sugars, fulvic and other organic acids, plant micronutrients such as zinc, iron, and copper, plus other metals, ammonium plus a host of others. Calcium is common in forest soils, some soils have high amount of sodium ions that greatly impact plant growth. The upper layers of soil water usually have higher organic content than the lower soil layers. Surface waters with high content of dissolved organic compounds (DOC) are typically found in peat and bogs

areas. Soil pH effects the type and amount of anions and cations that soil solutions contain.

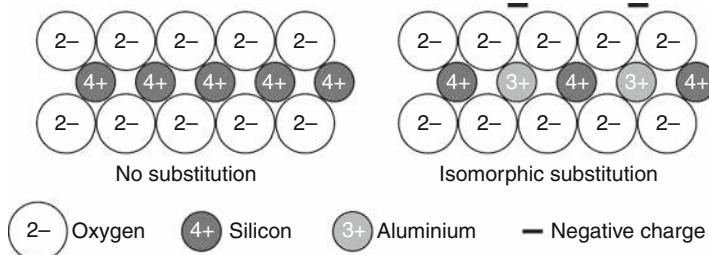

Colloids

Solutes dissolved in a solvent behave as a part of the liquid phase and they do not exhibit their surfaces (no phase boundary). If larger and larger particles (molecules) are dispersed in a liquid, they start to exhibit defined boundaries against the liquid and behave as individual phases (particles of approximate sizes above 0.002 µm). Such particles form a suspension named colloid. If particles size increase further to more than 0.2 µm, the mixture is formed, from which the particles tend to separate out quickly from the liquid phase. Colloids constitute the most chemically active fraction in soils, because the higher the contact surface in respect to the phase volume the more pronounced are surface phenomena. They are mineral or organic (humus) and could be crystalline (e.g., minerals and clay minerals of definite structure) or amorphous (e.g., hydrous oxides of iron, aluminum, and silicon). Behavior of soil colloidal systems depends on composition of soil solution in which finely dispersed mineral and organic particles are suspended.

Surface charge of soil constituents

The sources of charges on soil colloids are permanent (constant) charges due to isomorphic substitutions in clay minerals, and variable (pH dependent) charges due to broken edge, OH, and COOH groups.

Clay minerals are finely divided crystalline aluminosilicates. The basic building elements of the clay minerals are two-dimensional silicon–oxygen tetrahedral sheets and aluminum- or magnesium–oxygen–hydroxyl octahedral sheets. Kaolinite type minerals are built from one silica and one alumina sheet by sharing oxygen atoms between them (1:1 two-layer minerals). Montmorillonite type minerals are built from one octahedral sheet sharing oxygen atoms with two silica sheets (2:1 three-layer minerals). Isomorphic substitution of Si- and/or Al-ions in the crystal lattice by lower positive valence ions and accompanied “unsaturation” of oxygen bonds results in that clay lamellae achieve permanent negative charge exhibited on basal planes of the minerals (Figure 4).

Surface Properties and Related Phenomena in Soils and Plants, Figure 4 Isomorphic substitution of silicon by aluminum in the clay lattice.

Depending on the degree of substitution (influenced by conditions of mineral genesis) the layer charge density differs among different clay minerals. For most frequently occurring clay minerals, this charge amounts from a few thousands (kaolin group) by few tens thousands (mica group – illites) to hundreds thousands (smectites, zeolites) of coulombs per kilogram of the mineral (1 coulomb = $6,24 \times 10^{18}$ elementary charges). Frequently a part of the permanent lattice charge is neutralized by specifically bound cations inside the spaces between several subsequent structural layers of the mineral, as this occurs in illites due to binding of potassium cations. Permanent charge minerals dominate in mineral soils of the temperate climatic zone; therefore, soils of these regions are called permanent charge soils.

Contrary to the permanent charge, some mineral soil constituents can have either positive, zero, or negative charge of the magnitude depending on the composition of the soil solution (pH, concentration, ionic composition). In relatively low pH range, surface hydroxyl groups of these constituents may associate protons from soil solution via hydrogen bonds, thus, the surface becomes positively charged. In relatively high pH range, these surface hydroxyls may undergo acidic dissociation, resulting in formation of negative charge. At a defined pH value, the surface hydroxyls neither associate the protons from the solution nor dissociate their own ones and the surface has no charge. The latter value of pH is called point of zero charge (PZC). One can imagine the above reactions are similar to those illustrated in Figure 5 for aluminum (or iron) oxide.

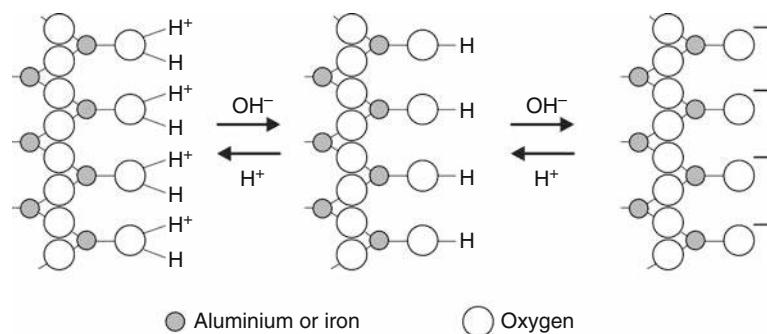

The point of zero charge for some most frequently occurring soil constituents is at pH values between 3 and 4 for silicon oxides, 5 and 8 for iron oxides, 6 and 10 for aluminum oxides. Tetrahedral Si–OH (silanol) and octahedral Al–OH (aluminol) groups situated at the mineral edges and hydroxyl-terminated planes of clay lamellae may be also involved in proton donor–acceptor reactions of hydroxylic groups; however, only 5–10% of the negative charge on 2:1 layer silicates is pH dependent, whereas 50% or more of the charge developed on 1:1 minerals can

be pH dependent. The PZC of edge surfaces of clay minerals is most frequently around 8.

Reactions of proton association/dissociation reactions on variable charge surfaces constitute important mechanisms of soil acid–base buffering systems.

Electrostatic charges dependent on pH are present to some extent in nearly all terrestrial ecosystems, however, they are predominately found in highly weathered soils of humid tropics and subtropics, as Oxisols, Ultisols, Alfisols, Spodosols, and Andisols (variable-charge soils), which collectively cover nearly one third of the global ice-free land surface area.

Humus is a major part of soil organic matter. It originates from a decomposition of animal and plant residues by soil flora and fauna to a point where it is highly resistant to further breakdown or alteration. Humic and fulvic acids are most important constituents of humus and their relative ratio increases with organic matter oxidation (mineralization). Humic substances are very complex, molecularly flexible polyelectrolyte materials with almost acidic (mostly carboxylic and phenolic) surface functional groups. Humic acids are larger and more aromatic than fulvic acids. Fulvic acids are more water soluble and more oxygenated than humic acids and have more total acidity and more carboxylic acid functional groups than humic acids. Surface functional groups of soil organic matter have very different acidic strength, depending not only on the kind of the group, but also on its locality. Surface groups of stronger acidic character are neutralized at lower pH values leaving a negative charge on the surface. The weaker acidic is the group, its neutralization requires higher pH value. Therefore the higher is the soil pH, the larger negative surface charge occurs on organic matter surfaces. Acidic surface groups located closely to each other, create common electric field surrounding these groups and within this field their protons become delocalized (proximity effect). The delocalized protons behave as strong acids and so the neighboring groups are very strongly acidic so the soil organic matter has some negative charge even at very low pH values. Charging of organic matter surfaces also markedly contribute to soil buffering.

Surface Properties and Related Phenomena in Soils and Plants, Figure 5 Formation of variable charge on surface of aluminum or iron oxides.

Bacterial cell walls expose numerous carboxyl, phosphate, and phenolic types of functional groups to the aqueous phase, and are negatively charged at pH values above approximately 2–3.

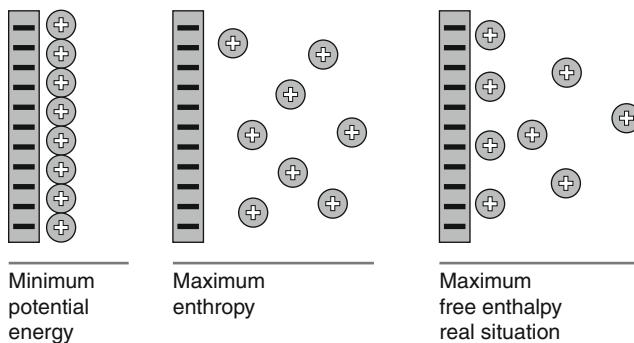

Electric double layer

The charged surface attracts ions of opposite sign of charge (counterions) from soil solution and repels ions of the same sign (coions). The tendency of the whole system to reach minimum potential energy would request the counterions to locate just near the surface and the coions to be repelled. The simultaneous tendency to reach maximum dissipation (entropy) would request a uniform distribution of both counter and coions in the solution. Thus, in the system, the potential energy factor is responsible for accumulation of most counterions close to the surface and repulsion of the coions while the entropy factor causes diffusion of some counterions out from the surface and of coions to the surface. As a result of these two opposite tendencies, the specific distribution of the ions near the surface occurs, which meets the conditions of minimum free enthalpy. The ions balancing surface charge together with the charged surface are called electric double layer (DDL) or diffuse double layer (DDL). The schematic buildup of this layer is shown in [Figure 6](#) wherein only counterions distribution is depicted.

The double layer can be roughly approximated as an electric condenser of one plate being the surface and the second being the layer containing counterions. The electric capacity of the condenser C equal to the plate (surface) net charge q divided by the electric potential U is proportional to the area between plates (i.e., area of the charged surface) S divided by the distance between the condenser plates d (i.e., the DDL thickness):

$$C = q/U \sim S/d \quad (5)$$

The rise in concentration and/or in counterion valence leads to the drop of the DDL thickness that, because the area of the charged surface is constant, leads to increase

Surface Properties and Related Phenomena in Soils and Plants, Figure 6 Distribution of counterions near negatively charged surface.

in DDL-condenser capacity. In the case of permanent charge soil constituents, (q is constant) this is connected with surface potential decrease. For variable charge components, the surface potential is governed by the point of zero charge PZC and this is constant at a given pH:

$$U \sim \text{PZC} - \text{pH} \quad (6)$$

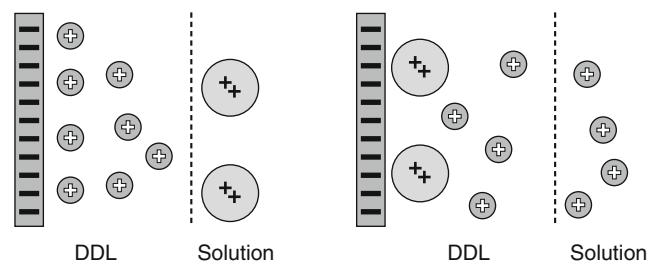

Thus, for such components, the increase of salt concentration and/or counterion valence leads to the increase of surface charge by the dissociation of surface protons to the solution (above PZC) or association of the solution protons to the surface (below PZC).

Prevalence of negatively charged surfaces in temperate climatic zone soils causes that they bound mainly cations. And so the troubles with anionic fertilization may arise. For example, the negatively charged nitrate anions are repelled to the solution and they are easily washed out from the soil with the rainwater. Therefore, this is better to apply the nitrate fertilizers in a few doses rather than in a single one, or to use foliar application. In mineral soils of humid tropics, having usually lower pH than the PZC, the deficit of cationic nutrients is a frequent phenomenon.

Ion exchange

The counterions present in the DDL may be easily exchanged with other ions being actually in an excess in soil solution as soluble salts. This process is called ion exchange and is schematically presented in [Figure 7](#). The formal boundary between the DDL and the bulk solution is drawn as a dashed vertical line.

Higher electrostatic force exerted by the charged surface on the higher valence counterions causes that they are better electrostatically adsorbed so their ratio to lower valence counterions is higher near the surface than in the bulk solution. When the surface potential drops to zero, this ratio approaches the ionic ratio in the bulk solution. The higher is the charge of the counterion and the higher is its mass, the higher is the force of its binding and so this ion is more difficult to be exchanged by other ions. Therefore, acidic soils may lose their ability to bind nutrient cations: trivalent aluminum cations or polymeric aluminum cations of large charge and mass may be so strongly bound that the soil charge becomes almost totally blocked.

Surface Properties and Related Phenomena in Soils and Plants, Figure 7 Schematic view on cation exchange.

Deblocking of soil surface charge and renovation of exchange properties of the soil requests neutralization of aluminum and its precipitation as oxides, which can be performed by liming.

Cations adsorbed in the DDL (cations of soil exchange complex) are easily taken by plants. To fulfill the condition of an electric neutrality of the system, the plant should release the equivalent amount of cations to the soil. These are hydrogen ions, because the plant cannot produce the other ones. This is one of the important mechanisms of soil acidification, and is more pronounced in agricultural areas from which the soil nutrients are removed from soils together with the taken biomass. Therefore, the crops need the mineral nutrients supply. In natural environments the cations taken from soils, or at least their large part, may return to the soil after decomposition of the dead plants. From this reason, this is advantageous to leave the crop residues in the field after harvesting.

The quantity of exchangeable cations in the zone adjacent to the charged surface that can be exchangeable for other cations is called the cation exchange capacity (CEC). Agricultural sciences regard CEC as the ability of the soils to supply cations. The range of soil colloid CEC ranges from about 4 cmol kg^{-1} for Si oxides to about 600 cmol kg^{-1} for humic acids. Thus, humus has the highest CEC in comparison with minerals like kaolinite, monmorillonite, smectite, and even zeolite. Contrary to constant charge clay minerals, organic matter does not have a fixed CEC and it increases markedly with increasing pH. So to measure the actual CEC of a soil, pH must be constant during the procedure.

The CEC of plant roots is mainly determined by the number and density of carboxylic groups of pectines and proteins present in cell walls, thus, this is dependent on pH. It is responsible for cations uptake from soil. The lower the CEC of the roots (lower surface charge density and lower surface potential), the lower is the ratio of polyvalent to monovalent cations at the root surface at the same composition of the soil solution and the uptake of polyvalent cations by the plant is respectively smaller. Therefore low root CEC ensures with plant tolerance on soil acidity (aluminum). As a rule, dicotyledonous plants have markedly higher CEC than monocotyledonous plants; therefore, they uptake relatively more polyvalent cations

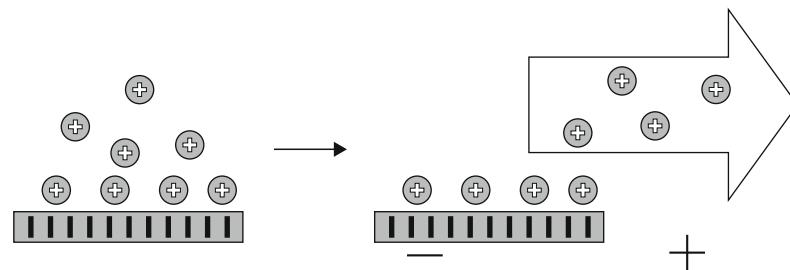

(e.g., Ca and Mg) and in natural environments poor in calcium and magnesium they eliminate monocots from mixed populations. And the opposite occurs in potassium poor habitats. The plant can modify the root CEC depending on nitrogen and phosphorus supply, availability of microelements, soil density (compaction), as well as oxygen, heavy metals, or aluminum stresses. During, the Al stress the density of variable surface charge of the roots decreases markedly that may lead to significant depression of the relative amount of multivalent aluminum ions present at the root cation exchange sites that may serve as a kind of plant self-protection mechanism.

Electrokinetic phenomena

Because counterions in DDL diffuse into the surrounding solution, they can move together with the liquid phase. So if an external force causes a movement of the liquid in respect to the charged solid, some of the counterions are taken apart from the surface by the migrating liquid as this is shown in Figure 8.

As a result, the electric field arises that brakes the further movement of the counterions. This electric field exists until the liquid movement stops. Thus the movement of the solution through a capillary tube with charged walls or a porous body composed from charged particles (soil) creates an electric potential between inlet and outlet of the liquid that is called streaming potential. Similarly, if the charged particle settles down in a liquid due to gravity (sedimentation process) or during centrifuging, the electric potential along the liquid phase arises that is called sedimentation potential.

On the other hand, if the external electric field is applied on two ends of a charged capillary tube or on opposite sides of a porous body composed from charged particles, the charges in DDL separate and the gradient of counterions concentration arises on both ends of the body inducing an osmotic pressure along it and a related movement of the liquid phase to "dilute" the counterions that is called electroosmosis. If the capillary tube is placed vertically, the electroosmosis goes until the hydrostatic pressure of the water column (plus capillary rise term) equals the electroosmotic pressure. However if the capillary is placed horizontally the electroosmosis lasts until the liquid is

Surface Properties and Related Phenomena in Soils and Plants, Figure 8 Separation of charges in diffuse double layer (DDL) due to relative movement of solid and liquid phases.

present at the inlet, so this whole liquid may be transferred through the capillary or porous body.

Electroosmosis has been frequently used in geotechnical and environmental soil engineering as a method of soil improvement including electroosmotic dewatering, contaminant removal, electrobioremediation, and electrochemical remediation. Electroosmosis is applied for consolidation of foundation soils and drying building structures. However numerous disadvantages accompany electroosmotic treatment in soils as electrolysis, hydrolysis, oxidation, reduction, local changes in pH, mineral decomposition, precipitation of salts, or secondary minerals.

Electroosmosis is applied in plant physiology to explain movement of water via the phloem. Preferential uptake of similar charge ions (e.g., K^+) to the interior results of the cells in ions unbalance alongside the phloem and accompanied electric field forces water molecules and other solutes present to move upward.

Movement of soil animals (having charged surface of the body) causes the electroosmotic flow in a micro thin layer of water at the body surface that serves as a lubricant against the rough particles of the surrounding soil.

If the electric field is applied to a liquid containing suspended charged particle, separation of diffuse layer charges on sides of the opposite particle results in differences in osmotic pressure that causes the movement of liquid around the particle to more ion concentration region. Thus, a liquid pressure is exerted on the respective side of the particle and it is pushed forward that is called electrophoresis. Electrophoresis is a very important tool to study biomolecules (genes, proteins, and enzymes).

Aggregation

The interaction between the colloidal mineral phases, with special reference to clay minerals, and colloidal humic substances, is a crucial step for the formation and stabilization of organo-mineral aggregates in soil. Since organic anions are normally repelled from the negatively charged surface of soil minerals, the interaction with humic substances occurs only when cations, present on the exchange complex, act as a bridge between the mineral and the organic phases. The effectiveness of cations in binding clay minerals and humic substances increases with their charge, so that polyvalent cations are more able to stabilize the aggregates than monovalent cations.

Although the overall particle charge of clay minerals is negative in general, both negatively and positively charged parts on the surface of clay mineral particles exist simultaneously below PZC that favors positively charged edge-to negatively charged face aggregation.

Repulsion forces between permanent charges of clay minerals may be diminished by increased concentration of soil solution due to decrease in DDL electric potential and in this case face-to-face aggregation takes place.

Below their PZC, positively charged iron and aluminum oxides act as cementing agents for clay minerals and humic particles.

Summary

A vast number of environmentally important processes occur on surface of soil solid phase. This surface is extremely complex due to diversified mineral, organic and ionic composition of soil constituents, and it constantly changes under various environmental factors. Soil surface become increasingly used for description and modeling of soil physical, chemical, and biological processes as fertility, mass and energy exchange, accumulation of various species, water retention, microbial life, catalysis, pollution, acidification and alkalization, soil organic matter leaching, and oxidation as well as for quantitative analysis of soil typological and genetic properties. Surfaces of plant tissues play very important role in plant transport processes, their reaction on stresses, and adaptation to environmental conditions.

SURFACE ROUGHNESS, EFFECT ON WATER TRANSFER

Frédéric Darboux
UR 0272 Science du sol, INRA, Centre de recherche d'Orléans, Orléans Cedex 2, France

Synonyms

Micro-relief; Micro-topography

Definition

Surface roughness is the height changes in reference to the general shape of a surface. For soils, surface roughness is the shape of a surface when the topographic slope has been removed.

Introduction

Roughness is the second most obvious feature of the soil surface after its color. Being at the interface between soil and atmosphere, surface roughness affects water transfer. Surface roughness can store water in puddles, enhance infiltration, and limit overland flow. It can also affect the path, depth, and velocity of overland flow.

Because surface roughness can present various characteristics due to field work and rainfall, its effect on water transfer vary in space and time. The complexity in determining roughness effects comes from this variability but also from its time-consuming measurement. However, relationship between characteristics of surface roughness and water transfer can be drawn. Defining several kinds of roughness helps in understanding them.

Surface roughness characteristics

Soil surface roughness is usually divided into two components: the random roughness and the oriented roughness (Allmaras et al., 1966). Oriented roughness is related to fieldwork and to soil erosion. When related to fieldwork, oriented roughness is described as ridges and furrows. It can be characterized by a wavelength (about 1 dm), an amplitude (ranging between 1 cm and 1 dm), and a direction. All these features depend on the type of fieldwork. As a soil erosion feature, oriented roughness consists in the rill network. It is characterized through the rill density (length of rills per unit area) and rill depth.

By contrast, random roughness is isotropic, meaning that its features do not change significantly with direction. It is related to clods and aggregates created by fieldwork at the soil surface. The amplitude of random roughness ranges between a few millimeters and 1 dm. When analyzing the correlation of height with the distance (e.g., through a semi-variogram), a correlation length is usually found. This correlation length ranges between a few millimeters and 1 dm. At distances smaller than the correlation length, a correlation is present. For distances larger than the correlation length, little correlation exists. So, even if

it has some randomness in its features, random roughness has nevertheless a spatial structure.

Usually soil cracks are not considered as part of the surface roughness. They are seen as vertical objects included in the soil and, as such, a constituent of soil porosity.

Surface roughness measurement

Because the geometry of the interface between the soil and the atmosphere affects transfer through this interface and on this interface, measurement of surface roughness is an important issue (Jester and Klik, 2005). The simplest device to measure surface roughness consists in a chain placed across the soil surface. The distance between the two ends of the chain is measured. Comparing the actual length of the chain with this distance gives an estimate of the roughness. The shorter the distance between the ends is, the rougher the surface is.

The most used device is called a “pin meter.” A pin meter consists of a frame holding a set of equally spaced pins. Set vertically above the soil surface, the pins slide down up to come into contact with the soil surface. Reference lines drawn on the frame allow for manual or automatic reading of pin heights. Hence, a profile of the surface roughness can be measured. The most sophisticated versions of pin meter replace the pins by a single laser pointer traveling along the frame. They allow for a smaller step of about 1 mm.

The most sophisticated devices are able to build digital maps of surface heights with a millimeter resolution. First devices were using a single laser pointer traveling over a surface of about 1 square meter. Most recent devices can measure the heights along a profile simultaneously. By acquiring a set of profiles parallel to each other, a height map can be built. Another way to build height maps is to use stereophotogrammetry, i.e., a set of two pictures of the soil surface taken from slightly different locations. First manual, automatic computing of height maps is now possible. The main interest of height maps is in the direct quantification of features such as flow network and volume of puddles.

It should be noted that, whatever the device used to measure the roughness, some features are ignored – such as overhangs under clods for example.

Another way of estimating the surface roughness is through the use of satellite or aerial radars. Radars are able to estimate surface roughness with a resolution of about 100 m² over large surface areas and can be of great help in estimating the roughness pattern at watershed scale.

A lot of work has been devoted to define indices to characterize random roughness. These indices aim at summarizing the random roughness features into a single number. Most of these indices are statistical values, such as the standard deviation of heights. Currently, there is no universal index accepted by all soil specialists. The random roughness index (usually noted RR) should not be confused with the random roughness: RR is a number aiming

at summarizing some features of the roughness while the random roughness per se is an object.

Surface roughness effects on infiltration

Infiltration is a vertical transfer of water. A surface will have a higher infiltration capacity if it consists of numerous clods or if it can hold water in puddles. The spaces between the clods are large pores able to conduct rainfall or irrigation water downward. With the addition of water, pores will be more and more occluded through sealing and crusting. This phenomenon will decrease soil roughness. Therefore, roughness amplitude and infiltration capacity will decrease with time, but the relationship between them is not linear: infiltration capacity can become very low with the roughness amplitude still being high (Helming et al., 1998a; Darboux and Huang, 2005). More than the roughness amplitude, it is the kind of roughness that is relevant to infiltration, specifically its cloddiness and the presence of surface depressions.

Both ridge-and-furrow oriented roughness and random roughness can create depressions on the surface. Depressions are able to store water into puddles (Planchon et al., 2001). Though temporary, this storage can represent a significant volume of the inflow water. It can also be important because the water stored in puddles will not take part in overland flow but will infiltrate or evaporate instead. The volume of water that can be stored on a surface unit is called surface storage capacity. Because of sealing and crusting, depressions can have a low infiltration capacity compared to other parts of the surface. Hence, because surface roughness cause variability in sealing and crusting, it leads to spatial variability in infiltration capacity.

Surface roughness effects on overland flow

The surface roughness can delay the triggering of overland flow. This effect is due to surface porosity and to puddle filling and has been discussed previously.

Surface roughness also affects flow path. In the case of rills, the direction of oriented roughness is also the flow paths. Except for this special case, above the scale of a few square meters, flow direction is controlled by the interaction between the slope gradient, and the amplitude and direction of oriented roughness (Souchère et al., 1998; Takken et al., 2001). If the slope gradient is large, flow paths will be controlled by the slope. Otherwise, flow path can be in the direction either of the slope or of the furrows. Hence, in agricultural fields with low slope gradient, the actual flow network can be quite different from the flow network computed from the digital elevation model of a watershed only. This strongly advocates for including the effect of ridge-and-furrow into the computation of flow networks of watershed management models.

Random roughness has several effects on overland flow: it can change the overland flow velocity, depth,

and direction. The effect of random roughness on flow direction can be characterized at the scale of 1 m² (Römkens et al., 2002). The geometry of flow networks in interrill areas is similar to the one of river networks. Because the depth of overland flow is similar to the height of random roughness, numerous mounds protrude through the flow. Therefore, in interrill areas, though this flow is usually called sheet flow, it looks more like a net than a sheet.

A larger random roughness is usually expected to slow down the flow. Hydraulic studies, mainly carried out in open channels, account for the random roughness of the walls through a friction coefficient (such as Manning and Darcy Weisbach coefficients). In these studies, the height of the roughness is always much lower than the water depth. The roughness of the channel affects the water velocity without changing the flow direction. Such roughness is termed hydraulic roughness.

Because overland flow in interrill area is very different from channel flow, the applicability of hydraulic roughness concept and coefficients to overland flow, though widespread, remains debated by the scientific community (Smith et al., 2007). Because the flow occurs between mounds, random roughness can cause the flow to be deeper than expected (Helming et al., 1998b). Consequently, flow velocity could be increased – and not decreased – by a larger roughness. In order to better account for this specificity of overland flow on agricultural fields without abandoning the hydraulic roughness concept, “equivalent” friction coefficient values are used.

Summary

The usual splitting of surface roughness into oriented and random roughness has been of great help to understand the effects of surface roughness on water transfers. Other sub-components, such as mounds and depressions are also meaningful in better inferring the interaction between roughness and water flow. The roughness measurement remains an issue for improving our knowledge.

SURFACE STORAGE CAPACITY

The maximal volume of water per unit area that can accumulate over the surface during periods of intense rainfall (i.e., rainfall exceeding the soil's infiltrability). When surface storage capacity is exceeded, overland flow begins.

Bibliography

TEMPERATURE EFFECTS IN SOIL

Graeme D. Buchan

Soil and Physical Sciences Department and Centre for Soil and Environmental Research, Lincoln University, Christchurch, Canterbury, New Zealand

Definition

Temperature effects in soil. The effects of temperature and its variations on the properties of soil, and on processes occurring in soil, including soil formation, physical properties and processes, and biological processes.

Introduction

Soil temperature plays a central role in all soil processes. Soil and near-ground air temperatures are powerful “biocontrollers.” In temperate climates, the transition from the nongrowing to the growing season occurs when temperature rises above a threshold or “base temperature,” T_b (e.g., about 5°C for temperate pastures). Temperature drives chemical and biological processes, leading to the Q_{10} concept described below. Biological “clocks” (e.g., the clock which determines the developmental stages of a plant) run not by time alone but by time (e.g., in days) multiplied by temperature (in degrees). This leads to the concept of “thermal time” (expressed as a “day-degree sum”).

Soil properties and processes are controlled by a complex set of factors, most strongly by soil water and soil temperature. Thus, it may be impossible to isolate and quantify the temperature dependence of a process in simple mathematical form, due to confounding effects, especially of soil water. Where possible, equations for temperature dependences are given below.

Climate change increases our need to understand temperature effects in soil. Globally, the “temperature increase

from 1850–1899 to 2001–2005 is 0.76°C” (IPCC, 2007). Of key importance for future climate are the changes in soil’s ability to act as a “carbon store,” and to emit or absorb other greenhouse gases (GHGs), and hence provide feedbacks on climate change (Smith et al., 2003; see *Greenhouse Gas Fluxes: Effects of Physical Conditions*; *Greenhouse Gases Sink in Soils*). Such feedbacks will operate until some new steady state between soil and atmosphere is achieved.

Soil temperatures cover a wide range, from subzero in frozen or tundra soils to hundreds of degrees Celsius under scrub or forest fires (see *Wildfires, Impact on Soil Physical Properties*).

This article summarizes the effects of temperature on the following:

- *Pedogenic processes*, including the weathering of minerals and soil formation and the accumulation of soil organic carbon
- *Physical properties and processes*, including the storage, flow and measurement of soil water, and the dissolution and diffusion of gases
- *Biological processes*, including the transformations of organic matter, CO₂ release from soil, microbial activity, and seed germination

Note that purely chemical processes (e.g., hydrolysis of soil minerals) are omitted above, since (a) they may be part of pedogenic weathering (e.g., clay formation) or (b) they may be part of a mixed system of chemical and biotic transformations (e.g., in the nitrogen cycle).

Pedogenic processes

The Jenny model of soil development (Jenny, 1994) identifies climate (i.e., temperature plus precipitation) as one of the five main controllers of soil formation. The effect of temperature is approximated by the van’t Hoff rule: *For every 10°C rise in temperature the rate of*

a chemical reaction increases by a factor of typically two to three. This approximate rule holds for numerous chemical reactions and biological processes. It applies to soil weathering and the process of “mineralization” (i.e., the release of soil mineral components from unavailable chemical combinations into available forms in the soil solution). Thus rates of soil formation are strongly temperature controlled, varying from roughly 0.02 mm/year or less (e.g., resistant parent material combined with cold or dry climate) to 1 mm/year (e.g., softer parent material, warmer and wetter climate) (Schertz and Nearing, 2006).

Physical properties and processes

Temperature differences in soil drive flows of both heat and of water (Buchan, 2001).

Here, we consider other less obvious effects of temperature, particularly on soil water.

Measurement of soil water content

The two main methods used to measure volumetric water content, θ_v ($\text{m}^3 \text{ water/m}^3$ soil) are the neutron probe (NP) and electromagnetic (EM) methods. The NP method can be regarded as unaffected by variations in soil temperature. EM methods (which include time-domain reflectometry [TDR], capacitance, and other methods) measure water content via the large dielectric permittivity of water, ϵ_w , which varies approximately as follows (Woodhead et al., 2003):

$$\epsilon_w = 89 - 0.37T \quad (1)$$

Thus, EM probe readings require correction for temperature variations (Stangl et al., 2009; Gong et al., 2003). For EM probes operating at higher (~ 1 GHz) frequencies (e.g., TDR probes), Equation 1 indicates a temperature sensitivity of ca. 4% per 10°C . However, for EM probes which operate at lower (e.g., 10–100 MHz) frequencies, variation of the soil’s electrical conductivity may further increase probe sensitivity to temperature (Western and Seyfried, 2005; Carrick, 2009).

Soil water potential

The total potential of water in soil is the sum of three main components: the pressure potential, ψ_p ; the solute (or osmotic) potential, ψ_s ; and the gravitational potential, ψ_g .

The pressure potential (or “suction”)

In unsaturated soil, ψ_p is negative. To simplify, we drop the negative sign and refer more intuitively to the soil water “suction,” s (i.e., $s = -\psi_p$). As temperature increases, suction decreases. The Philip–de Vries theory (Hopmans and Dane, 1986) postulates that this is accounted for by the decrease in the surface tension of water. However, experimental results indicate a temperature coefficient that is about two to three (or more) times larger than the value predicted by this theory (Hopmans and Dane, 1986).

Solute potential, ψ_s

For dilute solutions, ψ_s (in kPa) is given by (Or and Wraith, 2002):

$$\psi_s = -RTC_s \quad (2)$$

Here, $R = 8.314 \text{ J K}^{-1} \text{ mol}^{-1}$, T (in K) is absolute temperature, and C_s (mol m^{-3}) is the solute concentration.

Water flow

The literature reports conflicting results for the effect of temperature on hydraulic conductivity, $K(\Psi_p)$ (a function of the pressure potential Ψ_p). Some authors (e.g., Constantz, 1982; Hopmans and Dane, 1986) report that, as temperature rises, the rate of increase in K is well explained by the decrease in the viscosity of water, $\eta(T)$. By contrast, Stoffregen et al. (1999) report that it can be described using the exponential function:

$$K_{10^\circ\text{C}}(\psi_p) = K(\psi_p) \exp[0.04(10 - T)] \quad (3)$$

Here, $K(\Psi_p)$ is corrected to a reference temperature of 10°C , from the soil temperature (T) at which K was obtained. Equation 3 gives a temperature dependence about twice that based on the viscosity of water alone. The viscosity of water decreases by a factor of about 2, over the range 0 – 30°C . Therefore, infiltration and drainage rates will at least double over this range – a common winter-to-summer range near the soil surface in temperate regions (see *Soil Water Flow; Infiltration in Soils*).

Water vapor in the soil air space

Temperature controls the saturated vapor pressure (SVP) of water, $e_s(T)$. Of several approximate equations for the $e_s(T)$ function (Vomel, 2009), the simplest is the Bolton equation, accurate within 0.3% over the range -35°C to $+35^\circ\text{C}$:

$$e_s(T) = 6.112 \exp[17.67T/(T + 243.5)] \quad (4)$$

Here, T is in $^\circ\text{C}$ and $e_s(T)$ in hPa (=mbar). (Note: Equation 4 applies over liquid water, not ice). As the water potential $\psi_w = \psi_p + \psi_s$ decreases (i.e., becomes more negative), water is held more tightly, and hence the relative humidity (RH) in the soil air space also decreases, according to Equation 5:

$$RH = e/e_s = \exp\left[\frac{M_w\psi_w}{\rho_w RT}\right] \quad (5)$$

Here, e (mbar) is the actual vapor pressure in the soil air space, ρ_w (kg m^{-3}) and M_w (kg mole^{-1}) are the density and molar mass of water, respectively, ψ_w is in Pascal, and T (K) is temperature. Equation 5 is exploited in the technique called “psychrometry”: by measuring RH in the soil air space, one can determine the water potential, ψ_w (Mullins, 2001; Or and Wraith, 2002). If ψ_s is negligible, psychrometry gives the pressure potential, ψ_p .

Gases: dissolution and diffusion

The dissolution and transport of O₂ and CO₂ in soil water control root and microbial respiration, the redox conditions in soil, the pH of the soil solution and hence, the weathering and development of soils (see *Aeration of Soils and Plants*). As temperature increases, water will progressively “de-gas,” until the concentrations of O₂ and CO₂ become effectively zero at the boiling point (The Engineering Toolbox, 2005). The diffusivity D of a gas in the soil air space increases with temperature T as follows (Rolston, 1986):

$$D_{T2} = D_{T1}(T_2/T_1)^{1.72} \quad (6)$$

Coupled flows of heat and water (*Coupled Heat and Water Transfer in Soil*)

Temperature gradients drive flows of water, in both liquid and vapor phases. Vapor flows from warmer to cooler soil via a “distillation” process, carrying water itself and also latent heat. This can occur strongly in near-surface soil, and also in some “engineering” situations. The heat generated in underground electric cables can cause moisture to migrate away from the cable, drying the surrounding soil and increasing its thermal resistance, which can lead to overheating of the cables (Campbell and Bristow, 2009). Under paved surfaces, moisture can migrate upward and accumulate beneath the paving material (Morgenroth and Buchan, 2009).

Thermal properties and processes

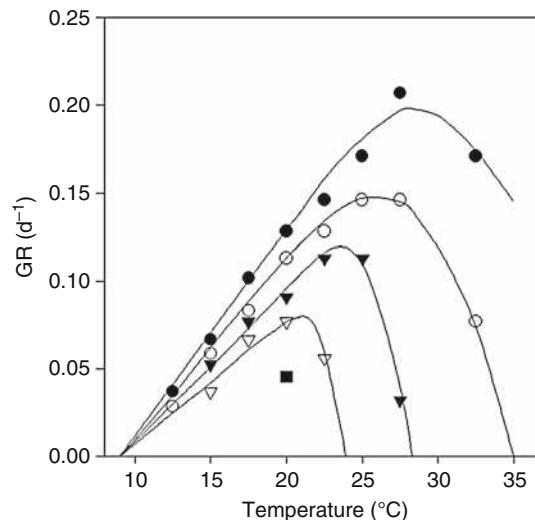

Soil thermal properties (heat capacity, thermal conductivity, and diffusivity) are weakly temperature dependent, so that the heat flow equation can be treated as linear. Freezing leads to expansion of water (Buchan, 1996). Freeze-thaw cycles contribute to soil weathering and microbial die-off, and can rearrange soil components, e.g., migration of stones to the soil surface (Kessler and Werner, 2003).

Biotic processes

Biotic processes are catalyzed by enzymes and typically respond to temperature as shown in **Figure 1**. The process rate increases in a rising (or thermo-stimulation) stage from c. zero at a base temperature, T_b , up to some optimum temperature, T_o (typically in the range 20–35°C). Above T_o the rate decreases, mainly due to denaturing (i.e., thermally induced deformation) of enzyme molecules.

The rising or suboptimal stage ($T_b < T < T_o$) illustrated in **Figure 1** may cover most of the actual temperature range in a soil, especially as temperature rises in spring, and is quantified in two distinct ways. The first and simpler approach assumes that the rising stage is approximately linear. Then, assuming T is within this range, the cumulative effect of soil temperature (e.g., on seed germination) can be described via the concept of “thermal time” or a “day-degree sum,” DD:

$$DD = \Sigma(T_{ave} - T_b) \quad (7)$$

Temperature Effects in Soil, Figure 1 Effect of temperature T on Germination Rate (GR) of radiata pine tree seeds. The diagram illustrates: (a) the typical T -dependence of biotic processes, starting at a base temperature T_b (here $\sim 9^\circ\text{C}$), then increasing approximately linearly to an optimum temperature, followed by decline due to thermo-inhibition; (b) the added complexity that real biological populations (here, a set of seeds) show variability in their response – the different curves represent the different responses of subpopulations, from fast responders (*uppermost curve*) to slow responders (*lowest curve*). (From Bloomberg et al., 2009.)

Here, Σ denotes a day-by-day sum and T_{ave} is the average temperature for the day. (Note: Days with $T_{ave} < T_b$ count zero in the sum).

However, soil moisture is also a strong determinant of some processes, so the thermal time concept has been extended to the concept of “hydrothermal time” (e.g., Bloomberg et al., 2009). **Equation 7** is then extended by multiplying it by a term $(\psi_p - \psi_b)$, where ψ_b is a base water pressure potential.

The second approach to quantifying the thermo-stimulation or rising stage recognizes that it is more generally curvilinear and should follow van't Hoff's rule, written as:

$$R_T = R_0 \exp(BT) \quad (8)$$

Here, R_T and R_0 are the process rates at temperatures $T^\circ\text{C}$ and 0°C , and B is a constant. This leads to the definition of the “ Q_{10} ” factor, i.e., the factor by which the rate of a process increases for a 10°C temperature increase:

$$Q_{10} = R_{T+10}/R_T = \exp(10B) \quad (9)$$

Q_{10} values vary with the process involved, and also with temperature, but are predominantly of order 2–3. The Q_{10} concept applies to a wide range of processes. It expresses the effect that increased molecular kinetic energy causes molecules to increase the frequency with which they either (a) escape from a phase (e.g., via

evaporation or volatilization) or (b) exceed the activation energy of a chemical or biochemical reaction.

Soil respiration, organic C content and climate change

Soil respiration (i.e., the rate of production of CO₂, caused by decomposition of organic substrates) is the sum of respiration by (1) roots and (2) microbial decomposers in soil. The latter represents the rate of organic matter (OM) decomposition in soil, a key quantity controlling the soil's carbon budget under climate change. Considering whole-soil respiration (i.e., both 1 and 2 above), Zheng et al. (2009) found that average Q_{10} values in soils in China followed the order forest (2.51 ± 0.78) > grassland (2.15 ± 0.44) > cropland (1.99 ± 0.24).

They also showed that Q_{10} is itself temperature dependent:

$$Q_{10} = a \exp(-kT_{\text{ave}})$$

Kirschbaum (1995) separated out the rate of microbial OM decomposition (under non-limiting soil water conditions) and found that Q_{10} decreased with soil temperature from about 8 at 0°C through 4.5 at 10°C to 2.5 at 20°C. This decrease of Q_{10} with temperature assists the simplifying assumption that the rising stage in Figure 1 is approximately linear, and hence the usefulness of the thermal time (day-degree) concept.

Note that the actual effect of climate change on the soil's carbon budget will be the net effect of two opposing processes: (a) increased OM decomposition due to rising temperatures versus (b) increased plant productivity due to the "fertilization effect" of increased atmospheric CO₂. Studies indicate that (b) is likely to be greater, so that (depending also on land use change) C sequestration by soils should increase under climate change.

Microbiological effects

Microbes such as bacteria can exist in two phases: the vegetative or normal growth phase; and the survival phase, when bacteria form resistant spores. Temperature controls die-off in the vegetative phase. However, to kill off spores typically requires either very high or very low temperatures. Microorganisms can survive longer in cold soils than in warm soils. Bacterial die-off rate approximately doubles with each 10°C rise in temperature between 5°C and 30°C (Reddy et al., 1981; Gerba and Goyal, 1985). In cold soils (<5°C) bacteria can survive for up to 100 days.

Manipulation of soil temperature

Techniques to manipulate soil temperature include mulching the soil surface, altering plant cover, ridging the surface, and soil solarization (see *Soilborne Diseases, Control by Physical Methods*). These techniques also alter near-ground air temperature, e.g., frost intensity is commonly reduced by controlling or removing plant cover in the inter-row spaces of frost-sensitive horticultural crops.

Conclusions

Temperature controls a wide range of soil processes, often in ways difficult to quantify, due to the confounding effects of other controlling variables, especially soil moisture. Key areas requiring further research include: (1) The net effect of future climate change on greenhouse gas exchanges between the atmosphere and soil-plant systems, due to the combined actions of (a) increasing temperature (which tends to decrease soil organic matter content, but increase plant productivity) (Portner et al., 2009), and (b) rising atmospheric CO₂ (which increases plant productivity via an atmospheric "fertilization effect"). (2) Description of the synergistic (coacting) effects on soil processes of temperature and other variables (especially soil moisture) e.g., via concepts such as hydrothermal time (Bloomberg et al., 2009).

TENSIOOMETRY

Krzysztof Lamorski

Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland

Definition

Tensiometry – methods and techniques of measuring soil water potential, by means of using tensiometers.

Introduction

Soil water potential is one of the key concepts in soil physics. Water potential determines many soil processes, including soil water movement, soil solutes and pollutants transport, and others e.g., soil heating phenomena. Availability of soil water for plants and its evaporation or transpiration is also influenced by soil water potential.

Soil water potential

Energetic state of soil water is formally defined as a total soil water potential. There are four main components of the total soil water potential (Campbell, 1988), which takes its source in different physical phenomena: matric, osmotic, pneumatic and gravitational forces. Matric potential results from interactions of soil water with soil solid phase. It is known also as a capillary potential. Osmotic or solute potential is associated with chemical solutes existing in water. Pressure or pneumatic potential is attributed to pressure differences between the place in the soil medium where it is determined, and pressure in reference to free water. Gravitational potential takes into account differences in water energy associated with the work done by gravitational force. Gravitational potential is calculated in relation to some reference level, where it is assumed to be equal to zero.

Matric potential plays special role in many soil processes and is very important for agriculture. Especially soil water content is related to matric potential via so called retention curve. Soil matric potential may be measured by devices called – tensiometers.

The first use of tensiometers is commonly attributed to Willard Gardner or Lorenzo Richards, which took place about 1920s. However, recent developments (Or, 2001) shows possibility that the tensiometer like devices were

used earlier. Burton E. Livingston in 1908 developed auto-irrigator device in which the same concepts as in tensiometer were used. In old tensiometers pressure was measured, by mercury pressure gauges, so these devices were neither portable nor easy to use.

Tensiometer

Tensiometers are devices used to measure value of the soil water matric potential. The name tensiometer, is taken from old soil science nomenclature, where soil water potential was called water tension.

The tensiometer consists of three main components (see Figure 1): a *porous cup* fixed on an impermeable *tensiometer body* and a *pressure gauge*. Dimensions and shape of the porous cup determines the place in the soil medium where soil water matric potential is measured. The device body is fully filled up with deaerated water.

The key concept in tensiometer functioning is equilibrium state achieved between soil medium and tensiometer cavity. When soil is dried water flows out from the tensiometer via ceramic cup, until pressure drop in the tensiometer, equilibrate suction from the soil medium. When soil moisture increases, water from the soil medium flows into the tensiometer, until a new state of equilibrium is reached. Water exchange between the tensiometer and soil medium

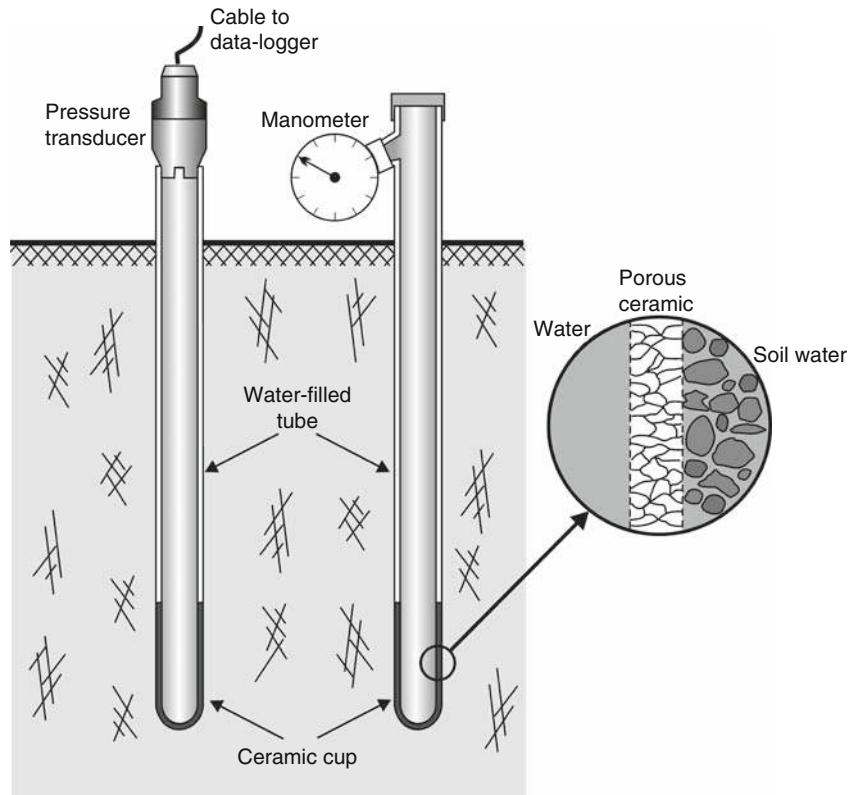

causes water pressure changes in the tensiometer itself. This pressure is related to the soil water potential.

Different kinds of pressure gauges may be used in the tensiometer measurements. Nowadays the most standard way of pressure measurements used in the tensiometers, is to use manometer, especially in the field devices. Electronic pressure transducers are also often used. They allow for automatic and remote soil water matric potential measurements.

Difficulties in tensiometer measurements

There are some technical issues with using tensiometer. Properties of the porous cup and its contact with the soil medium are the most important.

First of all, the tensiometer is not working properly for dry conditions. As the soil becomes dry, pressure in tensiometer decreases reaching the point when air enter into tensiometer. The measured pressure is no longer related to the value of soil matric potential. The pressure value in which this phenomenon occurs depends on pore sizes, of the applied ceramic cup. The thinner the pores are, there higher pressure is needed to remove water from them, and at higher pressure air entry occurs. Typical value of pressure at which air entry take place is about -100 kPa although ceramic cups with higher and lower air entry pressures are produced.

Tensiometry, Figure 1 Tensiometer.

The required condition of accurate tensiometer measurements is a good contact between pressure cup and the soil medium. Unfortunately, it may be difficult to ensure proper contact, due to improper device installation or soil shrinking and swelling. When there are gaps between soil medium and the tensiometer's ceramic cup, the measured pressure is not equal to the soil matric potential value and/or the tensiometer response time is longer.

The basic requirement for correct tensiometer measurements is to achieve equilibrium state between device and the soil medium. This may be an issue when the soil water content changes rapidly. The response time of tensiometer depends not only on the device itself, but also on water permeability of soil in which measurement occurs (Towner, 2006). When device response time is high, in comparison to rate of soil moisture changes, the device readings will lag behind true soil matric potential values.

Alternative methods of soil water potential measurements

The other devices for measuring soil matric potential are osmometers and psychrometers. The *osmometers* or *polymer tensiometers* used in soil potential measurements, are generally tensiometers, but filled up with other substances than water, e.g., polymer, which ceramics are semipermeable (de Rooij et al., 2009). Semipermeable ceramic cup is made of substances, which are permeable to water but non-permeable to polymer. Due to osmosis, water is exchanged between soil medium and the device, which cause registered pressure changes.

The *psychrometers* are generally devices for measuring the relative humidity of air, but in soil measurements *micro-psychrometers* are used for indirect measurement of soil water potential (Hillel, 1998). The concept of measurement is based on assumption that in equilibrium conditions soil vapor potential is equal to the sum of the matric and osmotic potential components. In soil measurements thermocouple micro-psychrometer are used, in which chromel-constantian thermocouple is placed in small ceramic cup. This thermocouple is cooled below the dew point of soil vapor phase, and the temperature is recorded. In the next step the condensed water evaporate and the temperature of the junction equilibrates with the temperature of soil medium. The difference of these two temperature values is related to the soil water potential.

Summary

Measurements of soil water potential belong to the first soil physical measurements performed in the past. Due to importance of water potential in the soil-plant-water system, the tensiometry is still technique widely used in agriculture and soil science research. Tensiometers used in such measurements, evolved and now are often controlled by electronic transducers and data-loggers. New type devices, such as psychrometers or osmometers are emerging in this field of usage.

THERMAL TECHNOLOGIES IN FOOD PROCESSING

António A. Vicente, Luís F. Machado
IBB – Institute for Biotechnology and Bioengineering,
Center of Biological Engineering, Universidade do
Minho, Braga, Portugal

Definition

The term *thermal technologies* encompasses the processes and equipment especially designed to heat a food with the purpose of processing it. This term is often used in opposition to *non-thermal technologies*, where food is processed but virtually no heat is involved.

Introduction

Thermal processing is probably the most important process in food industry that has been used since prehistoric times, when it was discovered that heat enhanced the palatability and the life of the heat-treated food. Thermal processing comprehends the heating of foods at a defined temperature for a certain length of time. However, in some foods, the high thermotolerance of certain enzymes and microorganisms, their physical properties (e.g., high viscosity), or their components (e.g., solid fractions) require the application of extreme heat treatments that not only are energy intensive, but also will adversely affect the nutritional and organoleptic properties of the food. Technologies such as ohmic heating, dielectric heating (which includes microwave heating and radio-frequency heating), inductive heating, and infrared heating are available to replace, or complement, the traditional heat-dependent technologies (heating through superheated steam, hot air, hot water, or other hot liquid, being the heating achieved either through direct contact with those agents – mostly superheated steam – or through contact with a hot surface which is in turn heated by such agents). Given that the “traditional” heat-dependent technologies are thoroughly described in the literature, this text will be mainly devoted to the so-called “novel” thermal technologies.

These novel thermal technologies have a common characteristic: heat is generated directly from inside the food, which allows the food thermal treatment while offering potential for improvement on preservation of vitamins and nutrients. The principal differences between ohmic, dielectric, and infrared heating are (Fellows, 2000):

- In ohmic heating, heat is generated due to the electrical resistance of a food, while in dielectric heating, heat is produced by friction of water molecules and infrared energy is simply absorbed and converted into heat.
- Ohmic heating depends on the electrical resistance of the food, dielectric heating is determined by the moisture content of the food, and infrared heating depends on the surface characteristics and of the color of the food.
- Ohmic heating generally is applied at normal electrical supply frequencies (50–60 Hz). The used frequencies of microwaves and radio frequency are defined in closed intervals to prevent interference with radio transmissions, whereas the infrared frequencies have a wider range.
- The used frequency defines the capacity of the energy penetration into a food. While ohmic heating penetrates throughout the food instantly, the lower frequencies used in dielectric heating allow a higher penetration rate than the ones of infrared heating.
- Electrical conductivity has a decisive role in the effectiveness of ohmic and dielectric heating, whereas in infrared heating, it is the thermal conductivity that limits the efficacy of the treatment.

Inductive heating

Inductive heating is based on the generation of an electric current through the food by electromagnetic induction. Heating occurs due to the induction of eddy current in the food that is placed in the generated magnetic field. An induction heater is constituted by an inductor (coil) which generates an electromagnetic field when an alternating electric current flows through it. The heating can be confined to an area immediately opposite to the coil where a secondary coil is placed and through it pass the food that is instantaneously heated (Piyasena et al., 2003). The existing information in the literature using this technology is nonexistent and was not possible to find studies of the application of inductive heating to food processing.

Ohmic heating

Ohmic heating (OH) presents itself as an alternative thermal method, being defined as a process where electric current is passed through foods to heat them. As the electric current passes throughout the food, heat is internally generated within the food which works like an electrical resistance.

OH has distinctive features that allow its distinction from other electric heating processes. In OH processing the direct contact of the foods with the electrodes is

required, whereas in microwave it is not necessary to have electrodes; OH does not have waveform restrictions, even though the sinusoidal type is preferred; and OH can use unrestricted frequency, excluding the defined radio or microwave frequency range.

Ohmically heated products present unique characteristics, with highly added value when compared to other products sterilized by alternative methods; this is especially the case of viscous products and of products with solid phases. The main advantages of OH are:

- Fast and uniform heating of liquids and solid phases by internal heat generation (without the limitations of the conventional heat transfer or microwave heating due to the dielectric penetration limit into solid phases).
- Continuous processing without heat-transfer surfaces, providing uniform heating that results in less thermal damage.
- High energy efficiency (approximately 90% of the electrical energy is converted into heat).
- Multiphase mixtures are not subjected to shear forces, as in scraped surface heat exchangers, due to low flow velocity and no moving parts.
- Reduced fouling and overprocessing of the food when compared with conventional heating, resulting in mechanical damage and better nutrients and vitamins retention.
- Simpler process control, with instant switch-on/switch-off and with reduced maintenance costs.

OH technology presents some disadvantages, such as the higher initial operational costs and the little information available on validation procedures for this heating process. In addition, the main advantage of OH (the heating is volumetric and dependent on electrical resistance) can, in some specific cases, be a significant disadvantage when heating products that are not ionically loaded, like products that include in their composition high amounts of fats, oils, and distilled water (Leadley, 2008).

Commercial applications

The longest running ohmic commercial system in England is a 75 kW unit which has been in operation since the 1990s. This system processed low-acid meat and vegetable products that were packed in bags. In Japan, a system with similar capacity was used to process whole fruits, including whole strawberries (Mans and Swientek, 1993).

Also in Japan, tofu is being processed using OH. Conventionally, the commercial tofu manufacturers use steam injection to heat the soymilk to denature the soybean proteins. Since steam temperature is higher than 100°C and steam condenses after injection, uneven heating and soymilk dilution are unavoidable. With OH, not only liquid food can be heated evenly, but also heating temperature and time could be accurately adjusted or controlled (Wang et al., 2007).

In the USA, a system for the pasteurization of liquid egg is being used, achieving flow rates over 10,000 kg h⁻¹. The

use of this system allowed not only the extension of the shelf life of the product to 12 weeks, but also the cleaning costs and downtime were reduced when comparing with the conventional heating exchange units (Raztek Corporation, 2009).

This technology is useful for the treatment of proteinaceous foods, which tend to denature and coagulate when thermally processed. Juices can be treated to inactivate proteins without affecting the final flavor. Other potential applications of ohmic heating include blanching, thawing, and peeling of fruits (eliminating the need of lye that is an environmental hazard) (Ramaswamy et al., 2005).

OH also has shown potential for a wide array of processes with great promise in future applications. The applications include the acceleration of fermentations; detection of starch gelatinization in solutions and pastes; pretreatments for drying, extraction, and expression; and reduction of water use during blanching (Sastry et al., 2002).

It is estimated that there are at least 18 commercial plants in operation across Europe, the USA, and Japan. As an example, Table 1 shows a summary of industrial plants, with the respective location, year of installation, product that is processed (Leadley, 2008).

Microwave heating

Microwave (MW) heating technology is based on the transfer of electromagnetic energy to the food product. Heat is generated mostly due to the presence of water in the food products. Because of the dipolar nature of this molecule, water is forced to move with the applied electromagnetic field – dielectric effect. This is an extremely fast oscillatory movement (due to the very high frequency of the field) that provokes molecular friction, which in turn causes the volumetric heating of the food. Furthermore, MW also provokes the generation of heat due to the oscillatory movement of ionic charges toward oppositely charged areas that causes multiple collisions and disruption of hydrogen bonds with water, both generating heat within the food (Kinn, 1947).

MW is characterized by wavelength and frequency. Frequencies used for MW heating are internationally established by Electromagnetic Compatibility regulations, and the respective frequency bands (known as Industrial and Scientific and Medical bands) are described in Table 2.

Generally, the frequencies of 2,540, 896, and 915 MHz are used for food processing. The 2,540 MHz frequency is used for home ovens and the three are used for industrial heating.

MW heating has a major advantage over conventional technologies, i.e., the ability to cause a rapid and volumetric temperature rise within the food. This characteristic leads to a number of significant advantages over the traditional heating techniques, namely:

- Increased product throughput: the time required to achieve the desired process temperature is reduced to one-quarter resulting in improved product quality, especially for particulate foods.

Thermal Technologies in Food Processing, Table 1 List of OH plants, year, processed product, process temperature, heating power and location installed until 2006 (Adapted from Leadley (2008))

Products	Installation year	Country	Heating power (kW)
Tomato sauces and pastes	1994	Italy	50
Tomato paste and mango purée	1996	Ivory Coast	64
Fruit slice and dices	1996	Italy	100
Peach and apricot slices and dices	1998	Greece	150
Peach and apricot dices, slices, and halves	1999/2000	Greece	150, 200, and 240, respectively
Diced pears and apples	2000	Italy	150
Low-acid vegetable purées	2001	Italy	100
Strawberries	2002	Mexico	250
Fruit preparations	2002	France	100
Meat preparations	2003	France	50
Tomato dices and peeled	2004	Italy	480
Vegetable sauces	2005	Italy	60
Diced mushrooms and tomato	2006	Italy	240

Tomato sauces and derivatives	2006	Italy	100
Peach and apricot dices and slices	2006	Greece	120

Thermal Technologies in Food Processing, Table 2 Specific frequencies for industrial, scientific, and medical uses (Adapted from Leadley (2008))

	Frequency (MHz)
Microwaves	896 (UK) and 915 (USA)
	2,450
	5,800
	24,125

- Improved energy efficiency: the heat is generated in the product, so it is possible to attain a more uniform temperature distribution in the product, simplifying the control of thermal treatment and avoiding overprocessing.
- The process can be instantly switched on or off.
- The food product can be pasteurized after being packaged.

The main disadvantages of this technology are the high equipment and operating costs and the difficulties in validating the heat treatment due to changes of dielectric properties during the heating process that are not yet fully understood, resulting in wide distributions of temperature across the food product. Being so, the validation of the process has to be done almost individually for each food product, which becomes a barrier for a wide propagation of MW heating in the food industry.

Commercial applications

Although MW heating is very popular in the domestic use, there has been a slow uptake of this technology in industrial food processing.

A combination of MW and hot air has been successful in speeding the drying process, of pasta drying (Decareau, 1985) and for producing dried onions (Metaxas and Meredith, 1983). Also, MW heating is used for drying

snack foods (e.g., puffed rice cake, seaweeds), vegetables, fruits, chocolate powder, and milk cake (Chen et al., 1982).

The use of MW heating allows the reduction of baking time, making possible the use of flour with high α -amylase content and low protein content (Leadley, 2008).

MW can be used to speed up the process of meat tempering, which is currently used in France for beef, lamb, and ham.

Pasteurization and sterilization processes where MW heating is used include yogurt and pouch-packet meals and the continuous pasteurization of milk (Decareau, 1985; Rosenberg and Bögl, 1987).

Radio-frequency heating

Radio frequency (RF) operates under the same principle as that of MW heating, allowing fast and volumetric heating of the food product. Heat is generated within the product and throughout its mass simultaneously due to the frictional interactions of polar dielectric molecules disturbed by the applied AC electric field (Kinn, 1947).

RF (as well as MW) are both non-ionizing radiations because they have insufficient energy (< 10 eV) to ionize atoms. The allowed frequencies for RF heating processes are 13.56, 27.12, and 40.68 MHz (Piayesena et al., 2003).

RF heating present similar advantages to ohmic and MW when compared with conventional processing technologies that are essentially due to the generation of heat throughout the volume of the food being processed. However, RF has some specific advantages over those volumetric technologies (Rowley, 2001):

- In contrast with OH, there is no need for electrodes in direct contact with the food (as well as for MW).
- The RF longer wavelength allows a deeper penetration of the radiation (tens of centimeters) in the foods than MW energy (several centimeters), depending on the dielectric properties of foods.

- RF systems are simpler in their construction than MW systems. RF is better suited for large industrial applications, having a straightforward application to continuous processes.

RF's main disadvantages are the higher equipment and operating costs, when compared to conventional systems, and are even more expensive than OH-based processes; RF systems are significantly bigger than MW systems for equivalent power output and have slower heating rates than MW.

As in MW heating, it is difficult to achieve the validation of RF due to lack of data regarding the RF dielectric properties of foods. Being so, it is necessary to gain full understanding of parameters that affect the dielectric properties of foods, such as mass, shape, water content, chemical composition, temperature, and frequency of treatment to solve common problems such as dielectric arcing and thermal runaway heating, allowing further development of this technology (Rowley, 2001).

Commercial applications

RF dielectric heating has been used in the food industry to replace conventional heating methods in a wide range of applications (Table 3).

Infrared heating

Infrared (IR) energy is a form of electromagnetic energy. It is transmitted as a wave, which penetrates into the food and is then converted to heat by interaction with molecules of the food. Heat passes throughout the food from the surface layer by conduction. The IR spectra can be divided in three classes, depending on the wavelength: short waves (0.7–2.0 μm); medium waves (2.0–4.0 μm); and long waves (4.0 μm–1 mm). The wavelengths from medium to long waves are the most advantageous to use in industrial applications since maximum radiation absorption occurs in the range of 3–10 μm for the majority of food products.

IR heating present similar advantages to the other types of electromagnetic heating when compared with conventional processing technologies, namely:

- The heat transfers occurs instantaneously, reducing processing time and energy costs (the savings can reach 50%).

- IR energy is only absorbed at the material being heated, allowing differentiating heating in nearby zones. Furthermore, the surrounding air does not absorb IR energy, so it does not heat up.
- The equipment can be compact and very easily controlled and with low-risk operation as no by-products are produced.

IR technology use in food industry is expected to grow as the main advantage of this technology over the traditional ones is the drastic reduction of processing times (up to 70% reduction), which, in turn, increases productivity while maintaining product quality. Nevertheless, it is still necessary to increase understanding of the interactions between energy transfer and its effects on the foods organoleptic and nutritional properties; in the area of process control; and innovations on IR heating equipment.

Commercial applications

Although IR heating is widely used in nonfood industries, such as medical, dye, automobile, electronics, and paper industries, for heating and drying purposes, in the food industry, IR heating is still relatively new. Recently, interest in short-wave IR (wavelengths approximately of 1 μm) and in intermediate IR (wavelengths approximately of 10 μm) has increased, since these wavelengths allow a rapid transfer of high amounts of energy reaching working temperatures in seconds. Nevertheless, in the food industry, long-wave IR is still used more than the other IR methods because the high-load energy is more difficult to control and it can damage the food. Being so, the industrial food applications described next are using long-wave IR heating.

IR heating has been successfully used in practical applications as a substitute of conventional processes, such as baking of bread and cookies (Nakamura, 1999; Kiyohira and Yoneda, 1999), roasting of coffee and green tea (Kino, 1999; Takeo, 1999), cooking of beef patties (Sheridan and Shilton, 2002), heating of legume seeds (Oladiran et al., 2001), drying of edible seaweed, vegetables, fish products, and pasta (Kimura, 1999; Itoh, 1986; Tokunaga, 1987; Ratti and Mujumdar, 1995).

IR pasteurization is particularly effective at the surface of foods and has been successfully used for the pasteurization

Thermal Technologies in Food Processing, Table 3 Examples of RF heating applications for food processing

Process	Food products	Reference

of oysters (Kutsunai, 1988) as well as in packaged products such as sausages and boiled fish paste (Ishi, 1985).

Summary

In recent years, consumers started to demand food products with enhanced safety and quality, along with extended shelf life. The traditional thermal processing is always associated with some undesirable degradation of heat-sensitive quality attributes. This all added to research and development of novel thermal-processing technologies that could take action towards these new challenges. The novel thermal-processing technologies addressed here are: ohmic, microwave, radio frequency, inductive heating, and infrared heating.

TILLAGE, IMPACTS ON SOIL AND ENVIRONMENT

Márta Birkás

Department of Soil Management, Institute of Crop Production, Szent István University Gödöllő, Gödöllő, Hungary

Definition

Soil tillage. Preserving or improving the soil physical and biological condition in a way and to a depth suitable for the required tasks of soil protection and cropping.

Arable land use. Production of plants regarding their various biological requirements and after-effects and the relevant cropping technologies; Categories: early extensive, conventional, early intensive, integrated, modern intensive, modern extensive, and organic.

Conventional tillage. Working the entire soil surface, using conventional plow for primary tillage, creating soil conditions assumed to be favorable for plant growth by an unreasonably large number of tillage passes and with excessive time, energy, and cost input; inconsistent, if any, adaptation to soil condition and, typically, repeating ineffective tillage interventions.

Environment conserving tillage. Creating and maintaining a harmonious balance between the requirements of the environment and those of cropping, by preserving or improving the quality of the soil.

Adaptable tillage. Improving or preserving the quality of the soil in harmony with ecological, climatic, and farming requirements.

Climate risk. Defects in the soil quality condition along with likely consequences of soil disturbance.

Climate stress mitigation tillage. Alleviation of soil sensitivity by reasonably controlling the soil water transport and the carbon balance.

Introduction

European authors of past centuries used to describe the importance of tillage in terms of satisfying plant requirements, thus, the era dominated by their concepts may also be referred to as the age of *crop-focused* tillage. The over-estimating of “crop requirements” contributed to the damaging of the soil both directly and indirectly. Soil degradation and its consequences inevitably drew attention in the early seventies to the need for protecting the soil as a multi-functional environmental element. According to the principle of *soil-focused* tillage, conserved soil meets the requirements of growing crops. Since the first years when the alarming signs of climate change began to appear, there has been a growing need for adopting

a *climate-focused* approach to tillage as well, since losses caused by climate change can be alleviated by preserving and improving the quality of the soil (Birkás, 2009).

Soil and land use

Soil is the loose fertile layer of the solid crust of the Earth; it is an environmental element whose condition and quality can be changed, renewed, or degraded (Várallyay, 2008). The use of soil for agricultural purposes is considered to be reasonable if the requirements for its renewal are met. The soil special capability of renewal can be maintained by continuous treatment adapted to the local circumstances (Birkás, 2008). The primary tasks of arable land use include, within the framework of landscape and environment protection, maintaining and improving favorable soil characteristics as well as preventing undesirable changes.

Direct impacts on soil by tillage

Tillage is a groundwork type element of cropping, preceding other technological components of crop production. Tillage does not influence the soil natural characteristics (e.g., clay content, particle size distribution, acidity/alkalinity), but it does change the soil physical state both directly and indirectly. Factors of importance for cropping, which can be altered by tillage, include the looseness of the root zone, the depth of the loosened layer, the soil structure, the shape of the surface, and the surface coverage. The *root zone looseness* can be described by well-known parameters such as bulk density, pore volume, and penetration resistance (Håkansson, 1990). These parameters give a numerical indication of the soil state – as well as the favorable or unfavorable impacts of a given tillage technique – at the given point in time (Sajko et al., 2009). Plants are less sensitive to the soil looseness if the soil contains enough water and nutrients. A compact soil is not a suitable habitat for plants, and this is particularly true if compactness is coupled with insufficient water and nutrient supply or with excessive water content. In dry years, the lack of water and excessive compactness are mutually aggravating risk factors. The *depth of the loosened layer* either helps or retards the plant root development. The depth of the loosened layer brought about by primary tillage is usually the same as the depth of the soil layer suitable for taking in water and for crops to take up water. A loosened state can be preserved if subsequent tillage passes are carried out when the soil moisture content is suitable for tillage, using tools that do not create watertight compact layers in the soil. What is referred to as *agronomical structure*, that is, the relative proportions of clods (>10 mm), crumbs (0.25–10 mm), and dust (<0.25 mm) is indicative of the processes occurring in regularly tilled soil. A ratio of crumb over 75–80% crumb fraction is characteristic of a climate stress-tolerant state. The *shape and coverage* (by chopped field residues) of the *soil surface* are important indicators of the soil water retaining capacity. More water is usually lost through

a larger surface and less water is lost through a smaller surface (Birkás, 2008). Bare soil is equally exposed to heat- or rain-induced stress and to the structure deterioration. The minimum cover ratios recommended are between 40% and 50% after harvest in the summer and 20–35% after primary tillage.

Indirect impacts on soil by tillage

Changes in the soil water transport patterns (the balance between intake, storage, and loss), in its biological activity and in its organic material balance are indirect changes but they are extremely important from the aspect of the future of soils and cropping. *Water intake* is the proportion of precipitation that actually ends up in the soil, it is up to 80% in favorable cases but most often it is around 65–70%. Tillage improves the soil water intake capacity but it may just as well increase its water loss. Outside the growing season, the degree of water loss is affected by the shape of the tilled surface, by the cover of the soil surface, and the depth of disturbance. *The ratio of water released from the soil* are affected by land use, tillage (loss increasing or decreasing), and crop water consumption. Drought-induced losses cannot be prevented in soils where water-loss increasing tillage has been applied for years. A soil with a large bare surface loses the largest amount of water in the summer, in the early autumn, or in the spring. Up to 40–48 mm of water may be lost from a clay loam soil after deep plowing (0.28–0.32 m), left in clods, in two dry summer months, in contrast to the 18–24 mm of water lost from a soil tilled to a similar depth but rolled after plowing (Birkás, 2009). The loss of water from soil with a large surface is further increased by persistent warm or windy weather. Owing to the current climate change, more attention needs to be paid to the loss of water from soils plowed and left without surface leveling. Up to 40–56 mm of water may be lost from a clay loam soil left in clods, during the mild winter months, while not more than 20–26 mm of water is lost from the same soil conditions if the soil surface is flattened. The soil *biological activity* has become a focal issue, as a consequence of the current climate change. By boosting aerobic activity, too frequent inverting and excessive airing of the soil will increase the loss of humus, an indispensable soil component for structure building (Szabó, 2008). Loosening and crumb-forming tillage coupled with adequate pressing are more advantageous from a biological perspective as well, since they result in reduced aeration of the soil, which in turn, limits aerobic microbial activity. Soil *humus or carbon balance* is a function of composition and decomposition. Soils that have never been tilled are in a state of balance, but once they are broken up, decomposition will be occurred. Continuous application of humus-conserving tillage may result in a balance near the original level. Under favorable conditions, the quantity of humus produced during a year equals or may even exceed the amount decomposed over the same period. Problems begin when the amount of

humus decomposed exceeds the amount produced. In a year of average precipitation, if there are 5 t ha⁻¹ wheat straw and 2.5 t ha⁻¹ root residues in the soil (since approximately 40% of it is carbon (La Scala et al., 2006)), the expected carbon yield is approximately 3 t ha⁻¹. The whole of this quantity may be released into the atmosphere if the soil is plowed deeply without surface flattening, while only about a third of the same quantity will be lost if a carbon-conserving tillage is adopted. If the straw is fully removed, leaving only the carbon content of the roots in the soil, carbon-conserving tillage will result in a smaller loss of carbon (0.6–1.2 t ha⁻¹) while a carbon-wasting tillage will lead to a greater loss (3.0–3.5 t ha⁻¹). Concern is raised by the cyclical carbon loss where plowing in the summer is the usual practice. Moreover, the soil state resulting in carbon loss is exactly the same soil state that induces water loss. While the water absorbing capacity of humus colloids is as great as that of clay minerals, so humus improves the water retaining capacity. From the aspect of their impacts on CO₂, flux tillage interventions qualify as preserving, balance keeping, or waste increasing techniques. *Earthworm activity* is a good soil condition indicator. Compacted, bare, or over disturbed soils make poor habitats for earthworms. Earthworm-friendly tillage has a loosening and crumb-forming impact, creating a small soil surface, with adequate (35–45%) mulch cover. Soil moisture content ensuring favorable workability is also good for earthworms.

Tillage impact to the environment

The quality of the soil affects the landscape and the quality of the environment. Therefore, one crucial requirement to be met by tillage is that neither the process, nor the soil state created over a shorter or a longer period should be detrimental. This expectation is a result of a multitude of tillage-induced soil defects caused by conventional tillage systems.

Tillage defects qualifying as environmental damage and their consequences

Multiple tillage traffics and excessive disturbance boost CO₂ emission and increase the loss of organic material (Chatterjee and Lal, 2009). The fuel consumption of multiple tillage passes is an indirect environment pollution factor. Diminishing organic materials in frequently and intensively disturbed soils undermines the soil bearing capacity and workability and it leads to growing exposure to the risk of compaction and pulverization (Lal, 2007). A deteriorated soil structure is more exposed to water and wind erosion, water causes silting in such soils while when they dry out crusting and capping appears. Tillage to the same depth year after year leads to detrimental compaction in the root zone (Birkás et al., 2009). Compacted state reduces water intake and transport in the soil and the water, accumulating above the compact layers inducing airless condition. Field residues are often inverted or burnt instead of being used for soil surface protection.

Conventional tillage

More than 3 decades of increasingly intensive criticism of conventional tillage inevitably raises the question of how, despite the detrimental impacts, this could remain one of the predominant prerequisites for crop production. The power required for conventional tillage and the clearly visible effects on the soil (inverting, clean surface), as well as the sentiments relating to the *plow* must have played a dominant role in this. Despite its large time, energy, and labor requirement, conventional tillage remained more attractive (Table 1) than the risks possibly entailed by a new method that should have had to be learned. These views were changed both by increasing fuel prices and by the recognition of the deterioration of soil condition.

Water, carbon, and structure conserving tillage

Distinguishing between tillage trends (conventional, reduced, soil conserving, etc.) and endeavors (energy saving, sustaining, etc.) has been enabled – in even a clearly defined way during the past 4 decades – by two crucial factors: (1) though much soil disturbance conventional crop-focused tillage leads to soil and environment threat and to reduced output, (2) crop needs concerning soil condition have proven to be possible to meet even without the conventional methods, with reduced inputs. The deterioration of the environmental conditions is forced to adopt techniques preventing and alleviating damage, that is, to use adaptable tillage.

Recommendations for soil and environmentally sound tillage

Tillage may cause soil defects, but proper techniques are also available for remedying damage so caused. Preserving soil quality requires avoiding techniques causing defects, along with applying remedial procedures (Birkás, 2008). Special recommendations have been worked out for the Central European region, in view of its particular climate. Because of the danger of moisture and carbon loss and because of the climate risk, the

depth and methods of tillage interventions in the summer will have to be changed. Conserving moisture and soil quality calls for shallow stubble treatment, and mulching the soil surface. Since the lack of knowledge of the soil state leads to wrong decisions, there is a need for regular soil state assessments. Recognition of soil defects helps choosing the most suitable techniques and avoiding losses. Adequate (35–45%) cover of disturbed soils protects soils against heat and rain stress in the summer, against desiccation, and the diminishing of biological life. The covering material is utilized as organic material, mixed into the soil after the passage of the critical months. Smaller soil surface – through which water is lost – must be created in all seasons, but most importantly in the summer months. Milder autumn and winter weather conditions call for extending the use of water conservation to primary tillage minimizing the surface for evaporation. Soil in clods in the surface is not favorable for weathering in the winter months without snow cover. Exceptions to this include too wet soils in the seasons, where the damage would be aggravated by secondary tillage. If the soil is suitable for traffic, however, the evaporative surface must be reduced. In the summer and in the spring soil surface evening and pressing, while before wintering, surface levelling is the preferred method following primary tillage (or soil disturbance). Compact layers blocking water intake and the seeping of water down into the root zone must be broken up, restoring thereby the soil harmonious water transports. The use of tools forming tillage pan should be avoided in wet soil, regardless of the tillage type. This requires knowledge of the water content range ensuring optimum workability of the soil. Crumb forming requires a favorable carbon balance, adequate moisture, and earthworm activity in the soil. The soil organic material content must be protected, since it is indispensable for retaining water, for keeping the soil workable, for resisting compaction, and for mitigating climate risk. Field residues should not be removed (e.g., for generating energy)

Tillage, Impacts on Soil and Environment, Table 1 Main characteristics of conventional and environmentally sound tillage

Factor	Conventional	Environmentally sound
Purpose of tillage	Meeting plant requirements	Soil quality conserving or improving
Depth	Excesses (deep or shallow)	Depending on soil condition
Mode	Inverting	Plowless
Surface	Free of residues	Covered to various degrees
Field residues	Something impeding tillage	Valuable material
Organic material	Diminishing	Preserving
Carbon balance	Input in soil < loss	Input in soil > loss
Tillage tool	Subordinated to tillage concept	Adapted to soil condition
Energy input	Excessive	Realistic
Adaptability to soil	Limited	Wide
Risks	Soil quality deterioration	Weeds, pests, pathogens
Impact on soil	Varying	Protection, renewal
Impact on plants	Sometimes positive	Positive
Long-term impacts	Increasing climate-induced sensitiveness	Alleviating climate-induced threats

where there is no other way for recycling organic materials. Soils that still have optimum levels of organic material should be taken care of just as much as those of low organic material contents.

Summary

Creating soil conditions best suiting crop requirements used to be considered as the most important goal of tillage for centuries. This type of crop-focused tillage is largely to be blamed for the degradation of soils. The old approach has necessarily been replaced by a soil-focused tillage approach to improve damaged soils and to preserve soil quality. Tillage can have peculiar effects, as it can just as easily damage the soil as it can remedy most of the damage already caused. The importance of the protection of soil quality and of alleviating tillage-induced environmental damage has been confirmed yet again, this time by the threats imposed by global climate change. Science assumes an important role and, based on soil quality research, offers a good chance for reducing climate-induced harvest losses. Soil- and environmentally sound tillage helps carrying out the tasks of climate stress alleviation by means of soil moisture, organic material, and soil structure protection.

Soil erosion by tillage

Definition

Tillage erosion. Tillage erosion refers to the net soil translocation on the hillslope due to tillage operations, expressed in units of volume, mass, or depth per unit width of tillage. The transport and resultant displacement of soil during tillage is referred to as tillage translocation.

Introduction

In agricultural practices, tillage has been used to prepare the soil for seeding, to improve soil physical properties, to enhance a rapid release of nutrients from the soil organic material, to control weeds, and the like. However, a major drawback of tillage arises when it becomes intensive and continuous, which causes soil erosion. Soil erosion is usually thought of as a natural process induced by natural driving forces such as water, wind, and gravity. Nevertheless, soil erosion is also caused by human driving forces, mainly derived from tillage in agricultural practices, independent of these natural processes. Tillage operation moves the soil mechanically in the tractive force direction, and on the hillslope this movement is enhanced by gravity during a downslope tillage operation. Soil is moved upslope during an upslope tillage operation, and likewise, a downslope soil displacement occurs during a downslope tillage operation under tractor-plow tillage. However, the distance over which the soil is displaced during the downslope tillage operation is normally greater than the displacement distance of the upslope tillage operation. In the case of animal-drawn plow and manual hoeing tillage, the soil is typically turned downslope to minimize energy requirements, and thus only downslope soil displacement occurs without upslope soil displacement. Tillage erosion redistributes soil in a landscape, and is typically characterized by soil loss from convexities (or upper slope positions) and soil accumulation in concavities (or lower slope positions) in the case of complex slopes (or linear slopes).

Although research on tillage erosion first emerged in 1929 (Aufrère, 1929), the first attempts were made to carry out a more systematic study on tillage translocation and erosion until the late 1980s and the early 1990s. During the several decades, only a few studies on tillage erosion had been conducted to specifically examine downslope soil translocation on the hillslope. Tillage erosion were quantitatively examined by Lindstrom et al. (1990, 1992) to comprehensively assess soil translocation and

erosion, showing that soil displacement from convex to concave slope positions was far from insignificant.

Measurement of tillage translocation and tillage erosion

Tillage translocation, defined as the transport and resultant displacement of soil by tillage, is normally measured with a tracer method, i.e., a volume of soil is labeled and tilled, and then changes in tracer concentrations (or weights) before and after tillage are used to calculate soil translocation (Lobb et al., 1995). The change in tracer concentrations as a result of tillage portrays soil shift during tillage, assuming that tracers moved along with soil. Several techniques including physical and chemical ones are used to trace the soil displacement by tillage. Physical tracer used in measuring tillage translocation has so far involved metal cubes (e.g., Govers et al., 1994), rock fragments (e.g., Nyssen et al., 2000) and stone chips (e.g., Zhang et al., 2004a, b), and chemical tracer radiocaesium (e.g., Lobb et al., 1995) and chloride (e.g., Lobb et al., 1999). Recently, the low-induction electromagnetic (EM) (De Alba et al., 2006) and magnetic tracer techniques (Zhang et al., 2009) are also used to measure soil displacement, which are characterized by a simple and quick manipulation.

For up- and downslope tillage, which is common in mechanized agriculture areas, tillage is conducted by successive passes in opposing directions. The soil flux due to tillage is expressed as:

$$Q_s = kS \quad (1)$$

In non-mechanized agriculture areas, tillage is typically conducted downslope. The soil flux due to tillage is expressed as:

$$Q_s = k_3 + k_4 S \quad (2)$$

where k , k_3 , and k_4 are soil transport coefficients (kg m^{-1} tillage pass $^{-1}$), and S the slope gradient (m m^{-1}).

The above empirical equations indicate that tillage erosion is mostly affected by slope gradient under controlled tillage implements. However, other studies also indicate that additional factors including soil conditions (e.g., soil bulk density, soil moisture) and tillage operations (e.g., tillage depth, speed) would be associated with tillage erosion rates (Lobb et al., 1999; Van Muysen et al., 1999).

Tillage transport coefficient in selected regions

Tillage erosion rates vary from 15 to 150 Mg ha^{-1} year $^{-1}$ depending on tillage implements and landforms in different parts of the world. In Europe, tillage erosion has been considered as the dominant process of soil redistribution in the landscape (Quine and Zhang, 2002). In shoulder slope landscape positions, tillage erosion was estimated to account for at least 70% of total soil erosion in southwestern Ontario, Canada (Lobb et al., 1995). High ratios of tillage erosion to water erosion have also been found on sloping terraces of hilly areas, southwestern China,

with tillage erosion accounting for about 70–80% of total soil losses from water and tillage erosion (Zhang et al., 2006, 2010). The tillage transport coefficient is an important indicator reflecting tillage erosion intensity, as it clearly indicates the process causing the soil transport. In mechanized agriculture areas, the tillage transport coefficient k ranges from 111 to 330 kg m^{-1} tillage pass $^{-1}$, and varies between 68 and 108 kg m^{-1} tillage pass $^{-1}$ in some parts of non-mechanized agriculture areas. In the other part of non-mechanized agriculture areas, tillage transport coefficients k_3 , k_4 are 31–89, 108–243 kg m^{-1} tillage pass $^{-1}$, respectively (Table 1). Under animal-drawn plow and manual hoeing tillage, farmers are accustomed to till downslope on the slope with downslope turning and/or pulling on every occasion, which is different from the mechanized tillage in which the soil is turned in opposing directions on successive occasions. As a result, there are still great tillage transport coefficients to be found in non-mechanized agriculture areas.

Tillage erosion versus water and wind erosion

Tillage erosion largely causes soil loss in shoulder slope or downslope sides of the field boundary, while water erosion usually occurs in middle to lower back-slope positions. Typically, tillage erosion is most severe in areas (in convex slope positions and downslope sides of the field boundary) where water erosion is weakest, whereas soil accumulation by tillage is present in areas (in depression positions) where water erosion is most intense, thereby showing that there are different patterns of water erosion and tillage erosion along the transect of the slope. Unlike water erosion that transports the soil off the field and over a long distance, tillage erosion moves the soil within the field and over a short distance in the course of each event. As a result, soil deposition by tillage occurs towards the downslope boundary of the field, resulting in an approximate balance between soil loss and gain within the field. Among landform factors, slope gradients and slope lengths are the two important factors controlling rates of both tillage erosion and water erosion. However, the tillage erosion rate is negatively proportional to slope length in contrast to the water erosion rate, while both are of similar effects with respect to slope gradients, i.e., the erosion rate increases with increasing slope gradient.

Soil loss by tillage occurs in surface soils, thereby impacting soil erodibility to water and wind erosion, as the removed topsoil has more organic matter, and thus more stable soil structure than subsoils. The process of tillage erosion may create an accelerating mechanism of soil erosion, i.e., tillage erosion continuously delivers soil into convergent areas of overland water flow where there is the most severe water erosion, resulting in more severe soil losses, as sediments are delivered beyond the field (Lobb et al., 1995; Zhang et al., 2010). In the terrace system where water erosion is insignificant, however, soil deposition by tillage is evident at lower parts of the terraces, as individual terraces represent a closed system in which

Tillage Erosion, Table 1 Tillage transport coefficients in mechanized and non-mechanized agriculture areas

major changes in soil redistribution occurs close to upslope and downslope boundaries of the field (Zhang et al., 2008).

Soil profile modification by tillage erosion

As has been stated, tillage causes soil loss in upper slope positions. In middle slope positions, the soil in the till layer is only transported downslope and the removed soil was replaced by the soil from upslope, and therefore the depth of soil profiles was not changed by tillage. Tillage operation mostly plays a transport role, creating zero soil loss and gain in middle slope positions, where the downslope transport of the till layer is similar to a conveyor belt from top to bottom of the slope (De Alba et al., 2004). In the toe-slope positions, tillage mixes the soil of the till layer in the short-term and the original soil profile becomes buried under the accumulated materials from upslope soils in the long term. Progressive effects of the long-term tillage create truncated soil profiles in convex (or upper) slope positions, and deep topsoil accumulations in concave (or lower) slope positions with inverted soil profiles, where subsurface soil material is deposited over original surface horizons (De Alba et al., 2004). The long-term tillage deletes surface soils in convex (or upper) slope positions due to no soil replacement from upslope, leaving subsoils, parent materials, or bedrocks exposed. In North America and Europe, farmers have to till into the subsoil, and therefore materials from subsoils are incorporated into the till layer. In order to offset such soil losses at the proximity of the upslope boundary in Asia, the farmers need to till into parent materials or bedrocks that are soft enough to be crushed by hoes or plows to obtain a replacement (e.g., in the case of Regosols derived from mudstone of Jurassic Age), which remains a certain thickness of the soil layer (generally <20 cm deep). In practice, although the exposure of bedrocks is not widespread, the thin soil layer with a high content of gravel and coarse texture is always found at the summit positions,

as a result of the incorporation of parent materials or mudstone fragments into the cultivated soil layer. In most cases, at the summit of the slope, the depth of soil profiles is generally so small that only the cultivated layer could appear due to soil erosion by tillage (Zhang et al., 2004b). This situation is different from that of the soil profile with multi-genetic horizons (e.g., Ap, AB, B), in which an original subsurface horizon becomes directly exposed at the surface and constitutes a new till layer (De Alba et al., 2004).

Control of tillage erosion

Conversions of conventional tillage to conservation tillage can diminish tillage erosion rates to a great extent. Contour tillage is a common technique and one of the most effective ones to control soil loss by tillage. In southeast Spain, by using a duckfoot chisel, contour tillage reduces soil translocation by 51% (tillage transport coefficient decreased to 139 from 282 kg m^{-1} tillage pass $^{-1}$), compared to conventional up- and downslope tillage (Poesen et al., 1997). Tillage-induced soil loss was also found to be reduced by approximately 70% using contour ridge tillage compared to moldboard plowing up- and downslope on steep lands in Claveria, Philippines (Thapa et al., 1999). A similar reduction (77%) was found in the Sichuan Basin, China, when contour tillage was performed by hoeing in comparison to downslope tillage (Zhang et al., 2004a). In some specific situations, a significant effect of reducing tillage erosion rates has been gained by “the non-overturning tillage,” in which tillage erosion rates can be decreased by 63% compared to those by conventional tillage (i.e., turning soil and pulling it downslope) (Zhang et al., 2009).

Conclusion

Tillage erosion is a gradual soil translocation downslope induced by tillage operations in agricultural landscapes. Several techniques including physical and chemical ones

can be used to trace the soil displacement, and therefore measuring tillage erosion rates. Among those techniques, the low-induction electromagnetic (EM) and magnetic tracer techniques are considered to be characterized by a simple and quick manipulation. Tillage erosion is far from negligible in agricultural ecosystems and is the dominant process of soil redistribution in most agricultural landscapes. The process of tillage erosion may create an accelerating mechanism of soil erosion by water, resulting in more severe soil losses. Tillage erosion rates in non-mechanized agriculture areas may be comparable to those in mechanized agriculture areas, as a result of much steeper slope of the former, despite smaller tillage transport coefficients with the former. As a whole, tillage erosion rates are equivalent to or even surpass water erosion rates, irrespective of agriculture area types. Consequently, tillage erosion is an important process of soil degradation on sloping cultivated land. However, such a degraded process can be reduced significantly by adopting conservation tillage methods, some of which are common to farmers in different parts of the world, e.g., contour tillage.

TILLAGE PAN

An induced soil pan which has a higher bulk density and a lower total porosity than the soil directly above or below it and is produced as a result of pressure applied by normal tillage operations or by other artificial means.

TILTH

See *Soil Tilth: What Every Farmer Understands but no Researcher Can Define*

TOP SOIL

The upper part of the solum, essentially the part affected directly by plowing (the plow-layer), synonymous with the A horizon.

TOPOSEQUENCE

A sequence of related soils that differ, one from the other because of topography as a soil-formation factor.

TRACE ELEMENTS IN CROPS: EFFECTS OF SOIL PHYSICAL AND CHEMICAL PROPERTIES

Holger Kirchmann, Jan Eriksson

Department of Soil and Environment, Swedish University of Agricultural Sciences, Uppsala, Sweden

Definitions

Elements present in crops at concentrations of milligrams per kilogram dry matter are defined as *trace elements* (Kabata-Pendias, 2001). A large number of trace elements are found in crops including rare earth metals (Gundersen et al., 2000). The trace elements boron, iron, copper, manganese, molybdenum, nickel, and zinc are essential for crops and are therefore often named *micronutrients*. Selenium has recently been also pointed out to be an essential micronutrient (Hartikainen, 2005). Some trace elements not required by crops are, however, essential for humans and animals, that is, fluoride, iodine, chromium, cobalt, and selenium. The term “heavy metal” refers to elements with a density higher than 4.5 kg dm^{-3} , but provides no information on the toxicity and effect of metals on organisms (Niebor and Richardson, 1980). Knowledge about the functions of *rare earth* metals in crops is scarce, some may be essential, others toxic or without any effect (Markert, 1993).

Soil properties

A number of different factors determine trace element concentrations in crops such as (1) soil properties; (2) addition of trace elements with fertilizers or manures; (3) atmospheric deposition; (4) crop variety; (5) weather conditions; and (6) developmental stage of the crop. Among soil-related factors, physical, chemical, and biological soil ones like soil structure, bulk density (pore

volume), water content, texture, redox conditions, soil pH, soil organic matter content, nutrient content, and microorganism activity are of importance. These factors interact often in a rather complicated manner and some have a direct effect on plant uptake of trace elements, while others have a more indirect effect. For example, texture and organic matter content determine soil structure. A well-structured soil with a low bulk density allows crops to develop large root systems resulting in accessibility to nutrients and trace elements in large soil volume. Soil pH, on the other hand, has a direct effect on uptake since it strongly influences trace metal solubility. Below, some important soil factors are discussed more in detail.

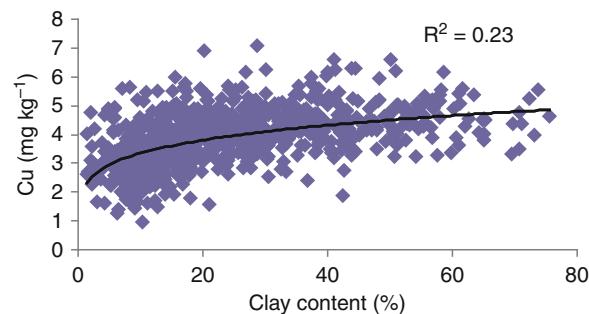

Soil texture

In general, soils with naturally high concentrations of trace elements also produce crops rich in trace metals. Many trace metals are bound to clay particles and consequently clay soils contain more trace metals than lighter soils. Eriksson et al. (2000) showed that there is a strong positive correlation between clay contents in soil and total concentrations of trace elements in soil (R^2 -values: Cr = 0.87; V = 0.83; Ni = 0.80; Co = 0.79; Cu = 0.73; Zn = 0.71). Also, concentrations of boron, manganese, molybdenum, and selenium in soil are correlated with soil clay contents, but weaker. This induces a positive correlation between clay content and trace metals in crops. For V, Ni, Co, and Cu, R^2 values range from 0.15 to 0.5. How the copper concentration in cereal crop increases with clay content in soil is illustrated in Figure 1. The data are from a large number of Swedish arable soils with varying clay content.

Redox conditions

The micronutrient manganese, taken up by crops in reduced form as a divalent ion, is rather easily reduced in soil. Thus, reducing microenvironments in soil are very important for Mn availability. Such conditions are most common in heavy soils, where small pores inside peds are temporally water-filled also when the soil on the whole is well aerated.

However, under strong reducing conditions (complete waterlogging for a period of time) root uptake of nutrients

Trace Elements in Crops: Effects of Soil Physical and Chemical Properties, Figure 1 Relation between copper concentration in cereal crops and clay content in soil.

may be inhibited for most crops, while, for example, a crop like paddy rice is adapted to high tissue concentrations of manganese. In addition, several trace metals may form sulfides (CuS , MoS , ZnS) under such conditions, which means very low or no crop availability.

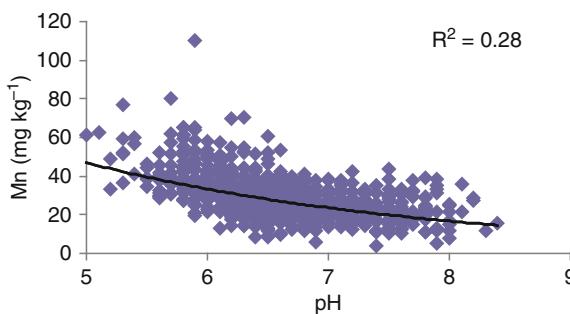

Soil pH

It is well-known that soil pH has a major influence on the solubility of trace metals. Changes in soil pH are followed by changes of the electrical charge on soil particles. At lower soil pH values, hydrogen ions are adsorbed that increase the positive charge on both inorganic and organic soil components resulting in weaker adsorption of positively charged ions. Thereby, cations such as manganese, zinc, iron, boron, and copper become more plant available. On the other hand, higher pH values in soil result in higher negative charge and anions including molybdate are repelled and become more soluble (Lindsay, 1974; Fageria et al., 2002).

Consequently, trace metal concentrations in crops are highly affected by changes in soil pH values (e.g., Öborn et al., 1995; Kirchmann and Eskilsson, 2010). Data in Figure 2 illustrate how manganese concentrations in cereals significantly decline at higher pH values in soil. The large variation in Mn concentration at all pH-levels illustrates that many other factors than pH influence trace metal uptake. The influence of redox conditions on manganese is mentioned above. In fact, manganese deficiency is most common on sandy soils high in pH. In addition, in acid arable soils, mycorrhiza can function as a supplier of copper, zinc, and nickel to crops (Clark and Zeto, 2000).

Soil organic matter and dissolved organic matter

According to a data set from Swedish arable soils (Eriksson et al., 2000), the organic matter content in soil is only weakly correlated with trace element concentrations in crops. For some metals, manganese, copper, cobalt, and zinc, correlations exist but for other metals there is no positive relationship. Selenium, for example, is selectively bound to soil organic matter and concentrations in crops actually decrease with higher soil organic matter content (Johnsson, 1992). Copper deficiency in

Trace Elements in Crops: Effects of Soil Physical and Chemical Properties, Figure 2 Relation between manganese concentration in cereal crops and pH values in soil.

crops grown on peat soils is another example of the insufficient supply of trace metals by soil organic matter.

However, dissolved organic matter can increase trace elements availability due to its capability to form complexes with metals. Functional groups (e.g., $-\text{COOH}$; $-\text{OH}$) of dissolved organic matter bind metal ions electrostatically or covalently. If the ion is bound by five or six functional groups, a chelate complex of high stability is formed. Chelated trace metals are efficiently taken up by crops (Chen et al., 2001). At higher soil pH, the role of dissolved organic matter as carrier molecules for trace metals becomes very important as their negative charge increase and thus the binding of cationic trace metals.

Outlook

Between 1974 and 1982, a total of 3,538 arable soils from 30 countries were analyzed for micronutrient levels by the Food and Agriculture Organization (FAO), (Sillanpää, 1982). In 10% of the soils of each country, micronutrient deficiency was found. In global assessments, it has been estimated that ca 1 billion people are affected by deficiency of iron, iodine, and zinc caused by too low intake. The basis for this, as pointed out many times, is a too low content of essential trace elements in soil leading to low levels in crops and thereby an insufficient supply of humans (e.g., Sanchez and Swaminathan, 2005). Nutrient deficiency in soils of the world is a major task to be overcome and requires our whole-hearted efforts.

Definition

Trafficability and *workability* are soil capabilities supporting operations of agricultural machinery. Trafficability is a soil capability supporting agricultural traffic without degrading soils and ecosystems. Workability is a soil capability supporting tillage.

Introduction

Agriculture is associated with mechanical impacts on soils to provide optimum conditions for all processes relevant to plant production. Processes like tillage, seeding, fertilization or harvesting are highly mechanized and require agricultural traffic. Soils have to support those operations, but the soil status may include periods that are unsuitable for agricultural traffic and tillage. Agriculture is climate and weather dependent. Due to basic soil properties, climatic and weather conditions and land use and management, the status of soils varies both temporally and spatially. Main limitations both of the mobility function of tractors and the risk of soil compaction are due to excessive soil water content. The term trafficability refers largely to soil moisture conditions providing or restricting field traffic by machinery. Trafficability is a significant factor in carrying out farm field operations, especially after rainfall events when poor trafficability can cause delays in planting, cultivating, harvesting, and transporting of field crops (Kornecki and Fouss, 2001). But also in forests and on grassland, trafficability of soils is a necessary operation. Besides this, some common traffic and transport is off-road in rural areas worldwide.

Workability refers to soil tillage and is most relevant to agroecosystems. In cropping agriculture, a soil structure of the main rooting zone has to be provided by primary tillage like plowing or cultivating. Operational parameters depend on soil status, specific requirements of crops and the kind of general tillage purpose to be produced by special tillage implements. The desired result will only be achieved if the soil has an appropriate workability. Tillage has many advantages in producing a desirable soil structure, but may be harmful also. Intensive tillage, plowing in particular, decreases soil stability, eliminates organic mulch from the soil surface and diminishes humus content at the soil surface and can cause greater surface crusting and erosion (Kay and Munkholm, 2004). If the diagnosis of the soil reveals a need for tillage, the soil's workability becomes relevant. Main possible limitations are due to too wet or too dry soil conditions. Important questions associated with workability are: (a) Which ranges of soil moisture in terms of water content and water potential are suitable for workability? (b) What is the probability that soil moisture states for optimum workability will be reached?

Ignoring the rules of trafficability and workability may lead to soil compaction, a threat to many ecosystems worldwide. Compaction is a kind of physical degradation of soils which has negative impact on almost all soil functions.

Interactions of soils with vehicles and tillage implements

The definition of trafficability and workability as soil capabilities is a simplification of more complex operational processes. In the case of field traffic, wheels or tracks interact with soils. The Association of German Engineers (VDI, 2007) defines trafficability as a property of the soil/chassis system, which is determined by physical parameters of the

soil, by biological and ecological parameters, as well as by technical parameters (wheel load, slip, and contact area of the chassis, etc.). This definition of trafficability as an interacting process between a particular vehicle and terrain is in accordance with others both in civil and military engineering. Depending on the discipline, this definition refers to the question of whether the status of soil will provide the mobility function of a particular vehicle. This holds for civil and military engineering. Additional to the mobility function, in agriculture including forestry, grassland and range-land management, damage to the ecosystem must be avoided.

Workability is concerned with soil-implement interactions. At tillage, plastic deformation of the soil has to be avoided as it leads to smearing and clodding of soil. Depending on the purpose of tillage, for example, basic tillage, seedbed preparation or crop management by hoeing, tillage implements have been optimized and work at different depths (Koolen and Kuipers, 1983). Thus, both the requirements of different tillage procedures to the soil moisture status may be different, and the requirements of tillage and associated field traffic to the field moisture status as well.

Soil criteria and measurement methods of trafficability and workability

Soil properties and states affect both the mobility function of vehicles, for example, the drawbar pull of a tractor, and the resistance against soil structural damage. Important factors are soil strength (Terzaghi et al., 1996), affecting the bearing capacity of soils, traction parameters of vehicles, and the energy required for tillage. Soil strength is largely influenced by soil water content and density and thus varies with climate, weather, soil hydrologic conditions, and status of pre-compaction. Common physically based soil measurement methods of the soil strength are shear resistance measured by vane shear testers (Kezdi, 1969), penetrometer resistance (Campbell and O'Sullivan, 1991) measured by soil penetrating cones, cone pressure resistance (Müller et al., 1990) measured by the sinking depth of a cone or drop-cone penetration (Campbell, 1976), precompression stress (P_c) determined as the transition of elastic to plastic deformation if plotted as a semi-logarithmic stress-settlement (Horn and Fleige, 2009). Also, plate sinking depth is a common measure of strength and bearing capacity (Kezdi, 1969). Penetrometer measurements are very often used in field studies because of their fast and simple handling and reliability to detect heterogeneities in soil strength (Usowicz and Lipiec, 2009). Results of those measurements can be expressed as units of pressure, for example, in MPa at a given soil depth.

The soil status directly at the surface is particularly sensitive to weather and external forces. Factors like a too wet soil surface leads to stickiness and slipperiness, which may seriously diminish both the mobility of vehicles on wet cohesive soil and the quality of the soil structure by remolding.

Soil engineering properties related to trafficability and workability

Indices based on soil engineering properties describe the behavior of soil in dependence on water content. They are a basis of planning in civil and underground engineering worldwide and may also be used to calculate trafficability and workability states.

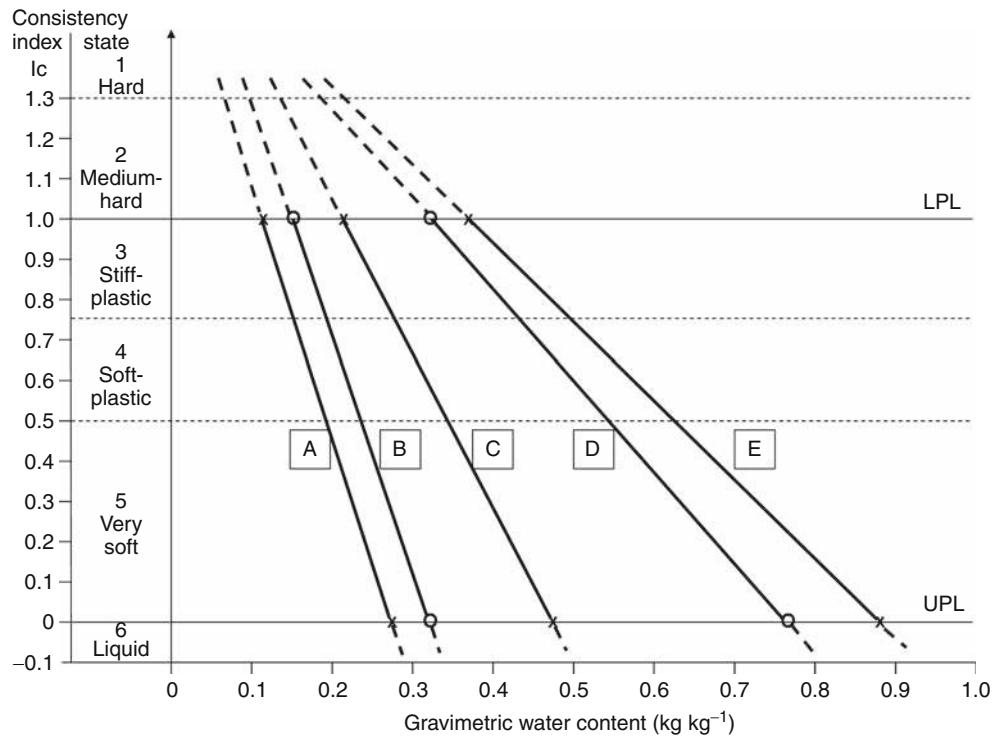

The Atterberg consistency diagram is suited to describe the moisture-dependent soil strength behavior in a simple manner. It is based on the upper plastic limit (UPL) and the lower plastic limit (LPL) (Kretschmer, 1996). The consistency index I_c is a crucial measure of relative soil strength.

$$I_c = (UPL - w)(UPL - LPL)^{-1}$$

(Kretschmer, 1996) where w is the actual soil water content, I_c is dimensionless, UPL, LPL and w are given in kilogram water per kilogram dry soil. A consistency index of $I_c = 0.75$ is an acknowledged arbitrary limit of workability. Figure 1 shows a consistency diagram for some soils of different texture. It demonstrates that soils of lower clay content change their mechanical behavior more rapidly with alterations in water content. The arbitrary workability limit ($I_c = 0.75$) ranges from about 0.16 kg kg^{-1} to 0.50 kg kg^{-1} over the range of soils indicated in Figure 1. A field assessment of consistency states and indices can be provided by Table 1.

In other studies, the soil water content corresponding to the Atterberg lower plastic limit (LPL) has often been used as an arbitrary threshold of workability (Thomasson, 1982). This limit is considered as a water content at which soil can be worked without causing structural damage (Tisdall and Adem, 1986). Arvidsson et al. (2004) found tillage at a water content close to the plastic limit produced the largest proportion of small aggregates. An advantage of the consistency concept is that it is suitable for field assessment (Mueller et al., 2003). However, it cannot be applied for non-cohesive soils which are either not plastic or highly compacted (Dexter and Bird, 2001).

Another important soil engineering procedure is the Proctor compaction test (Kezdi, 1969), which characterizes alterations in soil density with water content using a standardized energy input and compaction procedure. The maximum bulk density of the soil and the water content at this maximum are the most important parameters of this test. The water content indicates the moisture status for maximum compaction at a defined energy impact and has, like the plasticity limits, a crucial meaning in civil engineering (Terzaghi et al., 1996). Atterberg limits maximum dry bulk densities estimated by Proctor's test and the corresponding water contents belong to soil engineering properties. Those indices based on soil engineering properties can be used to define trafficability and workability criteria. Parallel measurements of field soil strength confirmed the suitability of consistency indices, to conclude on trafficability and workability of soil (Müller et al., 1997). Databases and pedotransfer functions for

Trafficability and Workability of Soils, Figure 1 Consistency diagram based on lower plastic limit (LPL) and upper plastic limit (UPL) including ranges of five typical topsoil substrates in north-eastern Germany (A, B: Glacial till, clay contents 15% and 20%; C: Holocene, clay content 30%, drained; D, E Holocene, clay contents 40% and 50%, wetland.) Field characteristics of consistency states are given in Table 1.

Trafficability and Workability of Soils, Table 1 Field assessment of consistency states for cohesive substrates

Consistency state	I_c	Field diagnosis
1. Hard	>1.3	Very dry, light, hard, brittle, no clods formable
2. Medium hard	1–1.3	Dry, not rollable to 3-mm-diameter thread, fissuring, and crumbling, weakly stable clod can be formed
3. Stiff plastic	0.75–1	Moist, rollable into 3-mm-diameter thread without crumbling, nonsticky
4. Soft plastic	0.5–0.75	Wet, easily deformable, rollable into 3-mm-diameter thread without crumbling, sticky
5. Very soft	0–0.5	Very wet and sticky, not rollable
6. Liquid	<0	Extremely wet, muddy, sliding out of the hand

the calculation of soil engineering properties from texture and organic carbon content exist (Mueller et al., 2003).

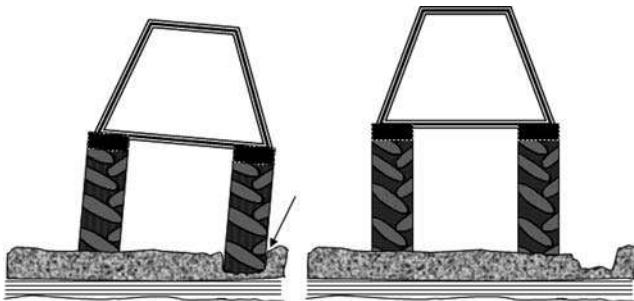

Matric potential and water retention curve defining trafficability and workability

For modeling purposes, suitable soil states for tillage and associated field traffic can be assessed by knowing the matric potential (suction) and the water retention curve of soil. This curve describes the relationship between suction and soil moisture content. Suction shall have positive defined values in this paper, and pF values are decadic logarithms of suction in hPa. Important fixed points on these curves relevant to trafficability and workability, are water contents at field capacity (FC) or at a defined equivalent of FC, mainly at suctions between 5 kPa (pF 1.7) and 30 kPa (pF 2.5), and the water content at the inflection point (Dexter and Bird, 2001).

Recommended suction thresholds of soils for trafficability and workability range from about 6 kPa in the upper 15 cm (Paul and de Vries, 1979) to 10 kPa in the upper 20 cm (Wösten and Bouma, 1985). This can be checked in the field by measurements using tensiometers (Earl, 1996). Those suction thresholds are arbitrary criteria of trafficability and workability and only rough estimates of acceptable conditions for field working operations. They do not consider real distribution of strains in the soil and possible compaction profiles during trafficking.

Discrepancies between trafficability and workability

In mechanized agriculture, soil tillage requires the use of tractors and thus field traffic. What trafficability and workability have in common is that both processes are combined in the case of tillage and that the desirable soil

Trafficability and Workability of Soils, Figure 2 Offland-plowing, i.e., running tractor wheels in the plow furrow (left) is responsible for serious subsoil compaction. It has to be banned from agricultural practice. If any plowing will be necessary, it should be done as onland plowing (right).

status is largely soil moisture dependent. During very wet conditions, both are limited, but if the soil gets drier, optimum soil states for both trafficability and workability do not coincide. Another main reason for conflicting decisions is the different soil depth of impact. During early spring periods the soil surface may be workable for seedbed preparation, but at the same time the subsoil may be too wet to bear traffic (Lipiec and Simota, 1994). Such situations may enhance vulnerability of soil to compaction.

In contrast, during or after harvest, too dry soil states or high soil densities may limit workability but provide best trafficability of most soils. At a given level soil surface, the higher the soil strength, the better the bearing capacity and the mobility function of vehicles. Also, a high tractor weight increases the drawbar pull. This may be conflicting with ecological soil functions like aeration and rooting ability, if thresholds of soil dry bulk density (Håkansson and Lipiec, 2000) or air capacities will be exceeded.

The discrepancy between trafficability and workability is most clearly demonstrated by the fact that optimum water content for workability is at maximum of the Proctor compaction curve (Wagner et al., 1992). This is the water content, at which soil is prone to be extremely highly compressed. In conclusion, soil tillage is responsible for soil compaction problems if the compaction impact exceeds the pre-compaction status at a depth deeper than the effective working depth of the following tillage implement. This extremely bad condition may often occur at “offland plowing,” i.e., the tractor tire runs in the furrow of the plow (Figure 2). Keller et al. (2002) revealed this by measuring the deep compaction effect, and Chamen et al. (2003) found this procedure most responsible for subsoil compaction in Europe. In conclusion, defining criteria for and assessing trafficability and workability, the first mentioned one is the decisive and more critical process (Botta et al., 2009).

Wheel ruts as a criterion of trafficability

Unsuitable soil structure features (see *Soil Structure, Visual Assessment*) indicate damage of the soil structure

by compaction or other over-consolidation. In the field, wheel rut depths are site-specific proper measures of the damage to soil structure (Lebert et al., 2003). Wheel rut depths of 5 cm or deeper on cropland (Müller et al., 1990), or deeper than 10 cm on peat grassland (Schmidt and Rohde, 1986), indicate exceedance of trafficability limits. Values on cropland refer to consolidated soil, not to freshly plowed soil, which is over-loosened. In soils under forest, Wronski et al. (1990) reported on acceptable rut depths of 15 cm. Lüscher et al. (2009) found rut depths more than 10 cm indicate clear compaction damage in forests.

Increased soil compactness may result in improved trafficability due to greater mechanical stability (higher densities and strengths) of soil as assessed by pre-compression stress (Horn et al., 1994). Sommer and Petelkau (1990) proposed conservation tillage, which is characterized by a higher top-soil pre-consolidation status, to improve trafficability. Botta et al. (2009) found that field traffic both in conventional tillage and direct sowing caused both topsoil and subsoil compaction. Higher pre-compacted soils have a potential for better trafficability only if the soil drainage is not hampered. However, as compaction may diminish infiltration and hydraulic conductivity (Gebhardt et al., 2009), stagnant water at the soil surface or perched water tables may appear. This is an indicator of a degree of soil compaction that does both exceed ecological thresholds (air capacities for plant growth) and the field’s capability to bear traffic or to suggest tillage operations. Stagnant water in wheel ruts over some days indicates that soil has been trafficked though trafficability was not given. Those wheel tracks are preferential flow paths for water and sediment transport and may initiate fast runoff and erosion (Basher and Ross, 2001). Roth et al. (1999) showed that the variability of soil hydraulic properties can be increased by field traffic and tillage, since wheel tracks in particular can influence local soil water balances.

Wheel ruts are indicators of ex-post assessments, for example, may indicate a damage that has occurred. Modeling (Hambleton and Drescher, 2009) or direct measurement of wheel rut depth can be used as preventive strategies to avoid damaging soil structure.

Off-road traffic and ecosystems

Outside of agriculture, the problem of trafficability is often less complex as the mobility of vehicles has priority. Studies in nonagricultural disciplines as military and civil engineering focus on having a terrain providing safe and rapid movement of vehicles. A most relevant topic of trafficability in engineering disciplines is developing and optimizing terrain mobility of cars and other vehicles including construction of planetary vehicles (Li et al., 2010). However, concerns about negative impacts of off-road traffic on the status of soil and vegetation in global ecosystems are growing. In forests and on grasslands, including range-land, awareness of possible impacts of machinery on the ecosystem status is increasing (Eisenbies et al., 2007). Keeping equipment out of wet lands is the single most important practice for avoiding soil compaction.

On agricultural land, installation of effective surface and subsurface drainage can minimize soil compaction due to increased water infiltration thus allowing for a soil moisture content suitable for sustaining agricultural equipment traffic. Controlled traffic farming can mitigate soil compaction of entire fields, by permanently using the same wheel tracks. This requires that tractors and agricultural machinery have identical tire spacing to fit the required path width. Implementation of controlled traffic patterns may be possible due to utilization of GPS and auto steering systems. But this would also require fixed field shapes and working width of machinery over several years. Another important factor in reducing compaction is to keep tire inflation pressure at the recommended minimum required to support heavy loads. Also using wider tires, dual wheels, or tracks can reduce soil compaction (Cramer, 2006). Reduced tillage or no-till can also minimize compaction by reducing or eliminating trips across the field.

Clearly defined rules in terms of soil trafficability thresholds or intensity of trafficking are still missing. Common approaches of calculating compaction depth and intensity are based on the assumption of free soil drainage profiles. However, for many soils worldwide, in particular in lowlands, for layered soils or heavy soils, this assumption is not valid, and natural soil drainage profiles show higher water contents in topsoils and subsoils by impeded drainage. Alakukku (1997) found a significant relationship between axle load and depth of soil compaction. Axle loads of 30–40 Mg compacted soils down to depths of 0.8–1 m. From compaction test, it is known that the water content of maximum compaction decreases with higher energy impact (Schultze and Muhs, 1967, p. 410). This means, dry soils may experience extreme compactions with increasing energy impacts. As long as loads of machinery will increase, the process of compaction of ecosystems, agroecosystems in particular, will continue. Besides agricultural fields, deep soil compaction occurs during ground construction work like pipeline construction (Berli, 2001).

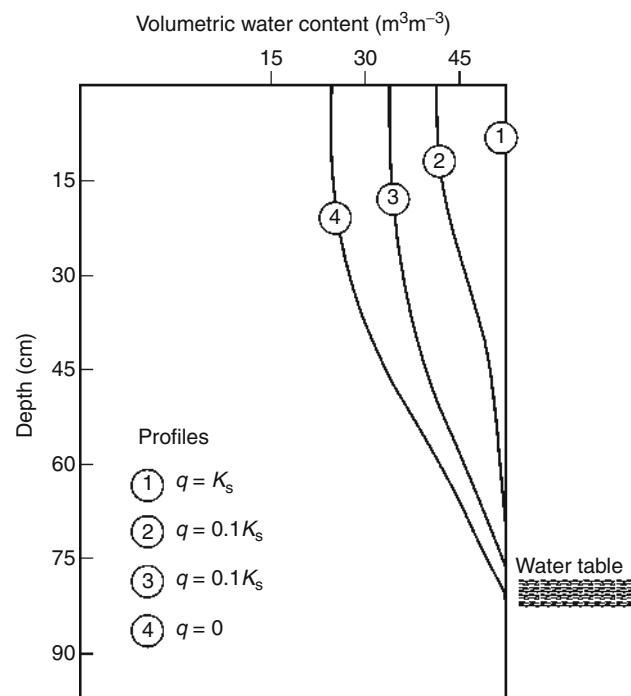

Risk assessment methods for soil compaction based on same principles like in common civil engineering, for example, containing probability and uncertainty criteria, do not exist. Environmental Impact Assessment procedures containing those criteria for very heavy vehicles would be a potential way to halt deep soil degradation through compaction.

Risk areas of trafficability

From a prevalent technical and economic point of view, soils of impeded drainage are risk areas of trafficability. Deep sinking or even tractor immobility may cause restrictions in soil management, and direct and indirect economic losses are a consequence. In very wet soils, structural damage is mainly due to soil remolding (plastic state of cohesive soils and oversaturated, quasi-plastic state of non-cohesive soils). If soils are cohesive and very

wet, they are not compactible in terms of increased density. Sometimes, remolding damage can be recovered by natural processes like alternating wetting and drying.

In boreal and temperate climates, frozen soil layers in spring may cause temporally impeded drainage and critical mechanical states on all soils. In lowland areas with shallow water tables, information on suitable water tables for providing soil trafficability in critical periods is necessary. Because the strength of the soil changes with water content, land drainage may alter the conditions for trafficability in lowlands or other soils of impeded drainage (Fausey, 2006). Figure 3 shows some possible soil moisture steady state profiles which may occur in a lowland soil in a humid climate. Profile 1 is fully saturated and drainage occurs with a maximum hydraulic gradient of 1, and the flow rate q is equal to the saturated hydraulic conductivity (K_s) of soil. Profiles 2–3 are transient hypothetical profiles, and profile 4 indicates the final drainage stage where the soil has reached a maximum drainage status. This profile is particularly important showing the minimum water content that can be achieved by gravitational drainage. The values of this curve are valid for a sandy loam. If, for example, the threshold moisture content required for workability of the particular soil is lower than the value of curve 4 at a given depth, additional evapotranspiration has to take place. Theoretically, also a very intensive and deep drawdown of the groundwater table could improve the situation slightly,

Trafficability and Workability of Soils, Figure 3 Field soil moisture profiles of a groundwater influenced soil (After Smedema, 1986).

but drainage curves of most soils (steep course of curve 4 in the upper part) show that there would be no real effect.

Several studies resulted in recommendations of water tables (see *Soil Water Management*). Kuntze and Wetjen (1984) found satisfactory trafficability with springtime water tables more than 75 cm below the surface in heavy marsh soils. Those recommendations are valid for the corresponding soil and climatic conditions but not transferrable to other regions. In a study of Müller et al. (1990), the trafficability of clay soils with shallow water table was analyzed. Alterations of trafficability and workability with time were derived from consistency and cone resistance data. The upper topsoil was trafficable if the cone resistance exceeded 0.3 MPa. At this resistance only shallow wheel sinkage (less than 4 cm) and no ponding in wheel tracks was observed.

Soft soils of high water table, peatlands, for example, are particularly sensitive to disturbances (see *Peats and Peatlands, Physical Properties*). High water tables may be tolerated by adapted vegetation but the bearing capacity of soils may be critical for any use of land if only common agricultural machinery will be available. Adapted machines lower in weight may provide for the agricultural use of those soils too, even at shallow water tables of about 40 cm (Prochnow et al., 2000).

From a prevalent ecological point of view, there are no areas of trafficability free of compaction risk. In other terms, soils that can be trafficked with any vehicle at any time do not exist. All soils have a potential to become severely and persistently compacted and degraded by heavy machinery. Rooting restrictions and crop yield losses are a consequence. This potential is even higher for lighter textured soils. Unsorted soil substrates (Sands, loamy Sands, and Loams of Moraine parent material) have a particularly high compaction risk (see *Soil Compaction and Compressibility*).

Operational forecasting of trafficability

Among strategies to halt soil degradation by compaction, operational forecasting could become an emerging tool in agriculture. In order to provide a sustainable use of resources in agriculture by planning or operational decision support systems of machinery use, models of trafficability of soils can be helpful. Predicting possible subsoil compaction by particular machinery is possible (Keller et al., 2007b). As a precondition, relevant parameters must be quantified. In a comparative field study over several years on heavy alluvial soils, Müller et al. (1997) measured some soil parameters along with field observations and ratings of trafficability. They found that the topsoil status in the upper two centimeters in terms of measured and field estimated parameters like consistency index or suction was most important. The main finding was that gradients or differences in the soil moisture and density status over the depth have to be taken into consideration. Averaged values over the total topsoil do not allow a reliable assessment of trafficability. Babeir et al. (1985)

used mainly soil moisture and climatic data for their prediction model. They calculated soil moisture dynamics for layers at depths of 0–15 cm and 15–30 cm, characterizing the soil as “workable” or “non-workable.”

Operational forecasting of field trafficability has not yet been resolved in agriculture. One reason may be the need to optimize too many ecological, economic, and technological factors. It is necessary to compromise between mobility function of vehicles and risk of soil compaction on the one hand and between different soil states across fields (spatial heterogeneity) on the other hand. Finally, ecological and economic risks of postponing or omitting field engaging operations have to be taken into consideration.

Available knowledge on soil engaging processes would provide a basis for the development of decision tools for operational forecasting of trafficability in agriculture based on weather forecasting. Anderson (1983) coupled a deterministic soil moisture submodel to a principal empirical soil moisture-trafficability model. Müller and Schindler (1998) proposed the combination of soil water models with expert-based matrices and presented a sample matrix for a wheeled tractor (Table 2). Based on available spatio-temporal data of field soil moisture and density states, and depths of wheel tracks, application of statistical approaches of auto-regressive one-step-ahead forecasting (Müller et al., 1997) seems also to be a feasible way to develop operational forecasting tools. A combination of both approaches, field validated and controlled by wheel rut depth and slip control sensors, seems to be most promising to resolve this problem.

Example for the use of the matrix

Referring to soil C of Figure 1, soil bears winter wheat which at field traffic time for spreading fertilizers (end of March) yields about 4 cm plant height. The effect of plant cover is negligible at this time. The density status is medium. The surface layer is dry with a consistency state of 1 which implies a water content less than 0.15 kg kg⁻¹. Layer 2 (2–10 cm) has a consistency state of 2 (water content about 0.15–0.22 kg kg⁻¹). Layer 3 has a consistency state of 3 (water content about 0.22–0.28 kg kg⁻¹). The resulting trafficability score is 1, practicable. After a rainfall of 3 mm the water content of layer 1 moves to a consistency state of 4 and the resulting consistency score is 2.5, limited practicable to bad practicable. Scores and threshold of 1.5 compromise both vehicle mobility and soil damage (rut depths, remolding). The matrix has been validated with more than 60 soils at different moisture conditions.

Defining appropriate moisture conditions for workability

The soil moisture status affecting mechanical behavior and aggregate friability, is the most influential factor of workability (Mosaddeghi et al., 2009). When drier, aggregates are stronger, so it is difficult to reduce their size, and when wetter, aggregates are weaker and can be compacted

Trafficability and Workability of Soils, Table 2 Trafficability in dependence of consistency and density of soils, wheeled tractor, medium tractive force requirements (Müller and Schindler, 1998, slightly modified)

Consistency states coincide with Figure 1 and Table 1 but refer to three layers of the upper 30 cm. Low soil density refers to freshly ploughed soils, medium soil density is valid for common consolidated soils, and high density for no-till soils. Numbers from 1 to 4 in the matrix characterize trafficability: 1 practicable, 2 limited practicable, 3 bad practicable, 4 not practicable. A score of 1.5 is a threshold for trafficability

and remolded (Dexter and Bird, 2001). Rübensam and Rauhe (1968) emphasized differences in soil texture on workability. Whilst sandy soils are workable at almost any water content, it is very difficult for farmers to find an optimum water content for clay soils.

In humid environments, workability will be mainly hampered by excessive soil moisture. Soil water contents often exceed the common field water capacity (Van Wijk and Buitendijk, 1988). An important soil hydrological parameter affecting workability is poor drainage, formation of perched water and increasing wetness of surface soils (Chamen et al., 2003). Soil and land drainage in combination with evaporation have to provide suitable conditions for tillage operations (Kværnø et al., 2007).

Petelkau (1984) recommended ranges of moisture contents of Figure 4 for workability. He used the water content at a suction of 5 kPa (pF 1.7) as a reference basis. The Figure demonstrates that sandy soils (upper part of the graph) are workable at about any water content if a free drainage status that corresponds to field capacity of sandy soils, will be reached. With higher proportion of fine particles (lower part of the graph), soil moisture states either too wet or too dry, may occur. In the field, the wetter range is commonly larger, as also states of free water may occur.

In lowlands, associated with drainage problems, thresholds of soil water potential for predicting number of traffable and workable days depend on soil texture and type of operation. In the Netherlands, Van Wijk and

Trafficability and Workability of Soils, Figure 4 Ranges of water content for tillage (After Petelkau, 1984, mod).

Buitendijk (1988) proposed water suction thresholds for operations preceding spring and autumn sowing or planting of spring cereals, sugar beet, and potatoes varied from 50 to 110 hPa and for harvesting from 50 to 180 hPa in variously textured soils. A wider workable range was reported for plowing than for seedbed preparation (Larson et al., 1994). The water content at the inflection point interpreted as the “breakthrough” matric potential of the water retention curve at which air first penetrates through the soil (mid-point between the lower plastic limit and the shrinkage limit) was found to be the optimum for tillage of Rothamsted soils (Dexter and Bird, 2001). Authors developed equations for prediction of the optimum water content for tillage (OPT), the upper tillage limit (wet, UTL) and the lower tillage limit (dry, LTL) which can be combined with the use of pedotransfer functions for the prediction of the parameters of the van Genuchten equation (Van Genuchten, 1980) for soil hydraulic properties. Figure 5 shows the relations of the limits to soil clay content indicating that the range of water contents for tillage decreases with increasing soil clay content. Keller et al. (2007a) confirmed the water content at the inflection point of the water retention curve as a workability criterion in field experiments.

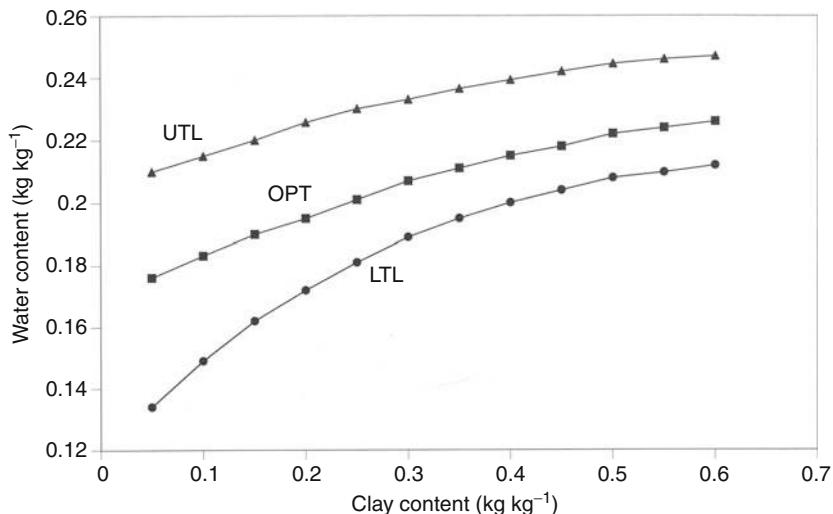

A comparison of some estimation methods of water contents for optimum workability revealed that most of them agreed well (Mueller et al., 2003). However, if the inflection point of the water retention curve will be calculated from existing databases, too high moisture contents are being expected, and the calculated value has to be tuned down by the factor 0.8 (Table 3). The coincidence between optimum water contents for tillage and for maximum compaction ($W_{optE} = W_{Proct}$) points up the risk of soil compaction by tractors during tillage operations.

Soil water status and specific energy for tillage

In drier as compared to wetter climates, workability concepts have to raise both problems of too wet and too dry moisture states (Canarache and Dumitru, 2000). Optimum workable range in terms of soil moisture is often quantified based on measurements of draft resistance to tillage implements and assessment of in-field implement effects on the structure (Dawidowski et al., 1988). Recent tillage studies showed tillage at a water content close to the plastic limit provided the lowest energy use for soil fragmentation (Arvidsson et al., 2004).

In terms of soil water potentials, the optimum working moisture obtained in a field study ranged between pF 1.9 and 3.1 for the loam soil and between pF 2.1 and 3.4 for the clay soil in Mexico (Cadena-Zapata et al., 2002, Figure 6). In this range of soil water matric potentials, specific energy applied in the loosening operation showed a minimum and an adequate seedbed was produced. Comparable workable ranges for same soils were also obtained by laboratory assessment based on a drop test (dry limit) and by air permeability and compression tests (wet limit) (Hoogmed et al., 2003).

Van Bergeijk et al. (2001) reported that plow draft varied between 30 and 50 kN m⁻² in a field where topsoil moisture content and clay content varied from 120 to 300 g kg⁻¹ and from 6% to 22%, respectively. The effect of soil moisture was lower in sandy than in clayey soils. The relation between optimum working range and soil texture and soil strength has been used to predict the draft requirement of primary tillage implements (Desbiolles et al., 1999). Greater resistance for tillage of compacted and stronger soil was accompanied by production of greater aggregate size (Guérif, 1994). Increased soil

Trafficability and Workability of Soils, Figure 5 Values of the upper tillage limit UTL, the optimum tillage moisture content OPT (inflection point), and the lower tillage limit LTL as functions of soil clay content (After Dexter and Bird, 2001).

Trafficability and Workability of Soils, Table 3 Orientation values of water contents for optimum tillage and tuning factors for alternative estimation methods (Mueller et al., 2003, shortened)

Methods: $W_{optA} = LPL - 0.15 * (UPL - LPL)$ (Kretschmer, 1996), Reference method, $W_{optB} = 0.9 * LPL$ (Dexter and Bird, 2001), $W_{optC} = W_{Infl}$ (Dexter and Bird, 2001), $W_{optD} =$ water content at 5 kPa, $W_{optE} = W_{Proct}$ (Wagner et al., 1992) UPL upper plastic limit (liquid limit acc. to Casagrande, Kezdi, 1969), LPL lower plastic limit (plastic limit acc. to Atterberg, : Kezdi, 1969), W_{Infl} water content at the inflection point of the water retention curve, W_{Proct} water content at maximum proctor density

compactness results in a smaller range of water content for tillage (Dexter and Bird, 2001).

In the procedure proposed by Canarache and Dumitru (2000) for droughty conditions in Romania, six classes of workability and six classes of trafficability were set based on the soil droughtiness and water logging risks as related to climate and soil hydrological parameters. The classes were defined by the number of days when tillage and traffic are impeded by too dry or too wet soil as determined by soil water models. Using GIS procedure, specific maps with classes of workability and trafficability were drawn.

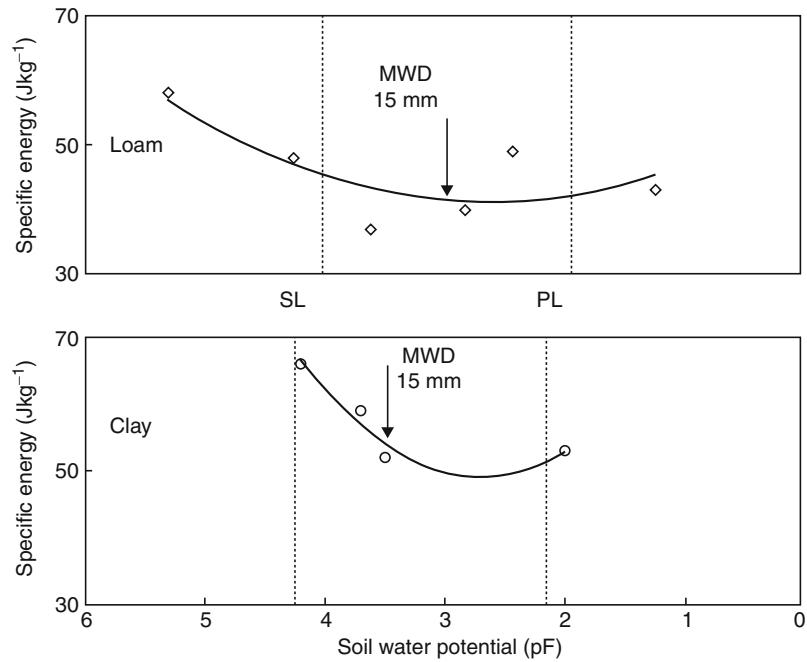

Consideration of natural effects forming a secondary soil structure

Tillage has to produce a favorable soil structure status for optimum establishment and development of crops. The desired and attainable soil structure in terms of aggregate size may be related to specific requirements of crops and has to consider possible changes of soil due to weather. For seedbed, preparation a very fine soil structure is being required. An old rule of thumb is that for seedbed preparation, the average diameter of aggregates should not exceed the threefold diameter of seed (Rübensam and Rauhe, 1968, p. 127).

While defining soil states for optimum effects of tillage, crop-specific requirements and natural forces on the tillage-induced primary soil structure have to be taken into consideration. In some cases, a soil drier than optimum for fine crumbling combined with a lower tillage intensity is more favorable. For example, fine seedbed consisting mostly of aggregates < 5 mm is suitable for emergence (Guérif et al., 2001; Håkansson et al., 2002) of most crops. However, in case of erosion risk, the seedbed has to be coarser and the surface rougher. Larger aggregates, for example, 15 mm are then more favorable because they provide depressions for water and thus allow more time for infiltration delaying runoff generation (Braunack and Dexter, 1989). Those processes may have implications for workability by the opportunity to accept suboptimum moisture conditions for tillage.

Achievable depth of tillage: soil moisture deficit and critical depth

The necessary soil moisture deficit (S_{MD}) is the amount of water that must be drained and/or evaporated from a typical wet springtime moisture status of soil to reach appropriate moisture for tillage (workability limit).

Trafficability and Workability of Soils, Figure 6 Specific energy applied for disc plowing. Curve fits: loam $r^2 = 0.77$, std. = 7.0, conf. ($P < 0.05$) = 7.4, clay $r^2 = 0.98$, std. = 6.2, conf. ($P < 0.05$) = 9.8. SL shrinkage limit, PL plastic limit, MWD mean weight diameter (After Cadena-Zapata et al., 2002)

S_{MD} is useful to calculate climate impacts on workability. The timespan in that S_{MD} can be reached, may be readily calculated from the climatic water balance obtained from agrometeorological databases (Earl, 1997). Depending on working depth and the difference between springtime soil moisture content and workability limit, S_{MD} ranges from about 10 to 200 mm in humid landscapes of central and northern Europe. In the case of heavy soils and deep tillage, it may be even higher.

Because of low water balance deficits in spring, appropriate soil moisture conditions for tillage of cohesive soils will be seldom reached. Only shallow tillage operations (<10 cm) are possible. Even small necessary soil moisture deficits of 10–20 mm can be rarely provided by evaporation. In Norway, Kværnø et al. (2007) calculated the time required for obtaining water contents for workability to about 5 days, which is longer than an average length of period without precipitation in the area, which is only 3.7 days.

Soil moisture deficits are of importance for quality drainage work or tillage of compacted subsoils. Subsoiling is a non-inversion deep tillage that utilizes shanks designed to disrupt subsurface compacted layers that restrict root growth and water movement. Though soils can be slightly wetter for some deep operating implements and procedures (Müller et al., 1990), soil moisture deficits for deep tillage are very high and cannot be provided in many years. Those situations can be used to adapt deep tillage implements to soil states. If soils require drainage, forming mole channels below the critical depth

may be a proper way to improve the soil moisture regime for arable farming (Mittelstedt and Müller, 1989).

Summary

In agriculture, soil management for plant production is provided by the use of efficient machinery. Many operations like tillage, fertilization, or harvesting require the application of tractors or other self-propelled and/or load-bearing machinery. Trafficability is a capability of land to provide field traffic operations without degradation of the ecosystem, particularly the compaction status of soil. Ecosystems include agroecosystems, forests, and grasslands including rangelands. Degradation includes all significant detrimental effects on soil structure, fertility, and vegetation. In agroecosystems, trafficability should be a precondition for mechanized soil tillage and is thus related to workability.

Trafficability can be measured and assessed by different parameters, characterizing shear strength, moisture, and density states of soil. Soil engineering properties as Atterberg's consistency limits are suited for the calculation and assessment of the soil's capability to provide for agricultural traffic. Weather conditions and ground or perched water tables influence trafficability significantly. Land drainage may reduce periods of limited trafficability. Based on available knowledge on field trafficking processes, evolving operational trafficability forecasting models seems to be feasible. This can be resolved by a combination of weather data with soil moisture models

and expert-based relational trafficability matrixes. Model combinations should include deterministic, probabilistic, and auto-regressive statistical approaches.

Workability is a capability of soil to be tilled. It is largely dependent on soil moisture and, thus, climate and weather. Defining appropriate moisture criteria and calculating suitable field moisture states may be important for planning tillage operations and land drainage. Parameters used for indicating potential soil wetness in relation to workability may be derived from the soil water retention curves (field water capacity, soil water potentials, inflection point of the water retention curve), from Atterberg limits or from Proctor compaction tests. Pedotransfer functions are available. In humid landscapes, soil moisture deficits for springtime tillage are critical and provide for only shallow operations. In subhumid and semiarid regions, restrictions of workability due to dry and hard soil conditions have to be considered.

While workability states can be reliably assessed, trafficability limits are largely unknown. Accelerated compaction of soils worldwide indicates failure to meet trafficability criteria by now. Besides existing recommendations for avoiding accelerated soil compaction, new measures should be taken into account. These are (1) restricting loads of machinery by environmental impact assessment procedures for heavy vehicles and (2) evolving operational forecasting of trafficability.

TRIAXIAL COMPRESSION TEST

Marek Molenda

Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland

Definition

Triaxial compression test – a test for the compressive strength in all directions of a sample of particulate material, using a triaxial cell.

Tests in which drainage is prevented are called undrained, when pores are allowed to empty tests are called drained. The specimen for triaxial compression test forms a circular cylinder of height-to-diameter ratio between 2 and 2.5 and contains volume of material representative for investigated bedding. The largest particle size shall be smaller than one sixth of the specimen diameter. The specimen stands, with axis vertical, on a pedestal containing porous plate. A stiff impermeable disc forms a loading cap. A flexible impermeable closely fitting membrane of negligible thickness envelopes the specimen and is sealed to the loading cap and to the pedestal. The specimen with loading cap, membrane, and pedestal is immersed in water in a transparent cell. The cell is connected with the pipe to the source of hydraulic confining pressure that generates normal stress acting on the cylindrical specimen. A stiff ram slides freely through the gland in the top of the cell coaxially with the specimen axis. With the assumption of uniformity of stress throughout the specimen, an axisymmetric state of stress can be induced, with two equal principal stresses $\sigma_2 = \sigma_3$ either smaller or greater than the remaining third principal stress σ_1 . In conventional strain-controlled tests, the loading ram is driven down at a constant rate that results in axial pressure acting through the length of the specimen. Axial

strain is applied at a rate of approximately 1%/min for plastic materials and 0.3%/min for brittle materials (ASTM D2850-03a, 2007). Loading is continued to 15% of axial strain, except loading may be stopped when the deviator stress ($\sigma_1 - \sigma_2$) has peaked then dropped 20% or the axial strain has reached 5% beyond the strain at which the peak in deviator stress. In a more sophisticated test, the confining pressure may vary to follow prescribed sequence of axisymmetric stress states. Obtained stress-strain curves represent behavior of a given material, and may serve for the selection of mathematical constitutive model.

TRICKLE IRRIGATION

Method in which water drips to the plant growth medium from perforated tubes or emitters.

TROPICAL FRUITS AND VEGETABLES: PHYSICAL PROPERTIES

K. P. Baiyeri¹, F. D. Ugese²

¹Department of Crop Science, University of Nigeria, Nsukka, Enugu State, Nigeria

²Department of Crop Production, University of Agriculture, Makurdi, Benue State, Nigeria

Introduction

The tropical environment of the world is broadly defined as the equatorial region of the earth that lies within latitudes 23.4° north and south of the equator; generally bordered by the Tropic of Cancer in the north and Tropic of Capricorn in the south [<http://en.wikipedia.org/wiki/Tropics>]. The region is generally hot and humid, and houses the world largest plant genetic diversity. The annual rainfall pattern demarcates two distinct seasons as rainy and dry seasons. The peculiar climatic factors and the soil types predicated the types of fruits and vegetables grown in this region. In this brief, few but economically important tropical fruits and vegetable will be discussed.

Fruit is any mature or ripen ovary, in botanical definition; however, culinary definition of fruits vary with peoples' group or context. In a general sense, fruits (when ripen) are usually any sweet tasting plant components associated with seed(s), and eaten with little or no cooking, as dessert. The Wikipedia (the free encyclopedia) loosely defines *vegetable* as an edible plant or part of

a plant; this definition is largely based on culinary and cultural tradition, thus, the application of the word is somewhat arbitrary and subjective.

Commonly cultivated tropical fruits

Musa species

Family: Musaceae

Common name(s): Bananas, Cooking banana, Plantains

Bananas and plantains are staple food in most part of the humid tropics. They are sources of rural income particularly for the smallholders who produce them in compound farms. Plantain (*Musa spp.* AAB) is a natural hybrid of *Musa acuminata* and *Musa balbisiana*. Desert bananas are either of the acuminata origin (having the AA genome) or the hybrids dessert banana having genomic complement of both the ancestral parents. Plantain is a giant herbaceous plant with a pseudostem (false stem) which is made up of overlapping leaf bases, tightly rolled around each other to form a ridged bundle. They can attain a height of 3–4 m with a short rhizome producing aerial shoot from lateral buds on the rhizome.

An underground stem (corm) functions primarily to perpetuate the plant by production of rhizome, and suckers, that are used for propagation. Plantain is shallow rooted and because it grows fairly tall, it is not well anchored. The leaf is very large. The fruits are formed parthenocarpically, each fruit is called a finger while a cluster of fingers is called hand (Figure 1).

Anacardium occidentale

Family: Anacardiaceae

Common name(s): Cashew

It is an evergreen, medium-sized tree with a mature height of 10–15 m. It has a spreading canopy which branches close to the ground. Leaves are long, simple, leathery, entire, lanceolate or ovoid, pale to dark-green, about 15 cm long, 7.5 cm wide, borne on short petioles. The leaves have reticulate venation.

The inflorescence is either axillary or terminal, has many floret bearing spikes. Panicles often consist of male and female flowers occurring together with the ratio of male to hermaphrodite flowers in the range of 6–7:1. The flowers are regular, with green calyx and red corolla, making them appear generally reddish.

The fruit has two parts – the cashew apple, which is pear shaped, swollen, and juicy, and the cashew nut which is the kidney shaped ovary at the end of the apple. The nut has a hard double shell. The kernel of the nut is rich in oil. The cashew has a deep taproot with deeply penetrating anchorage roots while the feeding roots occupy the top 50 cm of the soil layers. Generally, the lateral root system is vigorous (Figure 2).

Mangifera indica L.

Family: Anacardiaceae

Common name(s): Mango

Plantain hybrid [PITA 24]

Dessert banana [Nsukka Local]

Landrace plantain fruits

Banana fruits

Tropical Fruits and Vegetables: Physical Properties, Figure 1 *Musa* species.

Twig

Cluster of immature fruits

Ripe fruits

Tropical Fruits and Vegetables: Physical Properties, Figure 2 Cashew [*Anacardium occidentale*].

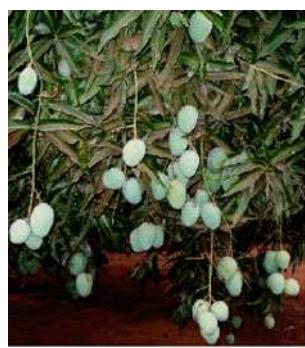

It is an erect tree, about 10–30 m tall. Canopy is oval shaped and upright; could attain a width of up to 3–8 m and with many branches. Leaves are alternate and entire, occurring mainly in clusters at the tips of branches or twigs, borne on petioles 2.5–10 cm long. Young leaves are pink or yellow, changing to green or dark-green with a shiny upper surface upon maturity. The mid ribs and the veins are quite pronounced. Mature leaves could be 10–32 cm long and 2–5.4 cm wide. The inflorescences consist of axillary or terminal panicles with hundreds or thousands of (sometimes up to 4,000) flowers. The flowers are small, regular, yellow, red, pink, or white, hermaphrodite, or male (25–98% male), both borne on the same panicle, normally without pedicels. Calyx is usually penta-sepalous, although number of sepals could sometimes be as high as seven or as low as three. Similar situation occurs with petals making up the corolla.

The fruit is a drupe showing remarkable variation in such attributes as shape, size and color. The fruit could be somewhat kidney shaped, round, oval or ovoid-oblong, 5–25 cm in length with a leathery, waxy, smooth skin whose color may be green, yellow, orange, yellow-orange, red-pink or purple-red when ripe. The mesocarp of the fruit is the main edible part in which is embedded a large flattened oval or kidney shaped seed called the stone.

The taproot is deeply penetrating (up to 6 m in some cases), the feeder root system is wide spreading with deeply penetrating anchor roots ([Figure 3](#)).

Persea americana Miller Syn:*Persea gratissima* Gaertn.
Family: Lauraceae
Common name(s): Avocado, avocado pear, alligator pear, butter pear

It is an evergreen, medium sized tree that can grow to a height of 10–20 m tall. Trees planted from seeds exhibit strong apical dominance giving rise to erect and vertical habit while grafted trees may be erect, round, or pyramidal. The root system is generally shallow, but deep in rare cases, reaching a depth of 1 m or more. The leaves are persistent, simple, coriaceous, lanceolate, 12–25 cm long, alternately arranged along the stem. They appear light

Plants carrying immature fruits

Ripe fruits

Tropical Fruits and Vegetables: Physical Properties,
[Figure 3](#) Mango [*Mangifera indica* L.]

green when young, appearing deep green at the mature stage.

Flowers are borne on axillary or terminal panicles. They are small, inconspicuous, greenish yellow, fragrant, about 5–8 mm long and 5–10 mm wide. A single inflorescence may contain from a few flowers to over a hundred. Flowers are androgynous. The fruit is a berry which could be pear shaped, spherical, oval, or elongated, measuring 7–20 cm in length with a weight of 50–1,000 g. The skin could be green, red, purple, or black and varies in thickness (from thin to thick). The creamy textured flesh is yellow-green to light-yellow in color with a pleasant smell. The seed is positioned in the central cavity of the fruit. The fruit is 3–5 cm in diameter, conical, spherical, or elongated with a double outer layer (seed coat) ([Figure 4](#)).

Citrus species

Family: Rutaceae

Some of the most important citrus species grown in West Africa are:

Citrus sinensis – sweet orange

Citrus aurantium – sour orange

Citrus aurantifolia – lime

Citrus limon – lemon

Citrus reticulata – tangerine, mandarine

Citrus species are small to medium sized evergreen trees, reaching a height of 5–15 m, the stems are often thorny. The leaves are unifoliate, margins entire with petioles that are most often winged. The leaves, oval and glossy, are alternately arranged on the shoot.

Flowers are strongly scented, large, perfect, and usually white in color. Each measures 2.4 cm in diameter with five- but sometimes four-membered perianth segments and numerous stamens. The stamens are usually arranged in five groups. The flowers occur singly (solitary) or in small clusters. The fruit of citrus is a hesperidium which is a specialized berry with the inner fleshy parts divided into various sections or segments (8–18) with an outer rind. The exocarp and mesocarp have a leathery texture. The fruit is more or less spherical or somewhat elongated, 4–30 cm long and 4–20 cm wide. Each of the easily separated segments or carpels or sections has many juice cells and several seeds covered by a leathery skin (exocarp) containing many oil glands. Some, like the tangelo, have no seeds while some have only few seeds. Rind color may be yellow to orange when ripe ([Figure 5](#)).

Psidium guajava

Family: Myrtaceae

Common name(s): Guava

The guava is a small tree that can attain a height of 6 m. The leaves are simple, elliptic to ovate, 5–15 cm long, very tough and dark, with entire margins. The white flowers are penta-petaloid but the stamens are numerous and conspicuous.

The fruit is a berry, round or pear shaped, 3–12 cm in diameter, with a soft or rough and thin or thick skin.

Mature fruits

Sweet orange plant

Plant carrying immature fruits

Young non-fruiting plant

Tropical Fruits and Vegetables: Physical Properties, Figure 5 Citrus species.

Skin color of ripe fruit could be pale green, yellow, or pink as distinct from the green color of unripe fruit. The pulp is creamy white to deep pink and contains many usually hard seeds ([Figure 6](#)).

Carica papaya

Family: Caricaceae

Common name(s): Pawpaw

It is a soft wooded evergreen tree, 5–10 m tall, usually unbranched. The leaves occur at the top position of the trunk and are spirally arranged. Characteristically, they are compound or palmately lobed with each leaf having seven lobes. Usually, leaves are large, 50–70 cm in

Tropical Fruits and Vegetables: Physical Properties, Figure 6 Guava [*Psidium guajava*].

diameter, and borne on exceptionally long hollow petioles. Lower portion of the trunk is marked by scars of former leaves and fruits.

The plant is dioecious, with small unisexual flowers. They occur in leaf axils. Fruits could be spherical or elongated, measuring 15–45 cm long and 10–30 cm wide and could weigh up to 9 kg. Many shiny black or grayish-black seeds are contained in the large central cavity of

the fruit. Ripe fruit shows an amber or orange colored skin ([Figure 7](#)).

Ananas comosus (L.) Merr. Syn: *Ananas sativus* Schult. f.

Family: Bromeliaceae

Common name(s): Pineapple

It is a herbaceous plant growing to a height of 0.75–1.5 m with a spread of 0.9–1.2 m. The stem is short and thick. It is surrounded by a rosette of large sword-shaped leaves, 30–180 cm long, about 30 or more in number. The leaves are waxy, with pointed tips and sharp spines on the margins. Leaf color may be green or have red or yellow stripes close to the margin or at the middle. The apical portion of the stem lengthens and enlarges to accommodate a head of small blue, purple, or red flowers. Each flower has a single bract, red, yellow, or green in color.

Each flower transforms into a fleshy fruitlet. The fruitlets become united with adjacent ones to form a single compound, juicy fleshy fruit, 30 cm tall or more. The pine cone-shaped fruit could be dark-green, greenish-orange, yellow-green, yellow, or reddish when ripe. The rind is composed of tough, waxy, leaf-like floral bracts arranged in hexagonal units. Flesh color could vary from somewhat white to yellow. Continuation in growth of the stem culminates in the formation of the crown at the tip of the fruit. The crown or top is made up of a compact tuft of stiff, much smaller and shorter leaves. Suckers arise from the

base of the plant. While offshoots (slips) grow from stem portion near the base of the fruit, shoots occur in the axils of leaves ([Figure 8](#)).

Passiflora edulis Sims

Family: Passifloraceae

Common name(s): Yellow or Purple passion fruit

The passion fruit is a woody perennial climbing plant with tendrils. The leaves are green, alternate, finely toothed, glossy on the upper side, duller on the underside, oval in shape, and 7.5–20 cm long. Fully developed leaves have three deep lobes. The leaves, young stems, and tendrils have red or purple taints.

Flowers are fragrant, solitary, 5–10 cm in diameter, positioned at the nodes. They have three bracts, green in color; five sepals, greenish-white in color; and five white petals. Flowers generally are predominantly purple. Fruits are oblong, 4–7.5 cm in diameter, green-brown, dark-purple, or light-yellow in color, with a smooth but tough rind. The juicy flesh is yellow or orange and could hold up to 250 seeds. The seeds are small, hard brown, or black in color.

The plant has a shallow root system ([Figure 9](#)).

Commonly cultivated vegetables

Leafy vegetables

Amaranthus cruentus L. Syn: *Amaranthus paniculatus* L.

Family: Amaranthaceae

Common name(s): Amaranth, African spinach, Indian spinach

Amaranthus cruentus is the most popular in Africa. It is an erect annual herb reaching up to 2 m in height. The often stout stems may have some red color taints and varying degrees of hairiness. The leaves are two to three times longer than wide and very often have pointed tips. They are typically described as lanceolate. Generally, they could be 2–18 cm × 2–15 cm although leaf length could be up to 30 cm in some cases. The leaves are simple, have no stipules, and are spirally arranged on the stem. They have long stalks.

The pronounced inflorescence is plume-like with raceme diameter of 10 mm and above, while terminal inflorescence could be up to 2 mm in length. The

unisexual flowers could have five petals of up to 2 mm length. The fruit is a capsule, 2.0–2.5 mm long, and contains the shiny and tiny (c. 1 mm long) seeds which are produced in great quantities.

Telfairia occidentalis Hook. f

Family: Cucurbitaceae

Common name(s): Fluted pumpkin, fluted gourd

It is a perennial herb and a recognized climber. Its climbing habit is facilitated by its tendrils which easily coil round objects. The vine can reach and even exceed a height of 20 m. The compound leaves are spirally arranged, have no stipules while petiole length vary from 2 to 15 cm. The leaflets have petiolules with lengths up to 3.5 cm. To a great extent, female plants have characteristically stronger and bigger shoots and larger leaves than male plants, although this is only reliably detected about 3 months after sowing.

The male inflorescence has small white flowers which attaches to the terminal point of the stem. Female flowers are solitary, borne on short stalks, and are found in the leaf axils, often hidden from view by leaves. The nectar is exclusively produced by male flowers. The cream colored flowers have pedicels (up to 4 cm long) and sepals measuring up to 5 mm in length. Of the two to three fruits that form on a plant, only one to two develop to maturity. The fruit is a berry, typically weighing 5–7 kg or even more, 40–95 cm × 20–50 cm, has 10 pronounced ridges, and is coated with waxy material. The pale green fruit has a yellow pulp housing the seeds. Each fruit contains 30–110 seeds. The oval shaped seeds could be black, reddish-brown, or dark-red and measure about 5 cm long.

The root system is mainly distributed in the top soil layers. Under dry conditions, female plants, which have better adaptive capacity than male plants, could develop thick and enlarged roots ([Figure 10](#)).

Vernonia amygdalina Delile Syn: *Gymnanthemum amygdalinum* (Delile) Walp

Family: Asteraceae (Compositae)

Common name(s): Bitter leaf, common bitter leaf

Horizontal view of pod

Vertical view of the pod

Tropical Fruits and Vegetables: Physical Properties, Figure 10 *Telfairia occidentalis* Hook. F [Fluted pumpkin, fluted gourd].

It is a shrub that can grow to a height of 3–5 m, in some cases reaching up to 10 m. When young, that is less than or up to 1 year, the rough basal portion of the stem is grayish while the apical portion is green in color. Trunk could be 40 cm in diameter. Wood is hard but not brittle. Stem is supple when bent. Leaves are simple, without stipules, alternate, petioles 2–4 cm long, lamina measuring 4–28 cm × 1–15 cm. Edges are uneven and toothed (dented). Leaf lamina appears greenish while main rib is pale in color. Leaves at the base of the shoot have wider laminas and longer petioles compared to those at the apex, near the flowers. The petiole emerges gradually into the leaf blade.

The inflorescence is a head. The flowers are white and pleasantly scented and are less than 1 cm in diameter. The fruit is an achene, 10-ribbed, and could be up to 3.5 mm long. The seeds are surmounted by a pappus ([Figure 11](#)).

Fruit vegetables

Lycopersicon esculentum Mill. Syn: *Solanum lycopersicum* L., *Lycopersicon lycopersicum* (L.) H. Korst

Family: Solanaceae

Common name(s): Tomato

Tropical Fruits and Vegetables: Physical Properties, Figure 11 *Vernonia amygdalina* Delile Syn: *Gymnanthemum amygdalinum* (Delile) Walp [Bitter leaf].

It is a seasonal herb with stems up to 2–4 m long. Usually, the hairy stems are prostrate while the tips are erect. Branches trail from the stems, normally, profusely. The large, hairy leaves have many leaflets, seven to nine. The leaves measure about 7 cm long while the outline of larger leaves could be up to 50 cm long and 30 cm wide. Leaflets have toothed margins. Both the leaves and the stems have a strong odor.

Flowers are small and yellow and grow in clusters of 4–12 on stems between leaves and could measure up to 1–2 cm in diameter. At times, the inflorescence could be compound with up to 100 flowers. Tomato fruit is typically a berry, 2–15 cm in diameter. Immature fruit is green and could have hairs. Ripe fruit is hairless and shiny with red, pink, or yellow color. Fruits exist in various shapes: could be large and round or elongated or could be small in size with diameter up to 2 cm. The brown and hairy seeds are flat-oval in shape with mean dimensions of 4 mm × 3 mm.

The main root system is fibrous, though there is a strong taproot reaching a depth of 50 cm or more into the soil. The stems readily give rise to numerous adventitious roots.

Abelmoschus esculentus (L.) Moench Syn: *Hibiscus esculentus* L.

Family: Malvaceae

Common name(s): Common okra, okro, lady's finger

It has a strong, erect stem up to 4 m tall, branched to a greater or lesser extent. The erect stem has many stiff somewhat prickly hairs. Branches arising from the stem could be straight or they could bend downwards. Okra leaves are simple, borne on long petioles up to 50 cm long, three to seven lobed, more or less divided, cordate at base, veins present on both abaxial and adaxial sides, with stiff hairs, 20–40 cm long and up to 50 cm broad. Petiole is normally red tinged.

The axillary, solitary flowers have five petals, large and pink, white or yellow in color. The center of the calyx is dark-purple or crimson. Epicalyx segments are 7–18 in number, 5–25 mm in length, and 0.5–3 mm in width. Fruits, cylindrical to pyramidal in shape, often vary in

color, from purple to green to pale green to yellow or even black. It is a capsule varying in size from 5–25 cm in length and 1–5 cm in width. Fruits could be borne on stem tips or the axes of leaves or on spurs. The inside of each fruit is made up of several narrow spaces or cavities called loculi in which up to 100 seeds, round, 4.5 mm in diameter, gray or brown when ripe are embedded.

The taproot is strong and firmly establishes the plant in the soil with the aid of secondary roots arising therefrom.

Solanum melongena L. Syn: *Solanum insanum* L.,
Solanum incanum auct. non L.

Family: Solanaceae

Common name(s): Eggplant, Aubergine, brinjal

The plant can grow up to 1.5–2 m tall although normal height is about 1 m, with many branches. Leaves are simple, without stipules, entire but most often lobed, with 8 cm long petioles and with rounded or cordate leaf bases. The leaves could be 3–30 cm long and 2–15 cm wide, alternately arranged along the stem. Hairs occur both on the leaves and the stems.

Flowers are violet or purple, with an average diameter of 4 cm. The inflorescence is a cyme with one to five flowers, although flowers most often occur singly (solitary). Petals are united. The fruit is a berry, 2–35 cm long, and 2–20 cm broad, often single. When ripe, fruit is normally yellow, brown or intermediate between the two colors or even reddish. Unripe fruit however appears white, green, violet-purple, black, sometimes striped. The fruits contain flattened light brown seeds 3 mm × 4 mm.

It has a long taproot.

Citrullus lanatus (Thunb.) Matsum. & Nakai Syn: *Citrullus vulgaris* Schrad. Ex Eckl. & Zeyh., *Colocynthis citrulus* (L.) Kuntze

Family: Cucurbitaceae

Common name(s): Water melon, egusi melon, egusi water melon, West African water melon

It is a trailing annual plant, could reach 4–10 m in length. Presence of tendrils facilitates climbing ability. Stem is soft and ridged. Leaves are simple, but deep clefts

gives rise to irregular lobes. Leaves are $4-25 \times 3-19$ cm, with serrate margins, alternate. Petioles are 2–14 cm long.

Flowers are solitary and axillary, 2–3.5 cm in diameter, yellow in color. Male flowers are borne on long peduncles with petals united at the base. Female flowers are borne on shorter peduncles, have an inferior hairy ovary. Fruit is a berry, green, white, with white stripes (markings) or yellow. The shape is round or oval to round, 5–80 cm long, 15–20 cm in diameter, weighing 0.1–30 kg. The flesh is white, pale green, yellow, red or pink. The seeds are oval, flattened, smooth, although margins rough and thick, 0.5–1.5 cm long, 0.5–1 cm wide, yellow or brown in color.

It has a tap root with numerous lateral roots although root system is generally shallow.

Capsicum annuum L.

Family: Solanaceae

Common name(s): Sweet pepper, bell pepper, paprika

It is a fast growing herbaceous annual plant that can reach a height of 1 m. The lance-shaped leaves are simple, hairless or pubescent, alternate, petioles up to 10 cm long. Flowers are white, solitary, and pending. Fruits are large, 3–12 cm in diameter, red, yellow, orange, purple or green when ripe, fleshy with a mild flavor. Ripe fruit is hollow with the center anchoring many seeds. It has a strong taproot and numerous lateral roots.

Capsicum frutescens L.

Family: Solanaceae

Common name(s): Bird pepper, chilli

It is a fast growing annual herb reaching a height of up to 2 m. Leaves are simple, glabrous or pubescent, alternate with petiole length up to 10 cm. Flowers are white, solitary, or in clusters of two to three in leaf axils, pending, 1–2 cm in diameter. Fruits are ovoid or elongated, 1.5–16 cm long, bright red or sometimes yellow or orange when ripe, and highly pungent. The central cavity has several seeds. It has a taproot and numerous lateral roots.

Root vegetables

Zingiber officinale

Family: Zingiberaceae

Common name(s): Ginger, garden ginger

It is an erect herb that grows 0.3–1.2 m tall and 3–6 mm in diameter. The leaves are green, thin or narrow, 1–3 cm wide, 5–30 cm long, sharp, arranged at right angles to the stem. Flowers, yellow or yellowish-green, are produced in dense or compressed spikes on a basal stem. The root system is an enlarged rhizome, 3–25 cm long, 2–3 cm in diameter, is highly aromatic. Flesh color is white to yellow or pale greenish yellow (Figure 12). Adventitious roots arise from the rhizome in the upper soil layers.

Daucus carota

Family: Umbelliferae (Apiaceae)

Common name(s): Carrot

The plant is a biennial usually cultivated as an annual. During the first season of its growth, it develops a rosette of finely divided leaves and stores its food in the stout taproot which becomes enlarged and fleshy. The taproot could be globular, elongated, or tapering. It is most often orange or yellow in color. If it is not harvested in the first season, the plant will utilize its resources to grow a flowering stem the next season. Thus, a central terminal bud grows into a stem, 0.9–1.5 m tall, bearing an umbel of small, radially symmetrical flowers. The flowers, white or pinkish, have five each of petals, sepals, and stamens. The central flower is normally purple. The fruit of the plant has two nutlets each containing one seed.

Summary

The tropical environment has a highly diverse nature of fruits and vegetables that have remarkable nutritional and economic importance. Fruits and vegetables are generally low in protein, fat, and calories, but they are rich sources of important minerals and vitamins. Some,

Rhizomes of Ginger

Sliced rhizomes showing yellowish or whitish color

Tropical Fruits and Vegetables: Physical Properties, Figure 12 *Zingiber officinale* [Ginger].

especially fruits, contain anti-carcinogenic and antioxidant compounds that protect the body against cancer and slow down the ageing process respectively. Their high fibre content is known to impact a number of health benefits such as lowered risk of obesity and heart disease, as well safeguarding against constipation and enhancing bowel movement.

Tropical fruits and vegetables exhibit wide variation in their physical attributes. For instance the stems of fruits which are mostly woody vary in height from very short to very tall while their diameters could range from less than a meter to few or several meters. Branches could be loose or compact, dense or sparse. Some tropical fruit species are evergreen while others are deciduous.

Most tropical vegetables have soft stem, which is normally a few to several centimeters long, except for some (like those with vines) where the stem could be few to several meters long. The diameter is also very small, usually not exceeding a few centimeters, except in a few cases.

For both fruits and vegetables, the leaves could be few or numerous, simple or compound with various sizes. Arrangement on the stem could be opposite, alternate, or whorled. Venation also varies as well as types of margin. Certain portions of the leaf could have projections or be completely without projections. The texture of the lamina could vary between smooth and rough or dull and glossy. Leaf color is variable and could range from pure to a mixture or blend of various colors. Flowers are equally variable. In some plants they occur singly while in others they occur in clusters or groups called inflorescence. They could be terminal or axillary, prominent or inconspicuous, scented or not. Some plants are monoecious, diecious, or hermaphrodite.

Fruits show variation in shape, size, skin and flesh color, texture, and seed quality. Seeds within a fruit could be single, few or many with varying sizes and shapes. Rooting profile could vary between the extremes of shallow rootedness to deep rootedness. Thus, the tropical environment is endowed with numerous fruits and vegetables with diverse physical and rich nutritional attributes.

TROPICAL SOILS, PHYSICAL PROPERTIES

Charles A. Igwe

Department of Soil Science, University of Nigeria,
Nsukka, Enugu State, Nigeria

Synonyms

Equatorial; Subtropical; Tropical

Definition

Soil. This is the unconsolidated mineral material on the immediate surface of the earth that serves as a medium for plant growths. It is also a product of soil formation.

Tropical soils. These are soils found within the vicinity and overlap the two tropics, Cancer and Capricorn.

Equatorial soils. Terminology often used to describe soils that overlap the equator and extend northward to the Tropic of Cancer and southward to the Tropic of Capricorn.

Subtropical soils. Soils formed on the periphery of the two tropics – Cancer and Capricorn.

Introduction

Of all the major soils of the world, the ones least understood by soil scientists are the soils of the tropics. Most soil scientists describe them as useless soils that are often lateritic and drastically leached. The Soil Survey Staff (1975) attempted to classify world soils to a very low level of generalization, but found it necessary to classify in detail the order of ultisols and oxisols, which are the very prominent tropical soils. It was in the subsequent editions and upgrading that further classification of these soils was attempted. Some years later, Soil Survey Staff (1999) again described the major soil orders of the world. Those identified in the tropics are Oxisols, Ultisols, Alfisols, Aridisols, Inceptisols, and Entisols. These soils occur in most tropical areas of Africa, Asia, and North and South America. They have certain properties in common. Most of these soils are very fragile and possess the characteristics of not holding water for a long time when saturated. In spite of all the literature highlighting the negative side of these soils, they still support agriculture, forestry, wildlife conservation, recreation, and other types of land use such as industrial, mining, sewage disposal, highway development, and rural/urban development. Most soils are deep, highly weathered except for some few mountainous soils. The soils however, offer some challenges in the management and its restoration following degradation. Sometime they are very fragile due to their physical properties.

In order to manage these soils better and put them to sustainable productivity, their physical properties have to be understood. There should be an understanding between the soil properties, their management, and land use strategies. A number of soil physical properties influence the nature of the soil and their productivity potential. These soil physical properties are soil texture, structure, rheology, and soil water retention and transmissivity.

Texture of the soils

A variety of soil textures occur in tropical soils. The International Soil Science Society (ISSS) recognized 12 classes of soils in the soil textural triangle. Almost all of these 12 soil groups occur in the tropics. However, the finesse or the coarseness of soil often depends on the soil-forming parent materials. In most tropical areas with heavy rainfall and excessive leaching, the soils are mostly coarse because the fine materials are removed by erosion, leaving behind the coarse particles. Igwe et al. (1995) reported that most of the soils they studied were mainly sandy loam to sandy clay in the subsoil. The clay contents they observed are low to moderate while the silt contents are very low except for profiles in floodplain as Atami

sl sandy loam, scl sandy clay loam, sc sandy clay.

(Table 1). The low silt content is attributed to the nature of the parent materials and the advanced stage of weathering. Sometime there are exceptions to these especially in floodplain soils that are entisols and inceptisols.

Structure of the soils and aggregate stability

One of the most remarkable characteristics of the tropical soils is their very high bulk density values. In most tropical ultisols and alfisols, bulk density values can sometime be more than 1.80 Mg m^{-3} . In the soils studied by Akamigbo and Igwe (1990), Igwe (2003b), and Igwe et al. (2005) bulk density values of between 1.34 Mg m^{-3} and 1.86 Mg m^{-3} were obtained for various soils (Table 1). These high bulk density values have been attributed to structure degradation and alterations within the profiles. The low level of soil organic matter (SOM) obtained in these soils also contribute significantly in the increased bulk density values. Studies by Mbagwu et al. (1983) and Igwe et al. (1995) indicated that bulk density of soils increased as organic matter decreased in the soil. The high temperature in the tropics and over use of the soil due to tillage contribute significantly to high mineralization of soil organic matter, thus low values of SOM in the soil. The negative influence of high bulk density is the development of compaction in the soil and sometimes development of hardpan or impervious layers, which hinders water movement in the soil.

One good characteristic of tropical soils is the stable aggregate potentials. The soils mostly are composed of kaolinite, oxides, and quartz. These minerals do not expand rapidly when wet and thus contribute to high aggregate

stability (AS) potential of the soils. Igwe et al. (1999) showed that for most soils the values of water-stable aggregates (WSA) greater than 0.5 mm can be as high as 85% for some soils while the unstable aggregates (WSA $< 0.25 \text{ mm}$) can be as low as 8%. Values of aggregate stability in most tropical soils are high. In some Nigerian soils, aggregate stability (AS) were between 10% in a degraded ultisol and 82% for highly weathered tropical soil.

The soil dispersion ratio (DR), which is the ratio of total clay and silt obtained with chemical dispersant and clay+silt obtained with deionized water dispersion only is moderate to high. Most often values of DR may range from values as low as 0.13–0.94. According to Igwe (2005) soils with high DR are very erodible while those with low DR are less erodible. The ease with which the soil disperses is also related to the level of sesquioxides, organic matter, and other cementing or binding agents in the soils.

Consistency

The pedological system of soil consistency determination indicates that the tropical soils can be regarded as being granular crumbs on the top soils while the subsoil is blocky to massive. The blocky structure can be angular blocky or subangular blocky depending on the over burden pressure and mode of soil formation. In the arid and semiarid areas, the structure of the B-horizon can be prismatic to columnar structure due to the effect of salt and other solutes. The aggregates are strong when dry, friable to firm when wet. Except the soils that contain a lot of clay particles, they are not very sticky and often not very

plastic. The *van der Waal's* forces binding the aggregates seem to be strong and make the soil particles adhere to one another very strongly.

Shrink–swell characteristics

Shrink–swell potential as a soil quality that determines its volume change with variation in the soil moisture regime is very important in citing agronomic and engineering infrastructure. As already stated, tropical soils with high 2:1 and oxides content hardly pose any problem associated with shrink–swell characteristics. Igwe (2003a) remarked that in some studied tropical soils with old parent materials, the coefficient of linear extensibility (COLE) were between 0.006 and 0.082 with corresponding volumetric shrinkage (VS) as 1.81 and 26.67. In another study on different soils, Igwe and Okebalama (2006) showed that COLE ranged from 0.03 to 0.09 with corresponding VS as 9.27 and 29.50. The shrink–swell hazard rating indicates that the soils fall within the class of slight shrink–swell class to very few severe shrink–swell hazard class. In most cases, the top soils fall within the slight shrink–swell hazard category while the soils with moderate shrink–swell hazard classes are those of the subsoil where there is increased clay size particle concentration due to translocation and accumulation of clay by illuviation or residual accumulation of clay.

Soil moisture retention

The moisture retention characteristics of the soils vary from soil to soil depending on texture, the inherent soil organic matter content, colloidal content, and other soil properties. The soils can retain about 10% to more than 60% moisture at 0.01 MPa suction and as low as <5% and 25% at 1.5 MPa. In most tropical soils, the available water content (AWC) have been shown from studies to range from <1% in coarse sandy soils to as high as >40% in clayey soils. In most cases, the topsoil retains more moisture than the subsoil except when there is accumulation of clay size particles.

Hydraulic conductivity, permeability, and infiltration rate

Land use, soil properties, and nature of soil biological activities determine to a large extent the hydraulic conductivity and infiltration rates of tropical soils. Hydraulic conductivity of soils can vary in tropical soils from very slow to rapid. In most soils, the conductivity is reduced due to structure degradation, high bulk density, and loss of structure due to soil erosion. These results are very rapid over land flow if there is reduced water intake into the soil. Numerical values obtained in the field and laboratories indicate that hydraulic conductivity of some tropical soils range from <0.12 cm h⁻¹ to >40 cm h⁻¹.

The high biological activities of the tropical soils and high porosity of the soils induces high infiltration rates. Values obtained from coarse-textured soils indicate that infiltration rates ranges from about 10 cm h⁻¹ to

>35 cm h⁻¹, while in fine-textured soils, Nnabude and Mbogwu (1999) obtained an infiltration rate of >20 cm h⁻¹. In floodplain soils, the infiltration rates are high, thus reflecting the excellent soil structure and increased biological activities on the top soil. Lithological discontinuity can also affect the easy flow of water into the soil and hence distorted infiltration rate.

Management of tropical soils

The greatest problem in management of tropical soils is soil erosion and problems associated with aridity. In areas of high tropical rainstorms, soil erosion by water remains the major problem. Soil erosion in these areas can be in the form of rill erosion, and interrill and gully erosion (Figure 1). Lal (1976) discussed in details the problems associated with soil erosion by water in a humid tropical environment. Associated with high rainfall is leaching of soil nutrient leading to decrease soil pH. As soil erosion by water poses problem in humid tropical environment, the tropical areas with less rainfall suffer from wind erosion. This form of erosion creates very serious

Tropical Soils, Physical Properties, Figure 1 Two different sites devastated by gully erosion in southern Nigeria.

environmental problem. Also associated with very low rainfall is the problem of aridity and salinity degradation of the soil. Salt-related problems can cause very severe damage to agricultural productivity.

Severe deforestation in this region has not helped in checking the erosion menace. Intensive afforestation and agroforestry programs are therefore recommended for soil erosion control in the region. Agricultural practices such as mulching, no-till farming, or zero tillage are also recommended. Other practices are contour plowing, strip cropping, and ridging across slope.

Summary

The soils of the tropical region are Oxisols, Ultisols, Alfisols, Aridisols, Inceptisols, and Entisols and occur in most tropical areas of Africa, Asia, and North and South America. They have some certain properties in common. Most of these soils are very fragile and possess the characteristics of not holding water for a long time when saturated. Their textures and particle distribution vary from location to location. They are well aggregated in that they lack swelling minerals and often do not undergo swell-shrink hazard except those with swelling clays. The greatest problem in management of tropical soils is soil erosion and problems associated with aridity and salinity. In areas of high tropical rainstorms, soil erosion by water remains the major problem.

TROPICAL WATERSHEDS, HYDROLOGICAL PROCESSES

Juergen Baumann

Hydroagricultural Infrastructure (SGIH-GDTT), National Water Commission (CONAGUA), Mexico City, Federal District, D.F, Mexico

Definition

Tropical watersheds refer to watersheds in the wet and seasonally wet (humid) tropics, including type A climates according to the Köppen classification system and tropical regions that fit with the criteria defined by Chang and Lau (1993). Hydrological processes in tropical watersheds are strongly influenced by particular climatic, geomorphologic, and soil conditions.

Climate: Rain amount and rainfall intensities are commonly much higher than in other climates. Erosivity of single rainstorms (EI_{30}) can be higher than total annual rainerosivity (R-factor) in temperate wet or semiarid regions. High temperature and wetness accelerate rock weathering.

Vegetation: Runoff in undisturbed forested tropical watersheds is generally low and Hortonian Overland Flow (HOF) is strongly reduced by high infiltration rates of the topsoil layers (Bonell, 2005). Disturbance of natural forest cover decreases interception and reduces the infiltration capacity, leading to increased superficial runoff and streamflow (Chaves et al., 2008).

Soils and Geology: The formation of deep weathered soil profiles (Regolith, Saprolite) is widely shown in the tropics, and catchments may have a high water storage capacity. Soil texture, clay mineralogy, soil hydraulic properties, and especially drainage conditions of the subsoil and depth of regolith are key factors in determining hydrologic flowpaths and runoff (Brujinzeel, 2004; Chappell et al., 2007).

Topography: Hillslope hydrology in the humid tropics is driven by a combination of fast vertical flows, near surface lateral flows, lateral subsurface storm flows, as well as saturated overland flow. The dominance of a certain flowpath depends strongly on soil and subsoil conditions (Elsenbeer, 2001). The influence of slope gradient as a controlling factor on runoff will increase with rainfall amount and intensity of single storms or rainfall accumulations.

TURBIDITY

Ewa A. Czyz^{1,2}, Anthony R. Dexter¹

¹Department of Soil Science Erosion and Land Conservation, Institute of Soil Science and Plant Cultivation (IUNG-PIB), Puławy, Poland

²Rzeszów University, Rzeszów, Poland

Introduction

Turbidity basics

The term turbidity refers to the cloudiness of a suspension. This cloudiness is caused by the presence of colloidal

particles that have sizes smaller than about 1,000 nm. These particles scatter light because they have a refractive index that is different from that of the suspending liquid. When the particles have sizes smaller than the wavelength, λ , of visible light (red light has $\lambda \approx 750$ nm whereas violet light has $\lambda \approx 380$ nm), then the Rayleigh scattering theory may be used. In the more general case of any ratio between particle size and the wavelength of the radiation, then the more complex Mie solution to Maxwell's equations must be used.

Measurement of the proportion of light that is scattered is the preferred method of turbidity measurement. Measurement of absorption of light is not satisfactory because absorption is also sensitive to the color of a solution whereas the scattering of light is not. Scattering is a function of the solid particles in suspension only.

Here, as an example, we consider the dispersion of soil colloidal particles in aqueous suspension, although the same principles apply to other types of dispersed particles. In the case of soils, it is mostly the clay particles that cause turbidity although there may also be a contribution from organic colloids present.

Dispersion and flocculation of colloidal particles

Colloidal particles can spontaneously disperse (separate) or flocculate (group together) when in suspension depending on several factors. These processes are extremely important for the environment and for agriculture as well as for a wide range of industrial processes.

It is necessary to be careful with terminology here: the term *stable* is used by colloid scientists to refer to the stability of a suspension (i.e., a fully dispersed state). In contrast, soil scientists use the term *stable* to refer to the flocs (i.e., a fully flocculated state). Usually, in soil science, we want the colloidal particles to be flocculated so that they can contribute to the structure and stability of soil.

Dispersion is greater when soil has a low content of organic matter, a high input of mechanical energy (i.e., is intensively tilled), a high content of exchangeable sodium, and a high pH. Also, a low concentration of dissolved salts in the pore water (as can be measured by electrical conductivity, EC), increases colloid dispersion. Flocculation can be increased by replacement of sodium by calcium, by using lower energy tillage practices and by building up the soil organic matter content.

Environmental consequences of dispersed particles

Dispersible clay within soil makes the soil hard setting upon drying. In simple terms, we can imagine that the clay “clogs” the micro-cracks that otherwise make the soil friable and easy to till. Such a soil will also tend to have a lower hydraulic conductivity and water infiltration rate and will tend to be anaerobic. Dispersible clay contributes in this way to the problems of surface sealing and crusting. The presence of dispersible clay is therefore associated with poor soil quality whereas the absence of dispersible clay is associated with good soil quality.

The brown coloration of runoff water from land during storms indicates the presence of soil particles in suspension. The turbidity of runoff water therefore shows that soil erosion is occurring. This turbidity travels with the water down into streams and rivers where the turbidity is a sensitive measure of the water quality.

A range of materials can be adsorbed onto the surfaces of soil particles and will therefore be transported in the environment if the particles are transported. These materials include plant nutrients (such as phosphate) that can cause eutrophication (e.g., algal “blooms”) in water reserves such as lakes and the sea, heavy metals that can be toxic in the food chain, and also microorganisms that can have the potential to spread diseases.

Methodology

Equipment

Turbidity is measured with a turbidimeter. This equipment has a source of white light (most commonly a tungsten filament lamp). The intensity of light that is scattered at some angle (e.g., 90°) by the particles in suspension is detected and measured as a proportion of the forward-transmitted light. This is the principle of a ratio turbidimeter. The ratio mode of operation has the advantage that the measured values are independent of fluctuations in the intensity of the light source due to power supply variations or aging of the filament lamp.

A valuable feature of this method is the highly linear relationship between the turbidimeter measurements in NTU (or nephelometric turbidity units) and the concentration of the colloids in the suspension (mass colloids per volume of suspension). Colloid concentrations in suspension can be measured easily by turbidimetry over a range of 1:10⁵. A turbidimeter should be calibrated periodically using freshly prepared Formazin primary turbidity standards.

Factors to be considered

(a) Antecedent water content

It has been found that drying of soil samples causes big reductions in the content of readily dispersible clay (RDC) and that this effect can be essentially irreversible (Dexter et al., 2010). Therefore, soil for assessment of RDC should be collected at the end of a long, wet period (e.g., winter in Europe), and should not be allowed to dry during storage before measurement. It is recommended that soil to be measured should have a water content corresponding to field capacity (here defined as a pore water suction of 100 cm water).

Note that soil that has been dried cannot be rewetted and used to assess the condition of soil as it was in the field. Drying and rewetting changes the soil profoundly and in effect, it produces a new material. Therefore, soil should be used only when it is freshly collected in a moist condition from the field.

Some effects of climate on the RDC content of soil and the consequences for soil strength were reported by Kay and Dexter (1992).

(b) Dispersion techniques

As a standard, but arbitrary, procedure we take a known weight (about 5 g) of moist soil that has been collected in the field with minimum disturbance, and drop it into about 50 mL of distilled water in a 150 mL plastic bottle. We then add distilled water to make a total of 125 mL of suspension. Note that the remaining 25 mL of air space in the bottle must be accurate because it affects strongly the energy imparted when the bottles are inverted.

The soil is allowed to stand in the water for 1 h, then the bottles are inverted four times to apply a small, standard input of mechanical energy to disperse the readily dispersible particles. Then the bottles are allowed to stand overnight for 18 h for the larger particles to settle to the bottom of the bottles leaving the RDC in suspension. The next morning, 30 mL of suspension is collected from the center of each plastic bottle and put into a clean, glass turbidimeter cell. The turbidity is then measured with the turbidimeter in NTU.

The turbidity due to the RDC is then expressed in terms of dry mass of soil per liter of suspension to give a normalized result in NTU/(g L⁻¹). The dry mass is calculated from the known sample weight and the gravimetric water content of the soil, which must be measured on a separate sample. It is also useful to measure the electrical conductivity (EC) of the suspension after measurement of the turbidity to check that conditions for flocculation were not present.

Experimental procedures for measurement of RDC by turbidimetry have been described in greater detail by Czyż et al. (2002), Czyż and Dexter (2008) and updated procedures are given in Dexter et al. (2010).

Examples of results

Effects of mechanical energy inputs

Any process that disturbs soil, for example, by shearing or compaction, can break bonds between soil particles and therefore has the potential to make soil particles more dispersible. Mechanical energy inputs from agricultural machinery (e.g., tillage implements) can destabilize soil in this way. Reducing the energy input can reduce the degree of destabilization. For example, it has been found that the use of reduced tillage (tynes working at 10-cm depth) instead of conventional tillage (moldboard plowing to 25-cm depth) resulted in lower content of RDC in soil (Czyż and Dexter, 2008).

A simple laboratory apparatus for applying known amounts of mechanical energy to soil samples has been developed (Watts et al., 1996a). These applied energies were related to the energies applied by different tillage implements to soil in the field (Watts et al., 1996b). Specific energy inputs of 100 and 300 J kg⁻¹ were found to correspond to deep plowing and to tractor-powered rotary cultivation, respectively. RDC increased with increasing energy input only at water contents wetter than the lower plastic (Atterberg) limit.

Effects of organic matter

Land use, including different cropping, affects the content of RDC in soil. The greatest effect is on the amount of organic matter, but there is also an effect of the quality of the organic matter. The most effective seems to be the organic matter produced by the decomposition of grasses. This has a high content of hydroxyl and carboxyl chemical groups.

How much organic matter is required to stabilize soil? It has been found for a range of French, Polish, and UK soils that the content of organic matter (%) required to stabilize soils is approximately 0.172 times the clay content (%). This content of organic matter, if it is in humified form, is sufficient to form stable complexes with all of the clay present (Dexter et al., 2008). The non-complexed clay in soils comprises the RDC. Clay-organic complexing can reduce the RDC to very low levels.

Organic matter not only stabilizes soil through reducing the content of RDC, but it also reduces the sensitivity of soil to destabilization by mechanical energy inputs (Watts and Dexter, 1997).

Dispersible clay in relation to soil physical quality

The physical quality of soil relates to its ability to fulfill a range of functions. For agriculture and the environment, it is important that excess water can drain rapidly, that the soil is well aerated and that the soil is easily workable by tillage implements over a reasonable range of water contents. Soil can fulfill all of these functions if it has a suitable structure that is stable in water. We have already seen above that the presence of RDC indicates lack of stability in water.

The S-index of soil structure is based on the shape of the water retention curve, which is itself a function of the pore size distribution in soil (Dexter and Czyż, 2007). It has been found that the S-index is a good indicator of soil physical quality.

Correlation of values of RDC with values of the index S of soil physical quality show that soil has a “good” soil physical quality if less than 40% of the clay is RDC and has a “poor” soil physical quality if more than 40% of the clay is RDC.

This inference illustrates how the value of RDC, as can be easily measured with a turbidimeter, can be used as an indicator of the physical condition of soil.

URBAN SOILS, FUNCTIONS

Thomas Nehls, Gerd Wessolek
Department Soil Conservation, Technische Universität Berlin, Berlin, Germany

Definition

Urban soils are anthropogenically altered soils characterized by contamination, compaction, soil sealing, as well as deposition, removal, or mixing of technogenic and natural substrates. Urban soils are primarily situated in urban areas and exhibit a high spatial heterogeneity, but are also

typical of industrialized, transport, and mining sites (Morel et al., 2005).

They are formed over a dynamic sequence of soil-building processes, influenced by frequently changing of land use types and a spectrum of human impacts throughout history. Even when ecological characteristics are substantially changed, urban soils can still fulfill the same functions as natural soils (see [Soil Functions](#)), although to varying extents.

Urban soils predominantly provide the physical basis for technical, industrial, and socioeconomic structures in cities. Soils are used to support housing settlements, traffic infrastructure, all kinds of cultural life, waste disposal facilities, and to supply natural resources. Due to these functions, soils are often mixed, compacted, or sealed to meet construction requirements. Industrial production, automotive traffic, and waste disposal often result in soil contamination, leading to a significant restriction of other vital soil functions.

In developed countries, urban soils are usually not used for [Biomass](#) production except in urban forests, inner-city gardens, and parks. In contrast, urban agriculture is of increasing importance in developing countries, especially in mega cities, where populations often engage in subsistence or subsidiary farming within city limits (Mugeot, 2005).

Inner-city agricultural plots are often irrigated and fertilized with sewage, which improves productivity but involves risks of food contamination (Singh et al., 2004).

Urban soils act as a biodiversity pool and gene reservoir as they comprise a great variability of ecological niches. Extreme site characteristics of urban soils such as high temperature, salinity, drought, or contaminations, as well as special carbon sources such as sewage, oil, or polycyclic aromatic hydrocarbons, can promote changes

in the abundance of rare species. (Lysak et al., 2000; Reineke, 2001).

Urban soils can still fulfill storage, filter, buffer, and transformation functions, which are of high ecological relevance as urban areas are often polluted. These soil functions may be limited due to soil sealing, conductive and sorption-low construction materials, diminished biological activity, and old contamination deposits (Nehls et al., 2008). The thickness of urban soils often increased due to deposition of materials while the groundwater often depleted due to drinking water abstraction (e.g., Mexico City). Thus, the larger soil column may filter, store and transform more pollutants, carbon, and nutrients. The higher soil pH of urban soils compared to nonurban soils may positively influence the filter and transformation function for some contaminants.

Urban soils can also provide *Raw Materials*. Apart from drinking water and water for industrial production, soil raw materials like gravel, sand, clay, minerals, and organic material are of minor relevance in urban areas. Urban soils especially function as archives of geological and archaeological heritage. For hundreds and thousands of years, cities grew on the residues of the former civilizations. Urban soils contain and preserve artifacts from every phase of settlement periods. Wood, tiles, bricks, perfume or milk bottles, ammunition, plastics, or chocolate wrappers shed light on various aspects of everyday life of former urban populations.

Definition

Machine Vision. A combination of imaging sensor and image processing to provide visual perception to machines.

Visible imaging. The application of machine vision using imaging sensors that operate within the visible region of the electromagnetic spectrum (400–700 nm).

Thermal imaging. The application of vision systems using imaging sensors that are sensitive to infrared radiation (7.5–15 μm).

Fruit robotic harvesting

Fruit and vegetable production in the USA is facing growing national and international market pressures that is affecting the economic viability of the agricultural products. Inexpensive imported produce, which freely flows in the US market, is a pressing concern resulting in the US Congress passing the Food, Conservation, and Energy Act, which provides funding for the Specialty Crop Research Initiative. This initiative is aimed toward specialty crop research, which includes fruits and vegetables, to develop science-based tools and technologies that can improve production efficiency, production quality, and postharvest operations (Burks et al., 2008).

Harvesting is a labor-intensive process and takes about 30–60% of the fruit production cost for apples and citrus. This has become a problem for farm producers with the uncertain availability of farm labor force and the increasing cost of harvesting. Mechanization of farming operation such as harvesting could solve this labor shortage dilemma and increase production efficiency (Srivastava et al., 2006). In the 1960, the mechanization of harvesting started with root and surface crops. By mid-1980, researchers developed mechanical mass harvesters for tree crops, and citrus had received much attention. Mechanical citrus harvesters remove fruit by some form of mechanical shaking applied to the tree (Brown, 2002). Some of the harvesters developed were canopy shaker, canopy pull and catch, trunk shake and catch, and continuous air shake. However, the commercial use of these harvesters has been limited mainly because of the damage to fruit and tree. Schertz and Brown (1966) recognized the

potential of individual fruit removal by mechanical means when they observed that 70–100% of oranges were visible from outside the canopy. The idea of Schertz and Brown gave way to the line of sight concept and eventually to robotic harvesting. This concept requires the detection of a fruit using an optical sensor, and then a fruit picking device can be guided along this line of sight toward the fruit.

Over the years, researchers have developed robotic harvesting prototypes for fruits like apples (Bulanon and Kataoka, 2010), cherries (Tanigaki et al., 2008), cucumbers (Van Henten et al., 2003), oranges (Plebe and Grasso, 2001; Bulanon et al., 2009), and tomatoes (Kondo et al., 1996). The robots developed by these researchers include four basic components: machine vision to detect the fruit, end-effector to detach the fruit, manipulator to extend the end-effector, and traveling system. In the following sections, we will cover machine vision systems for fruit detection, specifically visible imaging and thermal imaging.

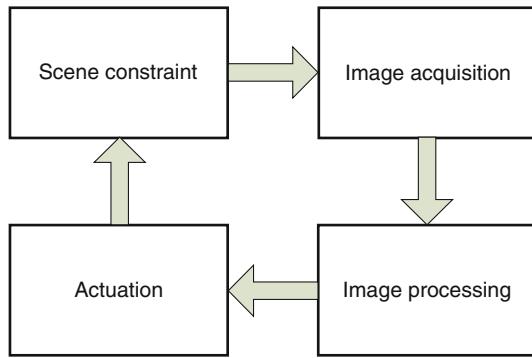

Machine vision

The first major task of a fruit harvesting robot is to recognize the fruit on the tree. Although locating the fruit on the tree is easy for human pickers, this task is challenging when applied to robotic harvesting. The robot has to locate the fruit, with variable color, shape, and size, and is randomly positioned in the tree. The robot is also subjected to various environmental conditions and usually operates under natural lighting condition. However, Parrish and Goksel (1977) demonstrated the feasibility of using machine vision to locate fruits on the tree. Since then, several researchers have used machine vision as a visual sensor to guide their harvesting robot prototypes.

Machine vision can be defined as a combination of an imaging sensor and image processing to provide visual perception to machines. The typical components of a machine vision system are lighting, image acquisition system, and a processing unit, usually a personal computer. In addition, a special software is developed to perform image processing functions. Awcock and Thomas (1996) defined a generic model for a machine vision system and this model can be adapted to robotic fruit harvesting application. The model, which is shown in Figure 1, is composed of four elements: scene constraint, image acquisition, image processing, and actuation.

Scene constraint

The scene constraint refers to the environment where the machine vision will operate. For fruit harvesting, the environment is the orchard or possibly a greenhouse. Included in the scene constraint is lighting. Lighting is a critical component in machine vision because it illuminates the object of interest. The color of an object is perceived differently depending on illumination. In the orchard, the primary source of lighting is the sun. This natural source of illumination is affected by the solar angle and cloud cover; therefore,

Visible and Thermal Images for Fruit Detection,
Figure 1 Generic model of machine vision system. The model has four elements: scene constraint (where target object is located), image acquisition, image processing, and actuation.

the machine vision implementation should take into account the lighting variability. Some researchers have supplemented their vision system with artificial lighting to eliminate lighting variation but this is still difficult to do in the field. Artificial lighting is useful for nighttime image acquisition. Results of fruit detection for nighttime-acquired images had a better performance compared to images acquired during the daytime (Sites and Delwiche, 1988).

Another component of scene constraint is the structure of the environment. In factory application, the object of interest is fixed, thus it is easy to locate. Moreover, the designer could simplify the background to facilitate image processing. However, in orchard application, the trees come in different shapes and sizes, and the fruits are randomly positioned in the tree. There are two ways to approach the unstructured condition of the orchard (Sarig, 1993). One is to adapt the robotic system to the present crop cultivation practice. The second approach to change the plant training system to adapt to the robotic system.

Image acquisition

Image acquisition is the subsystem responsible for capturing the scene into an image and saving to memory or disk, which can be processed to extract the required features. For example, in robotic harvesting, the robot needs the 3-D position of the fruit to pick it from the tree. Although the captured image provides 2-D information, there are techniques like stereo imaging that provides the depth information (Kondo and Ting, 1998).

The images can be acquired using a simple photodiode array, a monochrome or color video camera, or a thermal camera. At present, the solid-state image sensor is commonly used in robotic applications. Most monochrome and color video cameras use this type of sensor. The solid-state sensor consists of an array of photosensitive elements. One of the most popular solid-state sensor is the charge-coupled device (CCD), which has a high resolution and has a sensitivity from the visible region to the infrared region (400–1,200 nm).

On the other hand, a thermal camera or an infrared camera images the emitted infrared radiation from a scene. The sensor of a typical thermal camera consists of an array of infrared sensitive detectors known as microbolometer. When infrared radiation strikes a microbolometer, the radiation changes its electrical resistance, which can be measured, and creates the thermal image.

Image processing

After the image is acquired, the next task is to extract the features. Image processing is a technique to manipulate images with the goal of enhancing the image for human consumption or extracting useful information from the image (Castleman, 1996).

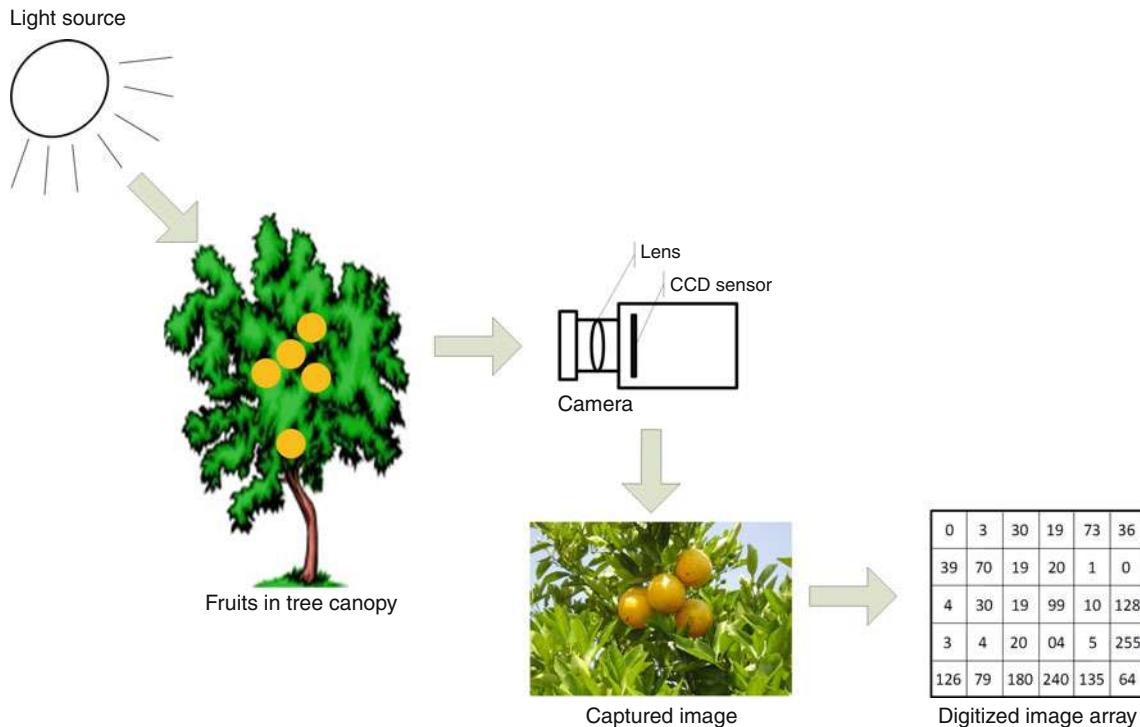

For robotic fruit harvesting application, the goals of image processing are to recognize the fruit and determine its position. The image processing for robotic application has four steps: preprocessing, segmentation, feature extraction, and classification. Preprocessing involves the manipulation of the image to make it suitable for the subsequent operation. Examples of preprocessing are cleaning up noise in the image and separating the red, blue, and green channels of a color image, or transformation from spatial domain to frequency domain. The next step, which is segmentation, is the most critical stage in fruit recognition. Segmentation separates the fruit from the background such as leaves, branches, sky, and ground. In the simplest case, the image is separated into a fruit region and a non-fruit region. Thresholding is one of the widely used segmentation techniques especially if the object has a different intensity than the background (Gonzalez and Woods, 1992). After the fruit is separated, the features of the fruit region are extracted. These are the area, perimeter, radius, and the number of the fruits. These features are used to guide the approach of the robot toward the fruit.

Actuation

Actuation completes the machine vision system model. It is the response of the system to the scene. When applied to robotic fruit harvesting, first the robot explores the scene and looks for mature high-quality fruits. Second, when the fruit is found and its position is determined, the robot approaches the fruit using the information from the image. This method of using an image to control robot motion is known as visual servoing (Spong et al., 2006).

Visible imaging

Figure 2 shows the basic process of visible image acquisition in the field. A light source, usually the sun, provides the source of illumination. Artificial light source may also be used when natural lighting is not available. When the canopy is illuminated, the light is reflected and the intensity of the reflected light, which is primarily dependent on the spectral characteristic of the object, is sensed. The captured image is then converted to an array of numbers, which can be manipulated to extract the important features, in this case the fruit.

Visible and Thermal Images for Fruit Detection, Figure 2 Visible imaging in the orchard under natural lighting condition. Spectral reflectance of the canopy is captured by a visible imaging sensor and processing the image to produce a matrix of the numerical representation of the scene.

In visible imaging, the machine vision system is operating in the visible region of the electromagnetic spectrum. The visible region ranges from 400 to 700 nm. Operating in the visible region works very well for fruits that have contrasting color compared to their canopy. Investigation of the spectral reflectance of orange fruits and leaves showed that the mature orange fruit has a different spectral reflectance than the leaf within the visible region specifically at 680 nm, which is the chlorophyll absorption band. It is well established that plants need light for photosynthesis, which is mostly the red and blue light; thus, the leaves reflect the green light (Kondo and Ting, 1998).

Taking advantage of the plant's reflectance properties, researchers used imaging sensors that are sensitive in the visible region. The first published attempt to apply visible imaging for fruit detection was reported by Parrish and Goksel (1977). They used a black and white camera combined with a red filter. The red filter allowed the camera to capture the red wavelength portion of the scene. Sites and Delwiche (1988) also used a monochrome camera supplemented with several different wavelength filters to detect peaches and apples. When color CCD cameras came out to the market, Slaughter and Harrel (1989) were the first of several researchers who used color cameras instead of specific wavelength filtering the scene. They used the color features of citrus fruits combined with a statistical pattern approach to segment the image. Using color has the

advantage of obtaining three bands, which are the red, green, and blue, of the scene instantaneously.

Image processing for visible images

In order to recognize and locate the fruits, the images need to be processed. Jiminez et al., (2000) categorized the basic approaches to image processing for fruit detection into two main groups: local-based and shape-based. These approaches are based on the extracted features used to detect the fruit.

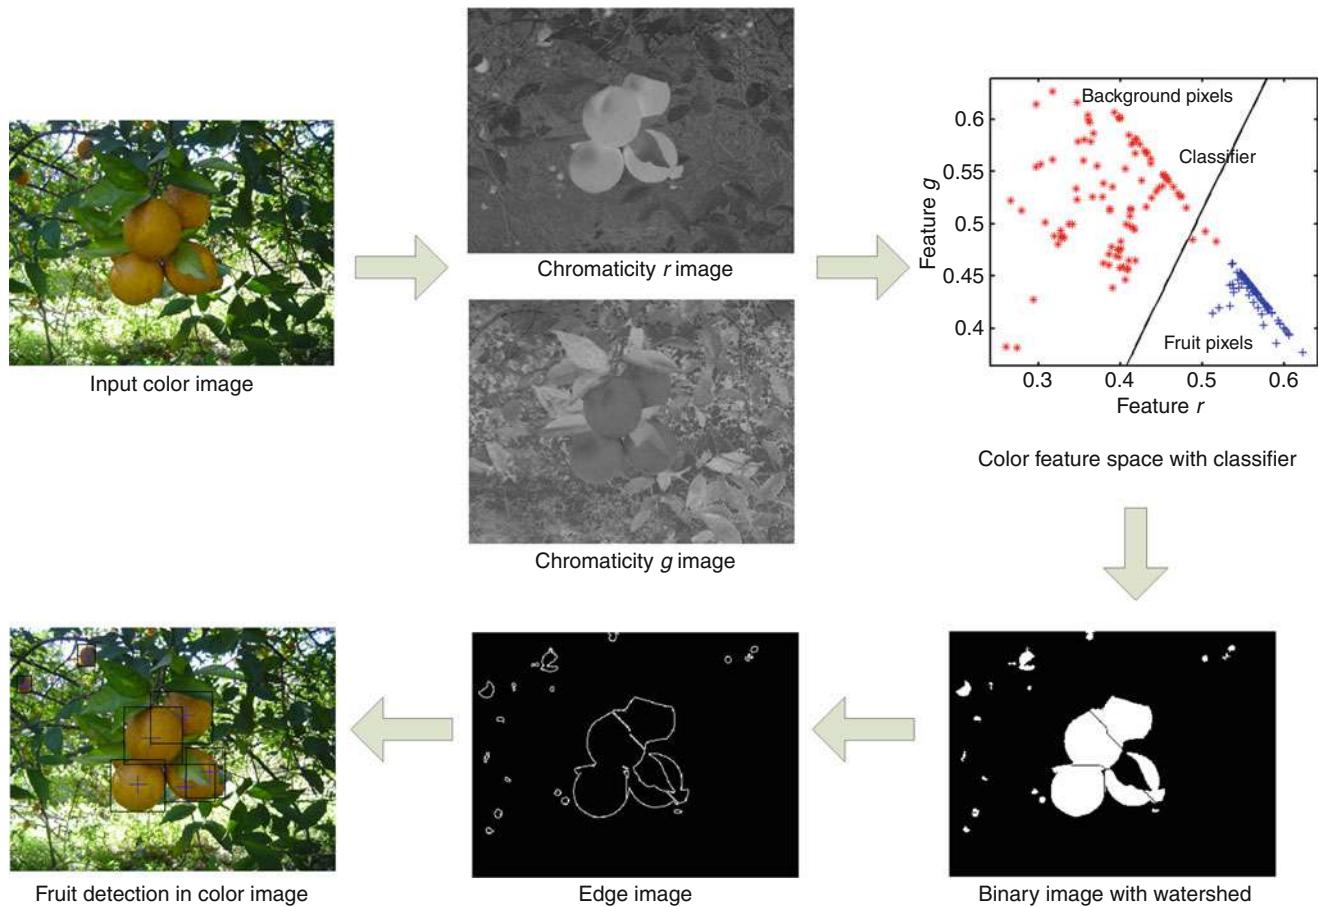

Local-based approach uses the value associated with each image pixel to determine whether it belongs to the fruit class or the non-fruit class (background). For a monochrome camera, the pixel value is based on intensity only, while pixels for color cameras are a function of the red, green, and blue values. These parameters (intensity and RGB) are used in an image segmentation technique to divide the image into regions of identical properties. Generally, for intensity images, the gray level thresholding is used to segment the fruit from the background. This thresholding operation uses the statistical properties of the image (e.g., gray level histogram) to segment the fruit from the image. Also, it requires that objects and background have different levels of intensity. Gray level thresholding is easily implemented in hardware and can be very fast. However, fruit and background are not easily segmented in the orchard.

The color segmentation method is a much better approach than gray level thresholding. However, the challenge of using color segmentation is to determine a group of color characteristics and a pattern recognition technique that would result in an efficient segmentation. Color can be represented using several color models (Gonzalez and Woods, 1992). The RGB color model represents any color using a combination of the three primary colors, red, green, and blue. Another color model that is used is the chromaticity model, which uses the chromaticity coefficients to describe hue and saturation. The chromaticity coefficients are defined as ratio between the intensity of one of the primary colors and the sum of all three. Once the color model is established, the next step is to develop a pattern recognition technique, which uses the color parameters as pattern, to segment the image into fruit class and non-fruit class. Statistical approaches such as linear discriminant classification and Bayesian classifier, and nonstatistical techniques like artificial neural networks are some of the pattern classification methods that have been successfully tested (Burks et al., 2000).

While the local-based approach depends on each pixel value, shape-based approaches analyze edge properties of region that form circular arcs to take advantage of the spherical shape of most fruits. The Circular Hough Transform is commonly used to find circular objects in the image. However, results of shape-based approaches for fruit detection are characterized by significant false detections. Illumination, transitions, shadows, and fruit and leaf occlusions are some of the factors that cause false detection (Plebe and Grasso, 2001).

A visible imaging system for orange fruit detection

In this section, a machine vision system for orange fruit detection is shown here as an example of developing a machine vision system. The machine vision system is composed of a 24-bit color CCD camera that has resolution of 640×480 pixels. The camera is connected to a personal computer through a frame grabber board. Solar lighting provided the source of illumination. The fruit detection process, which is shown in Figure 3, starts with

Visible and Thermal Images for Fruit Detection, Figure 3 Image processing for fruit detection using visible imaging. The chromaticity r and g images of the RGB image is calculated, which enhances the fruit. A linear discriminant classifier can be derived from the chromaticity plot and this can be used to segment the image (binary image). Digital image processing techniques such as watershed algorithm, edge extraction, and blob analysis are combined to detect the fruits in the image.

the color image acquisition. Using the RGB values, the chromaticity r gray level image and the chromaticity g gray level image were created. These two chromaticity coefficients enhance the fruit in the image and they are robust to varying lighting conditions. When the color properties of the fruit and the leaf background were plotted using these two color features, a linear discriminant classifier could be easily derived. The linear classifier was used to separate the fruit from the background, which is shown in the binary image. After segmenting the fruit, a filtering operation removed noise and small segmented regions. Then we applied a watershed algorithm (Gonzalez and Woods, 1992) to separate the fruits in clusters and identify individual fruits. Once the fruits were separated, we extracted the edge of the segmented region and analyzed the circular properties (e.g., radius) of the edge. This edge analysis allows us to detect circles in the region and ultimately detect the location of the fruit in the image. This image processing algorithm is a combination of both local-based and shape-based approaches. It has the advantage of dealing with the illumination problems by using the chromaticity color model, which decouples intensity and solves the problem of occlusion by using the spherical properties of the orange fruit. A similar image processing approach was also applied for the detection of apple fruits with minor modifications in the discriminant's classifier coefficients, and it had good fruit detection performance (Bulanon et al., 2001).

Thermal imaging

In contrast to visible imaging, thermal imaging does not rely on a light source to acquire an image. Instead, thermal imaging uses the electromagnetic radiation emitted from an object, processes the data, and produces a pseudo-image of the thermal distribution of the object. All objects, which have temperature greater than absolute zero, emit thermal radiation. The total amount of thermal radiation is expressed by the Stefan–Boltzmann Law:

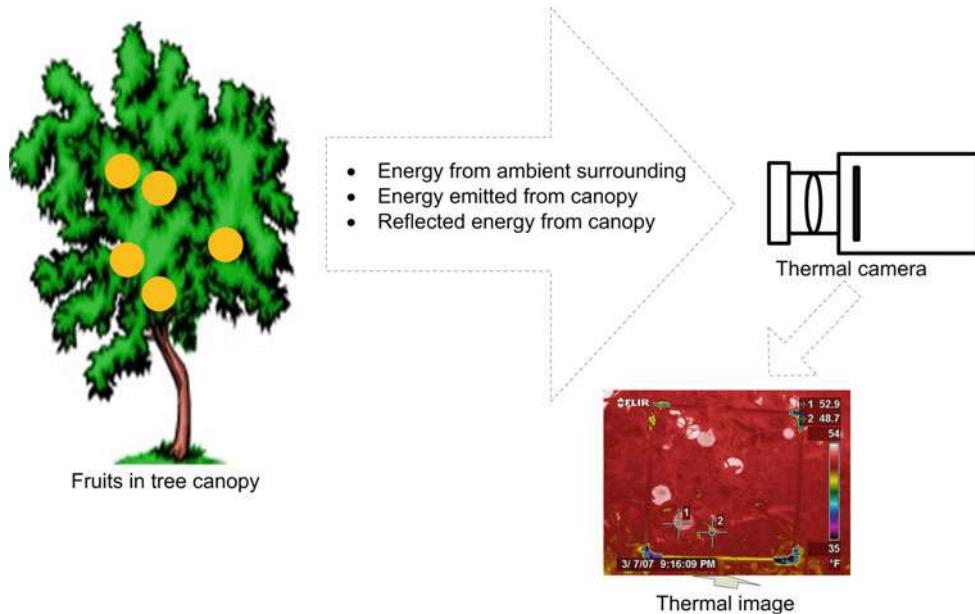

$$E = \varepsilon\sigma T^4 \quad (1)$$

where E is the emitted thermal radiation, ε is the emissivity of the object, σ is the Stefan–Boltzman constant, and T is the absolute temperature. The measurement of the emitted thermal radiation can be used as an indicator of the temperature of the emitting object. This is the underlying concept behind thermal imaging.

When applying thermal imaging to detect fruits in the orchard, other variables aside from the emitting object are taken into consideration. Figure 4 shows the thermal imaging process for fruit detection. The total radiation, E_{total} , received by the camera is:

$$E_{\text{total}} = \varepsilon E_{\text{canopy}} + (1 - \varepsilon)E_{\text{ref}} + (1 - \tau)E_{\text{atm}} \quad (2)$$

where E_{canopy} is the radiation emitted by the canopy (fruit, leaf, and branches), E_{ref} is the radiation from the surrounding environment, which is reflected by the canopy, ε is the emissivity of the canopy, E_{atm} is the radiation emitted by

Visible and Thermal Images for Fruit Detection, Figure 4 Thermal imaging in the orchard. The thermal camera senses the infrared radiation of the canopy including the radiation from the surrounding environment and its reflected radiation. A pseudo-RGB image of the temperature distribution of the canopy is created and this can be used to analyze the thermal variation of the scene.

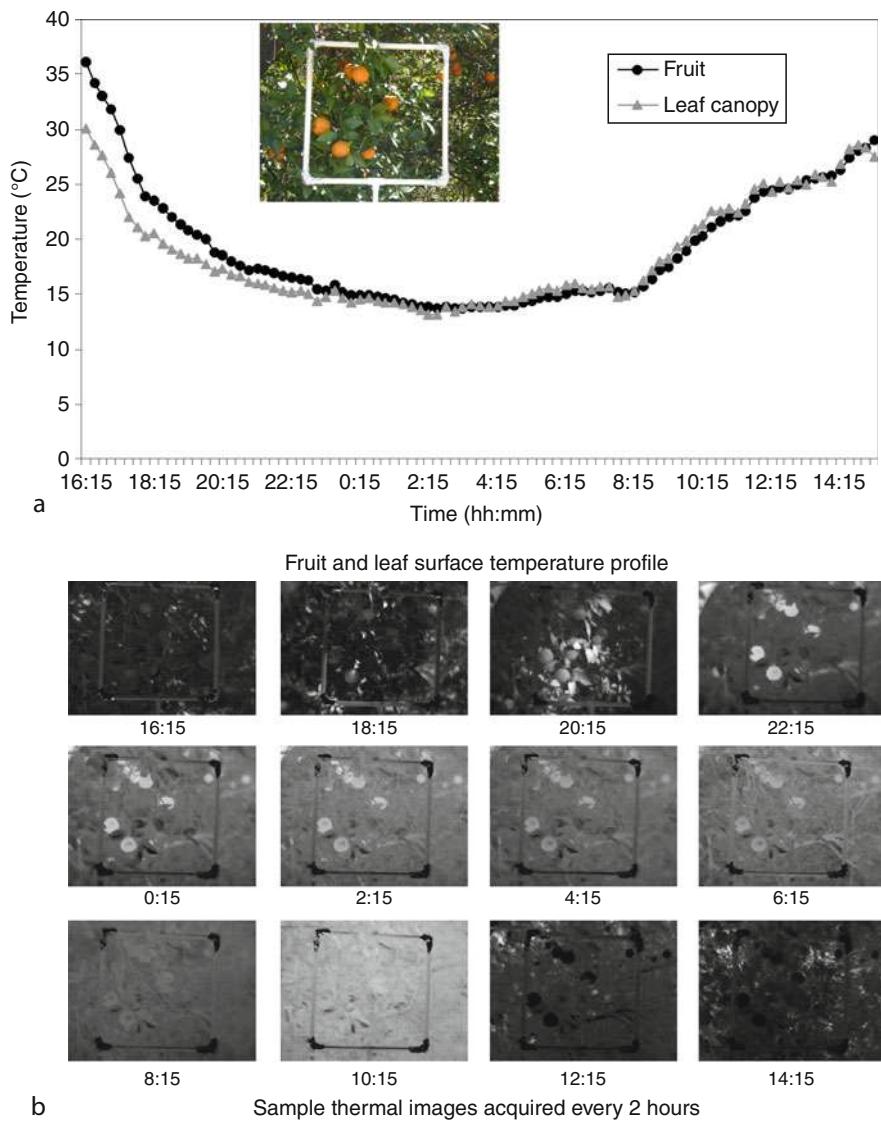

the surrounding environment, and τ is the transmittance of the ambient surrounding. And since we are interested on the fruit, which is part of the canopy, the emitted reflectance of the canopy can be expressed as:

$$E_{\text{canopy}} = \frac{E_{\text{total}}}{\varepsilon} - \frac{(1-\varepsilon)}{\varepsilon} E_{\text{ref}} - \frac{(1-\tau)}{\varepsilon} E_{\text{atm}} \quad (3)$$

which is the general measurement formula to create a thermal image.

Since we are interested in detecting the fruit using the thermal image, there should be a temperature variation between the fruits and the other parts of the canopy such as the leaves to differentiate the fruit using temperature. **Figure 5a** shows a typical 24-h temperature profile

between the fruit and the leaf of an orange canopy. The profile is comparable to a half sinusoid where the temperature rises in the morning until early afternoon and falls from mid-afternoon until early morning. There is not much difference between the fruit and leaf temperature in the early morning until early afternoon; however, temperature variation appears in the mid-afternoon and continues until late in the evening. **Figure 5b**, which are sample images taken over a 24-h-period, shows that the fruits are visible when the temperature of the fruits and the leaves are different. This temperature variation is due to the difference of heat capacity between the two objects and we can take advantage of this phenomenon to detect the fruit using thermal imaging. In the yield monitoring system for apples, Stajnko et al., (2004) acquired apple

Visible and Thermal Images for Fruit Detection, Figure 5 Sample thermal imaging in the field (a) Typical surface temperature profile of fruits and leaves (b) Sample thermal images acquired within a 24-h-period at 2-h-interval.

fruit images late in the afternoon to enhance the detection of fruit in the thermal images.

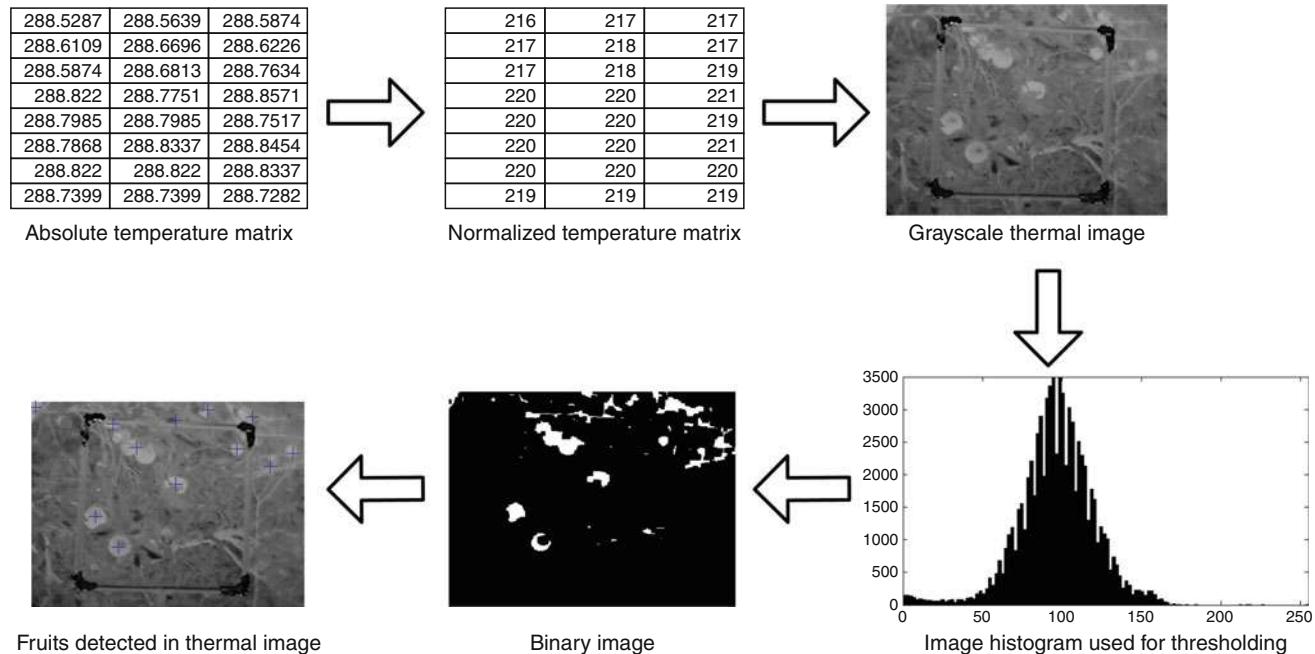

Thermal image processing for fruit detection

The raw data obtained from a thermal camera is a temperature array of the thermal distribution of the object's surface. Transforming this temperature array into an image format is required to create a thermal image and extract the relevant features of the object. [Figure 6](#) shows the flowchart of the digital image processing approach for thermal images. Although this flowchart was designed for orange fruit detection, this could be adapted for other applications as well. First, the raw data of 320×240 matrix of absolute temperature values is converted to an 8-bit gray level image. This transformation allows us to operate on the image using digital image processing techniques. By visual examination of the histogram and knowing that the fruit is warmer than the leaves, we used a thresholding technique called the "histogram-tail" method where the threshold is the sum of the mean intensity of the image and the standard deviation. Pixels with values greater than the threshold were designated as fruit pixels, and pixels below the threshold were marked as background pixels. After thresholding the image, standard digital image processing techniques such as blob analysis, labeling, perimeter and centroid detection are applied to detect the size and position of the individual fruits. Using this method, a fruit detection rate of 0.70 was achieved with a false detection rate of 0.06 ([Bulanon et al., 2008](#)).

Fusion of visible and thermal images

We have seen the potential of visible imaging to detect the fruit especially if it has a color contrast with the canopy. By using thermal imaging, fruits can also be detected provided there is a temperature difference within the canopy. Both imaging systems has its advantages and disadvantages. Thermal cameras do not require a light source for illumination; however, the fruit and the canopy must have a temperature variation. This variation is not constant and changes throughout the day. On the other hand, visible imaging requires illumination and in the orchard, illumination is mainly dependent on natural lighting. The changing solar angles and cloud cover causes lighting variations making fruit detection challenging. Nevertheless, we can combine the advantages of both imaging systems using image fusion.

Image fusion is a branch of multi-sensor fusion where the main goal is to combine information from two or more images of a scene into a single composite image ([Blum and Liu, 2006](#)). The images could come from the same or different sources, for example, combining a visible image and a thermal image. There are several image fusion techniques. These techniques can be classified as being pixel level, feature level, and symbolic level. At pixel level, the fused image is created by combining the individual pixels of the source images. Pixel correspondence between the source images is required for this method; thus the source images are registered prior to fusion. At feature level, feature from the source images are extracted and then combined to generate a new image.

Visible and Thermal Images for Fruit Detection, Figure 6 Image processing for fruit detection using thermal imaging. The temperature matrix is converted to a gray level image. The thermal gray level image can now be processed using techniques applied to RGB images. In this figure, a simple thresholding approach was implemented to compute the binary image and then blob analysis was used to detect the fruit.

Symbolic level fusion refers to processing the source images individually to acquire information and then use a higher level decision technique to combine the information.

Figure 7 shows a flowchart of image fusion to detect fruits using fuzzy logic (Bulanon et al., 2009). Fuzzy logic is widely used in control applications. Using fuzzy logic in image fusion is similar to a weighted averaging approach where the weights are determined using the fuzzy logic inference engine. The first step is fuzzification to convert the source images into information that can be applied to the fuzzy logic fusion rules. The two input membership functions, one for each source image, perform the fuzzification. Then we combine the fuzzified images using the fuzzy fusion rules as follows:

If (thermal is warm) then (fused is fruit)
 If (visible is red) then (fused is fruit)
 If (thermal is cold) and (visible is red) then (fused is fruit)
 If (thermal is average) then (fruit is non-fruit)
 If (visible is non-red) then (fruit is non-fruit)

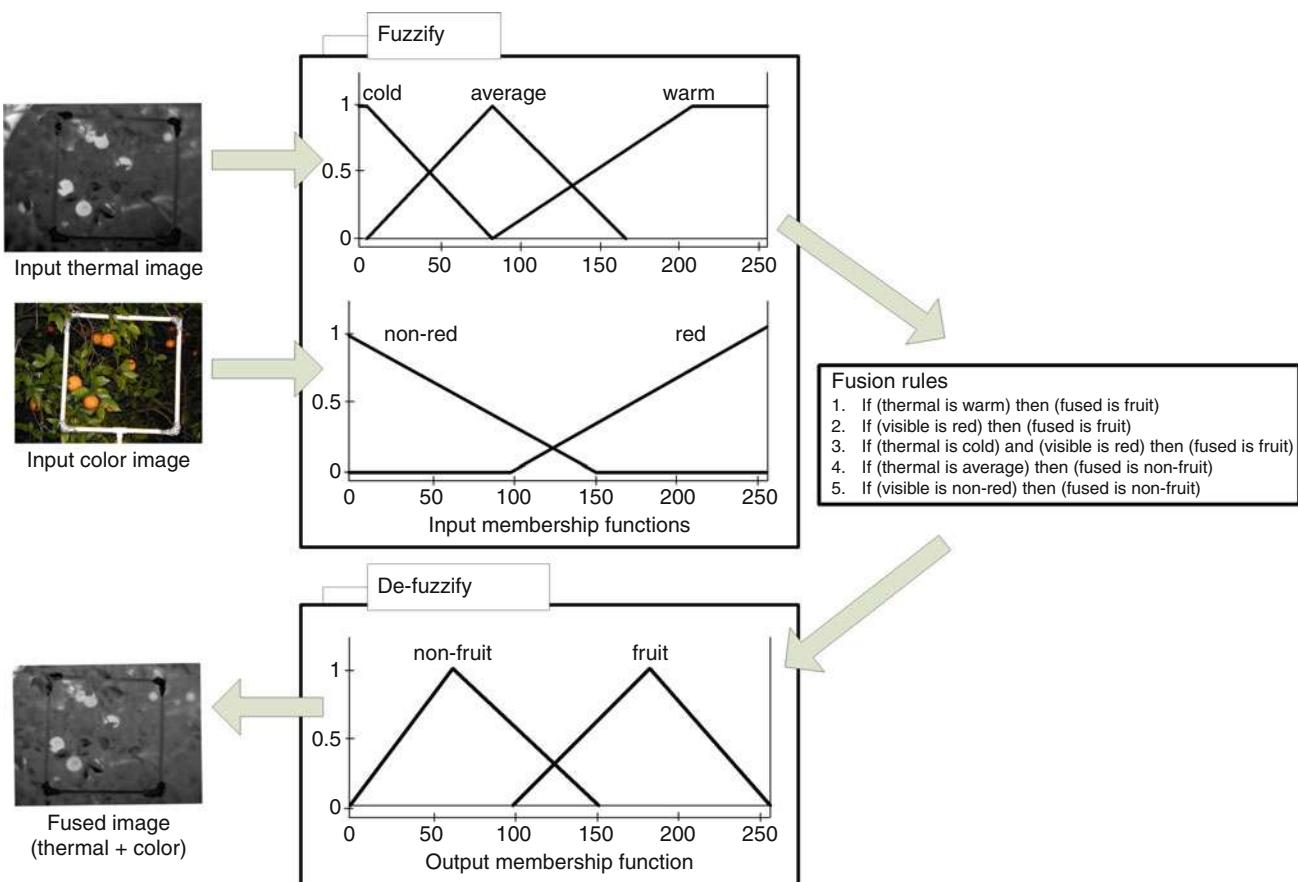

After applying the rules, defuzzification using the output membership function created the fused image.

We found that fruit detection was improved when image fusion was applied. Although there are other fusion techniques available, fuzzy logic is an intuitive approach to combine the thermal and visible images. The membership functions and the fusion rules, which are based on heuristics, closely resemble how humans approach a problem.

Image fusion will play an integral part in future orchard management and planning. Several studies have established the potential of thermal imaging like determining crop stress, irrigation requirement, and disease detection (Alchanatis et al., 2006). Combining these thermal images with other information using fusion techniques will be an effective tool for decision making.

Multispectral imaging

Multispectral imaging is another type of imaging system that has gained increasing popularity in the field of remote sensing, defense, medical field, manufacturing, and agriculture. This imaging system acquires images over contiguous narrow-wavelength intervals across the visible and near-infrared regions and can generate a pixel-level reflectance spectra. Each image is often referred to as a band

Visible and Thermal Images for Fruit Detection, Figure 7 Fusion of visible and thermal images for fruit detection using fuzzy logic. The source input images, color and thermal, are fuzzified so that they can be combined using the fusion rules. These fusion rules were based on the properties of the fruits and its background. The combined data is defuzzified to produce the fused image.

or a channel. Multispectral images contain information about a number of spectral bands where the human eye fails to capture.

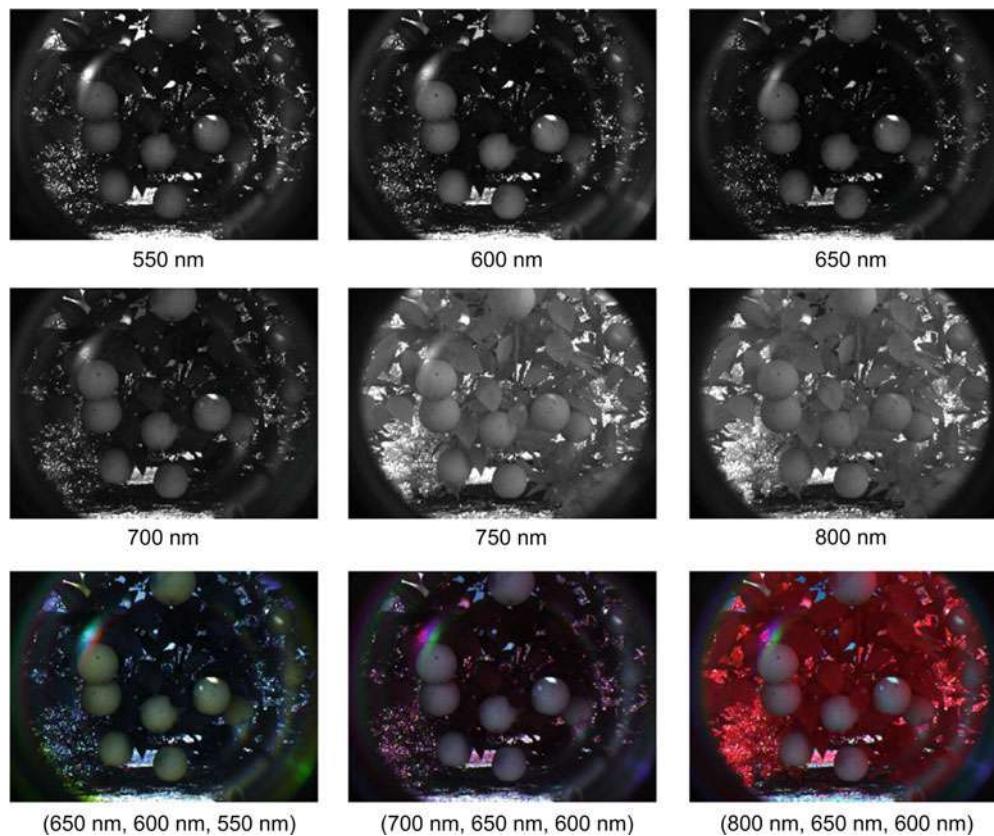

The simplest way to acquire multispectral images is a combination of a CCD monochrome camera and several narrow or broadband optical filters. The images can then be processed using conventional digital image processing. Other methods of obtaining multispectral images are by using a liquid crystal tunable filter, an acoustic-optic tunable filter, a common aperture multichannel imaging camera, and hyperspectral imaging.

Multispectral imaging for fruit detection

Bulanon et al., (2010) developed a multispectral imaging system to detect mature orange fruits. The imaging system was composed of a 12-bit monochrome CCD camera fitted with a filter wheel that holds six optical band-pass filters with central wavelengths of 550, 600, 650, 700, and 800 nm and each filter has a bandwidth of 50 nm. The selection of these filters was based on the high discriminability between fruit and leaf within this region. A sample scene of an orange canopy taken with this multispectral imaging system is shown in Figure 8. The first

six images are the individual bands and the last three are different combinations of three bands, which are pseudo-RGB images. In all the bands the fruits have high reflectance while the leaves have low reflectance in the visible bands. When the visible bands are combined with a near-infrared band, the different plant parts and the background can be easily distinguished.

As compared to visible imaging and thermal imaging, multispectral imaging has more images to deal with. One effective approach to reduce the number of features while increasing the variance is principal component analysis (PCA). PCA is a projection method used to analyze the variance of a multivariate dataset to simplify and reduce dimensionality. However, the loss of dimension does not cause any loss of information. The projection (principal component) is calculated by obtaining the eigenvectors of the covariance matrix of the multispectral images. In our study, the first three principal components were used as input to an artificial neural network that was developed for fruit detection. A fruit detection rate of about 0.90 was achieved. In an analysis of the weights of the principal components combined with feature selection, three wavelengths were found to effectively discriminate the fruit from the background: 600, 650, and 700 nm.

Visible and Thermal Images for Fruit Detection, Figure 8 Sample multispectral images acquired in the orchard under natural lighting condition. The first six images are the individual bands and the last three are different combinations of three bands, which are pseudo-RGB images.

Summary

Robots will play an integral role in the future of agriculture to maintain food sustainability and economic viability. An important component of the robot is its visual sensor, to be able to perceive its environment and interact with it. In the development of robotic fruit harvesting, recognizing and locating the fruits is the first task of the robot. Integrating visual sense to robots can be done using machine vision. Vision systems for apple, cherries, cucumbers, oranges, peaches, and tomatoes have been developed to guide robotic harvesting prototypes. Since most of the fruits have colors different from their background, sensors for detecting the fruit use the visible region of the electromagnetic spectrum. Once the image of the fruit is acquired, digital image processing combined with pattern recognition techniques detects and locates the fruit in the image and uses these 2-D information to determine the 3-D location of the fruit to guide the robot. Aside from spectral reflectance, the thermal radiation of the fruit can also be used to differentiate it from the leaves. Thermal cameras are able to image the infrared radiation of the canopy and transform the data into a thermal image that can be processed using digital image processing. Other than visible and thermal imaging, multispectral imaging is an emerging technology in agriculture. Multispectral imaging acquires images of a scene at different wavelengths, determined to have a high discriminability between fruits and the background. The detection of fruits using these imaging systems is critical to the success of the fruit harvesting robot development. Furthermore, these imaging systems have the potential to become as one of the tools used for agricultural management such as disease scouting, yield monitoring, and pesticide application.

W

WATER APPLICATION EFFICIENCY

The net amount of water added to the root zone as a fraction of the amount applied to the field. Surface irrigation methods such as flooding or furrowirrigation may result in runoff and/or in percolation beyond the root zone, thus reducing the application efficiency. Sprinkling irrigation may involve losses due to wind-drift. Microirrigation methods, if well managed, offer the potential for relatively high application efficiency.

WATER BALANCE IN TERRESTRIAL ECOSYSTEMS

Joanna Sposób
Department of Hydrography, Institute of Earth Sciences,
Maria Curie-Skłodowska University, Lublin, Poland

Synonyms

Hydrologic budget; Hydrologic cycle; Hydrologic equation

Definition

Water balance. The cyclical movement of water between the atmosphere and the ground surface, considering precipitation, evaporation, and runoff (Whittow, 1984).

Water balance equation. Equation presenting elementary parts of water balance: precipitation, evapotranspiration, and runoff, expressed as volume of water.

Terrestrial ecosystem. The continental as distinct from marine and atmospheric ecosystem.

Ecosystem. Ecological system formed by the interaction of all living organisms with each other and with the chemical and physical factors of the environment in which they live, linked by the transfer of energy and materials (Clark, 2003, p. 130).

Introduction

The hydrological cycle is the occurrence and movement of all waters above, on and below the Earth's surface. Nearly all water is continually in motion and it obeys basic universal laws – especially the principle of mass conservation. The water balance equation for a river catchment (terrestrial ecosystem) indicates the relative values of inflow, outflow, and change in water storage for the area. The water balance equation components may be expressed as a mean depth of water over the basin or water body (mm), as a volume of water (m^3), or in the form of discharge ($\text{m}^3 \cdot \text{s}^{-1}$) (Scientific framework of world water balance, 1971; Sokolov and Chapman, 1974). The hydrologic cycle is the term applied to the general circulation of water, but the term the runoff cycle describes portion of the hydrologic cycle between precipitation over land areas and subsequent discharge through river channels or direct return to atmosphere through evapotranspiration (Linsley et al., 1949).

Development of the water balance concept

The first quantitative approach, based on the water balance concept, was that of P. Perrault in 1674, who showed that the annual volume of precipitation on the River Seine basin in France was at least seven times the volume of discharge of the river. He also correctly established the concept of the allocation of precipitation as evaporation, transpiration, runoff, and groundwater recharge. In 1802, J. Dalton inquired into the quantitative relations between precipitation, evaporation, and runoff, he also was the first one

who determined the water balance of England (Scientific framework of world water balance, 1971). The problem of water balances also attracted much attention of Russian scientists S. G. Gmelin, M. V. Lomonosov, P. I. Rychkov, and others (Scientific framework of world water balance, 1971) who were concerned with the water balance of the Caspian Sea basin. After the invention of reliable velocity meters in the nineteenth century, discharge measurements were systematized. This permitted more effective study of the relations among hydrological parameters of the river basins. In 1894, F. H. Newell presented a direct relation between runoff and precipitation and prepared maps showing their mean values in the USA.

A. Penck in 1896 and E. V. Oppokov in 1906 made some theoretical generalizations and were the first to develop a water balance equation (known under the name Penck–Oppokov equation) for river basins:

$$R = P - E \pm \Delta G \quad (1)$$

or, after modification:

$$P = R + E \pm \Delta G \quad (2)$$

where: R – runoff; P – precipitation; E – evaporation; and G – ground water (Scientific framework of world water balance, 1971).

Oppokov also introduced the term of the catchment retention, which was equal to ground retention. Thus, it was denoted in the form

$$P + S_1 = R + E + S_2 \quad (3)$$

or

$$P = R + E \pm \Delta S \quad (4)$$

where: P – precipitation; R – runoff; E – evaporation; S_1 – the state of retention at the beginning of the balance period; S_2 – the state of retention at the end of the balance period; ΔS – variations of retention.

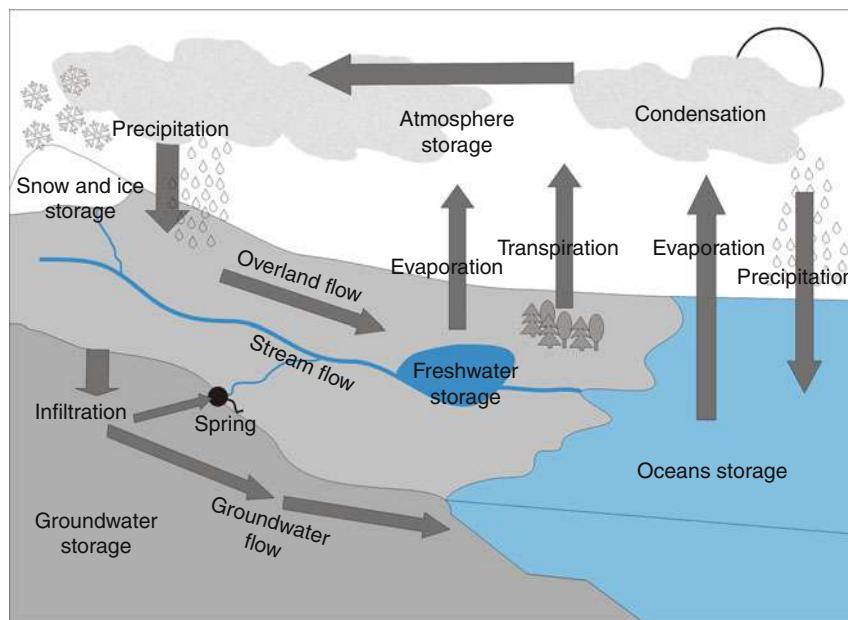

For a long time, water balance equation was treated in the form described above (Equations 3 and 4), which was developed by M. I. Lvovich (Scientific framework of world water balance, 1971) and C. Dębski (1963), who introduced two more parts: surface and ground runoff. Thus, the water balance equation can be expressed as the formula

$$P = R_g + R_s + E \quad (5)$$

where: P – precipitation; R_g – groundwater flow; R_s – overland flow; E – evaporation.

Global water balance

Global water balance comprises circulation of water between atmosphere, lithosphere, and hydrosphere. Water from the surface of oceans is evaporated into the atmosphere (Figure 1). This vapor is condensed by various processes, and falls as precipitation on the seas (80% of total), and the remaining 20% the lands. A portion of that precipitation falling on the land is retained temporarily in the soil, in surface depressions, and on vegetation and other objects until it is returned to the atmosphere by processes of evaporation and

Water Balance in Terrestrial Ecosystems, Figure 1 Global water circulation.

transpiration, or generally evapotranspiration. The remainder, moving by devious surface and underground channels to rivers, lakes, and eventually to the sea, is likewise subject to evaporation and transpiration throughout its travels.

Hydrological cycle is also determined as water balance equation. Water cycle for the Earth is characterized by balance between precipitation and evaporation:

$$P = E \quad (6)$$

where: P – total precipitation falling on seas and lands; E – total evaporation from the seas and lands surfaces.

Each phase of hydrological cycle can be described as separate water balance equation. For land phase of water cycle, it can be as follows:

$$P_L - E_L - R_L = \Delta S_L \quad (7)$$

where: P_L – total precipitation on the land surface; E_L – total evaporation from the land surface; R_L – total runoff from lands to seas; ΔS_L – changes of water retention on lands.

Following parts of the water balance can be denoted for oceanic phase of the cycle

$$P_O - E_O + H_L = \Delta R_O \quad (8)$$

where: P_O – total precipitation on the ocean surface; E_O – evaporation from ocean surface; R_L – total runoff from lands; ΔS_O – changes of water retention in the ocean.

In accordance to modern estimates, the Earth's hydrosphere contains amount of water of about 1,386 million cubic kilometers. However, 97.5% of this amount are saline water and only 2.5% fresh water. The greater portion of the fresh water (68.7%) is in the shape of ice and permanent snow cover (Table 1).

Water Balance in Terrestrial Ecosystems, Table 1 Global water distribution (Shiklomanov, 1993)

Parameter	Volume (km^3)	Percent of freshwater	Percent of total water
World oceans	1,340,000,000	–	96.5
Glaciers	24,064,000	68.7	1.74
Groundwater	23,500,000	–	1.7
Soil moisture	16,500	0.05	0.001
Permafrost	300,000	0.86	0.022
Lakes	176,400	–	0.013
Atmosphere water	12,900	0.04	0.001
Wetlands	11,500	0.03	0.0008
Rivers	2,120	0.006	0.0002
Biological water	1,120	0.003	0.0001
Total	1,386,000,000	–	100

Rhythm of the water cycle in the catchment – the runoff cycle

In the hydrological cycle of the ecosystem can be considered in four phases determined by the rhythm of precipitation. Presented cross section (Figure 2) shows part of the catchment – stream valley and adjacent areas in a humid climate, assuming the absence of snow, ice or frost (Linsley et al., 1949).

I phase of the cycle: end of dry period

All surface and channel storage resulting from the last previous rainfall has been depleted, except for that in reservoirs, lakes, and ponds. The only source of streamflow is groundwater feeding the channel from groundwater resources (Figure 2a). The streamflow, known also as base or sustained, has decreased with time in accordance to the storage depletion curve, slightly modified by transpiration from vegetation along the stream bank and evaporation from the stream surface. Evapotranspiration and discharge from subterranean storage result in gradual lowering of the groundwater table. If the dry period has been sufficiently long to allow the water table to drop below the level of the stream channel at all points above the cross section, streamflow ceases (Linsley et al., 1949).

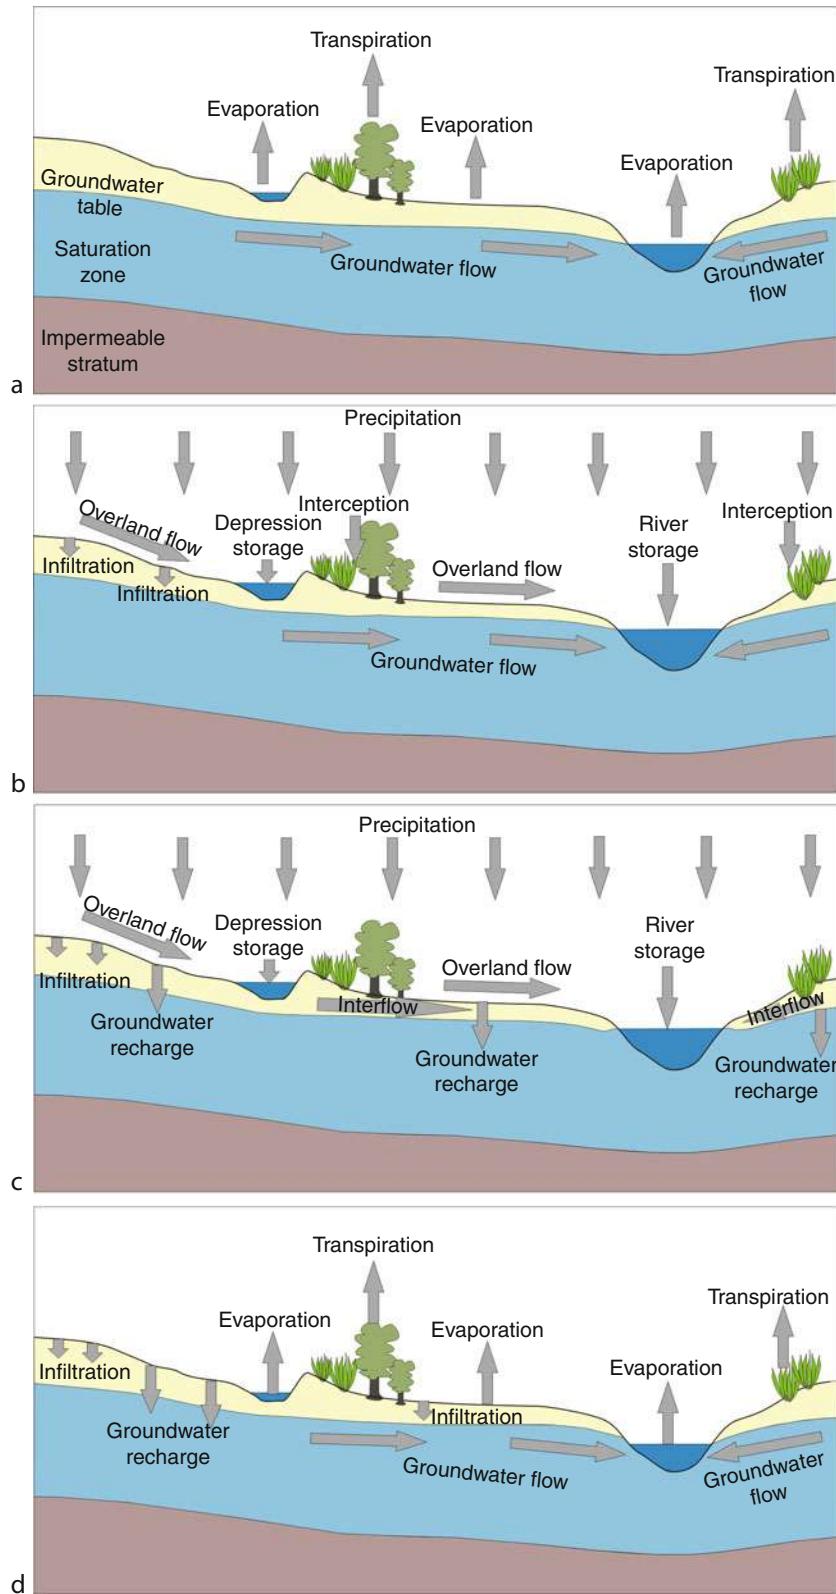

II phase of cycle: after beginning of rainfall

Part of the rain intercepted by vegetation (Figure 2b) does not contribute to runoff, but can be eventually returned to the atmosphere through transpiration. Most of the rain reaching the ground surface is retained on the surface as depression storage or passes through the soil surface as infiltration. Once below the surface, the water begins to satisfy the soil-moisture deficiency, which has gradually built up in the aeration zone during the dry period.

During the initial stage of rainfall, overland flow occurs only from impervious areas (urban roads, roofs, and other surfaces), and extremely steep slopes. On the most of the area, infiltration, interception, and depression storage preclude overland flow unless the intensity of rainfall is very great (torrential rains). The rate of groundwater flow during the initial stages of the storm is probably about the same as just prior to the beginning of rainfall. Flow may or may not be taking place, depending on the elevation of the groundwater table with respect to the water surface in the channel. High humidity is the reason for extremely slow rates of evaporation and transpiration as compared with those under fair-weather conditions.

III phase of cycle: near end of rainfall

After many hours of heavy rainfall, all depression and interception storage is filled, the soil-moisture deficiency is satisfied to considerable depths, and the infiltration rate is near a minimum (Figure 2c). The vegetation is saturated, and rain falling on it is balanced by an equal amount

Water Balance in Terrestrial Ecosystems, Figure 2 Water balance in the catchment.

falling from the vegetation to the ground, except for the small quantity being returned to the atmosphere through evaporation. The flow into filled surface depressions is essentially balanced by overland flow and infiltration.

Overland flow is taking place over nearly the entire basin, and streamflow is beginning to bear some relation to the rate of precipitation. Subsurface flow is contributing to stream discharge, and subterranean storage is being replenished in some portion of the basin.

IV phase of cycle: after end of rain

Rainfall and overland flow have ceased and that streamflow is composed of groundwater and channel storage. Evaporation is taking place at an active rate from soil moisture and depression and interception storage (Figure 2d). Transpiration has begun to take place from vegetal cover. Water in surface depressions is continuing to enter the soil mantle through infiltration, while gravity water within the aeration zone continues to replenish subterranean storage. The groundwater table is either raising or falling, depending on whether the downward-percolation rate exceeds the rate at which groundwater is contributing to streamflow.

Summary

Water balance in terrestrial ecosystems is the cyclical movement of water between the atmosphere and the ground surface in the water divide of the catchment. It can be presented in the form of water balance equation concerning elementary parts of water circulation: precipitation, evapotranspiration, and runoff.

Water balance in soils; Hydrologic budget or balance

Definition

Water budget – the quantification of water volume and water fluxes in soils.

Introduction

This entry deals with the quantification of the water balance in soils using mathematical models. Topics such as the measurement and modeling of soil hydraulic properties, direct measurement of soil moisture, and water fluxes are deliberately not dealt with in this entry. Moreover, we focus explicitly on the hydrological processes relevant at the point and field scale, while deliberately letting apart catchment scale and stream hydrological processes. Also, precipitation is considered an input to the soil, and measurement and modeling of rainfall, snowfall, accumulation, and melting are not a topic of this entry. References to these topics are provided at the end of this entry. We rather focus here on the definition of soil hydrological properties determining the distribution of water within a soil profile, the identification and quantification of the different types of water flows within the soil, and their interplay in the definition of the soil water budget. The soil water budget can be calculated for daily and monthly time steps, the former being generally needed for management applications, while the latter being often satisfactory for planning applications and general assessments, e.g., in the field of land use or climate change effects modeling.

Soil hydrologic and hydraulic properties

Water in soils occupies the empty spaces (pores) to a degree depending on the properties of soils themselves. A first essential parameter of soils is porosity, i.e., the ratio of the volume of the pores over the total volume of a soil sample, which we will denote with the symbol φ . Porosity is related to the soil bulk density ρ_b by the relationship

$$\rho_b = \rho_g(1 - \varphi) \quad (1)$$

ρ_g being the density of soil solid grains, usually not appreciably different from 2700 kg m^{-3} . Porosity φ is a dimensionless measure of the total empty volume within a soil sample, and is usually in the order of 0.4–0.6 for agricultural soils, which corresponds to usual values of ρ_b of 1.1–1.6. Porosity, or bulk density, depends on the degree of compaction of soils. Often, the total volume of pores quantified by porosity is not completely available

to be filled with water. It is therefore preferred to refer to a measure of “effective porosity,” which is usually between 50% and 100% of the total porosity. It is also current practice to distinguish between “primary” or “matrix” porosity, i.e., the volume of pores present in an undisturbed soil sample, and “secondary” or “macro-” porosity, which includes the volume of cracks, animal burrows, litter and debris enclosures, and other empty spaces appearing in soils in the field but typically not measured in the collected samples. Due to the complexity and variety of processes originating soil porosity, this parameter is in itself rather difficult to predict *a priori* on the sole basis of other elementary soil properties such as texture and structure. It is worth noting that porosity usually decreases significantly within the first 100 cm or less of the soil column, being as high as 0.6 at the top and usually approaching 0.4 lower down.

Porosity or effective porosity does not account for the water content of soils, but only for its upper bound. The actual conditions of soil water are usually described in terms of soil moisture θ , i.e., the ratio of the volume of water to the bulk volume of a soil sample. The ratio of soil moisture to soil porosity is usually termed soil water saturation. When the soil moisture equals soil porosity, the soil is said to be saturated.

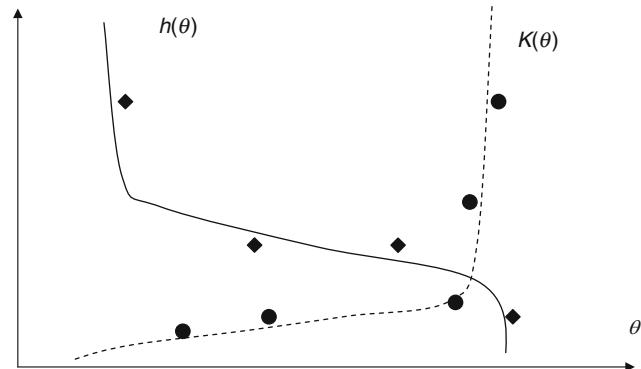

Water is retained in soils against the action of gravity, which tends to drive it downward. The forces by which soils retain water can be interpreted as pressures lower than the atmospheric pressure, so that the pressure difference on each drop of water contrasts the force of gravity. These forces are sometimes called “suction pressures.” It can be checked experimentally that suction pressures increase in absolute value with decreasing soil moisture. An experimental curve representing soil suction pressure as a function of soil moisture is sometimes termed “soil retention curve.” The suction pressure represents ideally the action plants have to provide to extract water from the soil.

In field conditions, soils tend to keep a minimum amount of water even after long dry periods and persistent high air temperatures. This amount is referred to as “residual soil moisture.”

Moreover, when soil moisture in a soil sample exceeds a given threshold, dripping starts to occur from the sample. This threshold is often called “field capacity.” Below a certain threshold of soil moisture, on the other hand, plants are not able to effectively extract water from the soil and start to wilt. This threshold is called therefore “wilting point.” The definition of wilting point and field capacity is essentially conventional. In order to make these quantities unambiguously measurable, it is common practice to refer to the soil moisture at the pressure of 150 cm and 15,000 cm of water head as “field capacity” and “wilting point” respectively.

Another essential property of soils is hydraulic conductivity. This is the measure of the discharge of water conveyed downward by a vertical soil column with cross section of 1 m², when the soil is at saturation. One may think of water flow through soils as the combination of

two processes: one of filling of pores by water, and another of transfer of water through the saturated soil. In reality, some transfer of water occurs simultaneously to filling, and reaches appreciable intensity after field capacity. Most numerical models of soil water budget represent this combination of the two processes by introducing the concept of “partially saturated hydraulic conductivity,” i.e., an experimentally derived curve relating the hydraulic conductivity (or vertical water discharge through a 1-m² cross section of soil) to the soil moisture conditions. Typically, when the soil is above field capacity, the hydraulic conductivity would be quite close to the hydraulic conductivity measured in saturated soil, while below field capacity it sharply drops to much lower values. For reasons of mathematical convenience, in numerical models soils are described using predefined functional forms of retention curves and partially saturated hydraulic conductivity curves, among which the most commonly used are the Brooks–Corey (Brooks and Corey, 1964) and Mualem–Van Genuchten (Mualem, 1976; Van Genuchten, 1980) models. These models predict the suction pressure (h) and the hydraulic conductivity (K) as a function of θ , using appropriate parameters calibrated on the basis of experimental curves (Figure 1). When no experimental curve is available, it is common practice to assign parameters on the basis of elementary soil properties such as texture, bulk density, and organic matter content. Rules to assign parameters based on such properties are derived from databases of soil hydraulic properties, often in the form of regression equations or through inference techniques such as the artificial neural networks (ANN). A database and software package commonly used worldwide for the parameters of the Mualem–Van Genuchten model is Rosetta (<http://www.ars.usda.gov/Services/docs.htm?docid=8953>). Wosten et al. (1999), have derived rules for the prediction of Van Genuchten parameters representative for western European soils.

Water Budget in Soil, Figure 1 Typical shape of retention $h(\theta)$ and hydraulic conductivity $K(\theta)$ curves in soils. Spots represent experimental measurements (♦ = suction, ● = conductivity), while continuous lines represent the interpolating mathematical models.

Fluxes of water affecting the soil water budget

Following a rainfall or snowmelt event, the soil absorbs water up to its capacity. Water fluxes in excess originate surface runoff, and water absorbed by the soil undergoes evaporation, transpiration through plants, infiltration to deeper soil, and eventually to the groundwater, possibly intercepted by soil draining mechanisms operating through artificial devices (e.g., subsurface tile drains, man-made ditches) or through the natural drainage network. Each of the types of fluxes described above has been extensively studied and represented in mathematical models, which are briefly recalled in the following.

The capacity of the soil surface to absorb water

When pouring water to a very dry soil, it can be observed that water initially tends to remain on the surface. After a few seconds, while the soil is wetted, infiltration through the surface starts. The initial difficulty of dry soils to absorb water can be associated to the experimental result that the hydraulic conductivity decreases in dry soils ([Figure 1](#)).

Occasionally, the presence of cracks due to soil drying facilitates infiltration. When the topsoil is completely saturated with water, it is common to observe that the rain tends to originate ponds, which may later disappear as the drainage progresses. These observations suggest that there is an optimal range of conditions for infiltration, corresponding to soils sufficiently wet to allow infiltration, but not so wet to be saturated, hence not able to accept additional water. Up to now, no widely accepted theoretical model is available to describe the flow at the interface between the surface and the soil, and the description of water absorption at the soil surface is completely conventional and phenomenological. Commonly used models of infiltration at the soil surface are the ones of Horton, Philip, and Green and Ampt. For an overview and description of these models, the reader may consult Ravi and Williams ([1998](#)). These models predict infiltration at a rate decreasing with increasing soil water content, or – equivalently – with increasing duration of the water input (rainfall). Usually, in water budget calculations, soil water absorption in dry conditions is simply not considered, and soils are assumed to be able to absorb up to their water holding capacity, in excess of which surface runoff starts to occur.

Surface runoff

The occurrence of surface runoff can be interpreted through two distinct mechanisms, namely “infiltration excess” and “saturation excess.” The first one is identified when rainfall or snowmelt intensity exceeds the capacity of soils to absorb water. This may happen in soils with low hydraulic conductivity, besides the trivial case of sealed soils. The other one occurs when the soil is completely saturated, so that it is not able to accept further water input. A commonly used method is to assume that a percentage of the water input ends in surface runoff without infiltrating.

Evapotranspiration

Usually, the sum of evaporation from bare soils and transpiration by vegetation is lumped together in a term called “evapotranspiration.” If the soil is supplied with water in quantities sufficient not to limit plant transpiration, the amount of water lost by evapotranspiration corresponds to the “potential” evapotranspiration. Potential evapotranspiration (PET) depends on the climate (the solar radiation and thermodynamic conditions of the atmosphere driving water vapor volatilization) and the type of vegetation present on the soil. It is common practice to refer to grass with conventional characteristics to determine a “reference” potential evapotranspiration. Formulas to calculate such reference potential evapotranspiration have been derived on more or less empirical grounds, among which one of the most widely used is the Penman formula. An overview of common formulas is provided by the food and agriculture organization (FAO) ([Allen et al., 1998](#)), along with practical guidance on their application. It is worth stressing that potential (non water-limited) evapotranspiration is a very complex process, for which no widely accepted theoretical model has been developed yet.

When the availability of water limits evapotranspiration, the latter will be less than its potential value. Calculations of soil water budget account in different ways for the reduced availability of water, and in more complex models the specific type of vegetation is also accounted for, by distributing evapotranspiration according to the plant rooting depth, stage of development, and water availability. The detailed assessment of evapotranspiration is usually included in plant models, among which WOFOST (e.g., [Supit et al., 1994](#)) is operationally applied for crop yield forecasting.

Flow in variably saturated soil

Once water has crossed the soil surface, it flows within the soil subject to fluid-dynamics laws, which are rather complex and not fully understood. Factors determining the complexity of water flow in soils, just to mention a few, include the presence of two fluid phases (air and water), macropores, variable soil properties, and complex boundary conditions. A widely accepted phenomenological description of the water flow is the well-known law of Darcy, stating that the water discharge q through a unit-area soil cross section is given by the product of the hydraulic gradient ($\text{grad}(h)$) by the soil hydraulic conductivity K , the latter depending on soil moisture

$$q = -K(\theta)\text{grad}(h) \quad (2)$$

Darcy’s law with soil moisture-dependent hydraulic conductivity, combined with the continuity equation of mass in soil, can be shown to yield the so-called Richards’ equation, which can be solved numerically in one and two dimensions (e.g., [Campbell, 1985](#)) or three dimensions (e.g., the InHM code: <http://inhm.org>; CRITERIA3D, [Bittelli et al., 2010](#)).

Richards' equation describes processes including redistribution of soil moisture within the soil, deep percolation, lateral drainage, once appropriate boundary conditions, and particularly an upper ("atmospheric") boundary condition (water input from rain, snowmelt, and output from evapotranspiration), and a "bottom" one (e.g., an impervious base layer in the soil profile, free drainage, a prescribed level of the water table) are specified.

Soil water budget calculations

In principle, soil water budget calculations may be conducted using numerical models solving Richards' equation. However, in practice simpler methods allow the quantification of the average soil moisture and water fluxes using only the continuity equation for water mass, or a simplified form of Richards' equation not requiring numerical solution. Here we present one well-known and widely applied method, originally developed by Thornthwaite (Thornthwaite, 1948; Thornthwaite and Mather, 1955), applicable at daily as well as monthly steps.

The method can be applied both at monthly and at daily time step. We refer here to the daily step, but replacing in the equations monthly quantities to daily ones would yield consistent monthly results for the soil water content. The method takes precipitation (P , mm day $^{-1}$) and potential evapotranspiration (PET , mm day $^{-1}$) as an input to compute a water mass balance in soil. The latter is characterized by an available water capacity (AWC , mm), which is the amount of water that the soil profile can hold. A possibility to compute AWC (in mm) is

$$AWC = (FC - WP) \times RD \quad (3)$$

where FC and WP (dimensionless) represent field capacity and wilting point soil water content, and RD (mm) is the crop rooting depth. The calculation is performed daily as follows (subscript i indicates the generic day). We first compute the net input to the soil (mm day $^{-1}$) as

$$\Delta P_i = P_i - PET_i \quad (4)$$

Subsequently, if $\Delta P_i > 0$ or $AW_i > AWC$, daily soil water content AW (mm) is computed as

$$AW_i = AW_{i-1} + \Delta P_i \quad (5)$$

Otherwise, we may assume that soil depletion is proportional to ΔP_i through the AW/AWC ratio

$$\frac{dAW}{dt} = \frac{AW}{AWC} (P - PET) \quad (6)$$

or, equivalently

$$AW_i = AW_{i-1} e^{(\Delta P / AWC)} \quad (7)$$

Water in excess of soil AWC (mm day $^{-1}$) contributes to surface runoff and infiltration; the method does not distinguish between the two fluxes, for which additional

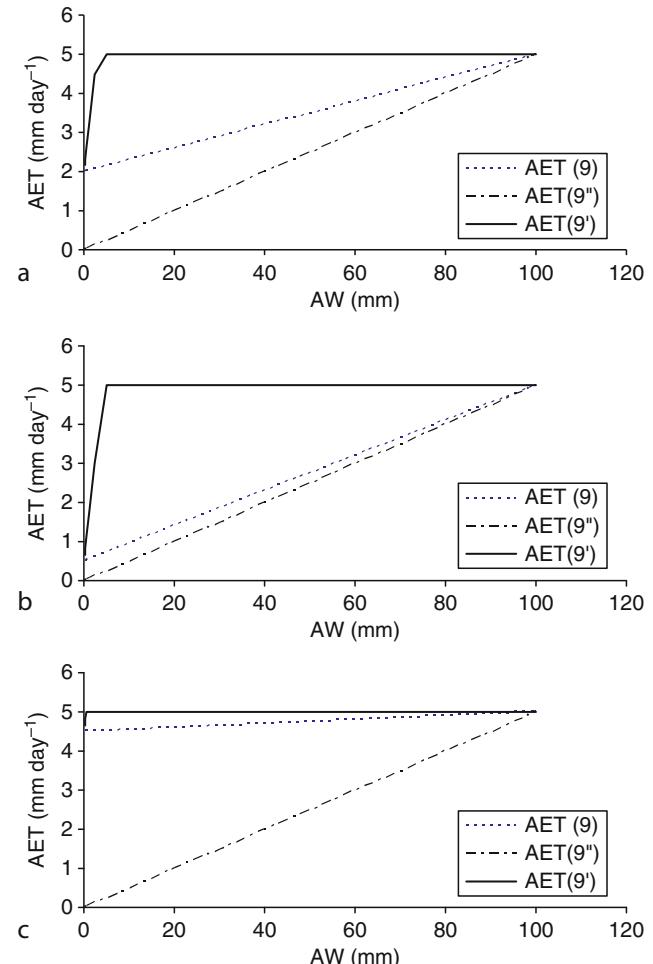

assumptions need to be done (e.g., Steenhuis and Van der Molen, 1986); it is computed daily as

$$E = \max(0, \Delta P_i + AW_i - AWC) \quad (8)$$

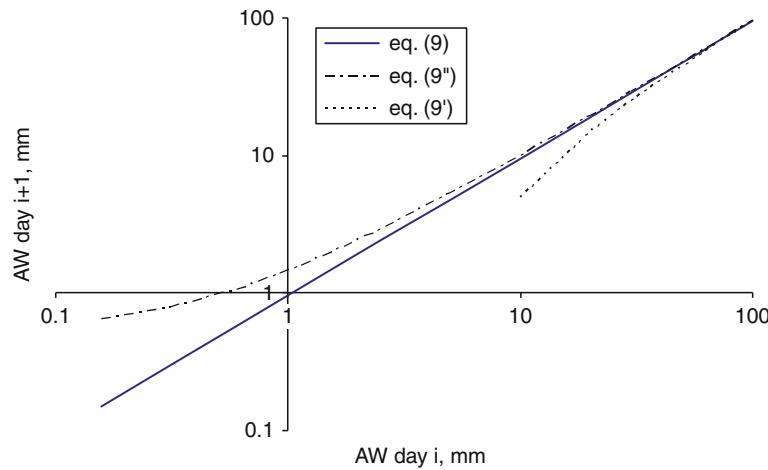

The depletion term $\frac{AW}{AWC} (P - PET)$ equates the difference between precipitation and actual evapotranspiration (AET), so that the latter may be computed as

$$AET = \frac{AW}{AWC} (1 - P) + \frac{AW}{AWC} PET \quad (9)$$

It is worth noting that the assumption of Equation 7 is rather arbitrary. As alternatives, one may select other functions. If we assume that actual evapotranspiration during the day is limited only by potential evapotranspiration and the availability of water, i.e., water is extracted at the same rate irrespective of the soil water content AW , we get

Water Budget in Soil, Figure 2 Behavior of actual evapotranspiration (AET) according to Equations 9, 9' and 9'', for Potential evapotranspiration (PET) = 5 mm day $^{-1}$ and available water capacity (AWC) = 100 mm. Case (a): $P = 2$ mm day $^{-1}$; Case (b): $P = 0.5$ mm day $^{-1}$; Case (c): $P = 4.5$ mm day $^{-1}$.

Water Budget in Soil, Figure 3 Computed AWC depending on the depletion equation (case of $P = 0.5 \text{ mm day}^{-1}$, $PET = 5 \text{ mm day}^{-1}$, $AWC = 100 \text{ mm}$).

$$AET = \min(P + AW_0, PET) \quad (9')$$

Neglecting precipitation during the days when $\Delta P_i < 0$ would yield instead

$$AET = \frac{AW}{AWC} PET \quad (9'')$$

This assumption corresponds to situations where precipitation is not immediately available for evapotranspiration during the same day (e.g., nighttime precipitation). Equations 9' and 9'' are two extreme cases of Equation 9. In (Figure 2) it is shown how, depending on P in relationship with PET , AET according to Equation 9 tends to approach the one according to Equations 9' and 9'', highlighting that Equation 9 modulates AET so to maintain it close to PET when precipitation is high, and close to a linear function of PET when precipitation is low. The different equations affect the soil water content at the end of the day: water balance calculations with Equations 9' and 9'' yield results close to the ones with Equation 9 at high water content, while they diverge at low contents (see Figure 3).

A relatively simple, but more detailed method has been proposed by Pistocchi et al. (2008) for the calculation of the soil water budget at daily step. In this case, aggregation at the monthly step is made not just by taking monthly quantities, but specific semiempirical functions. An alternative approach is the one presented by Eagleson (1978), referred to the yearly water balance. However, the above described Thornthwaite method remains a simple and widely adopted model of soil water budget that can be flexibly adapted to many practical situations.

Dihydrogen monoxide; Hydrogen hydroxide; Hydroxilic acid; Oxidane

Definition

Water is a chemical compound made of two hydrogen atoms and one oxygen atom. Its structure is H_2O . It is the most abundant chemical and the only compound occurring in all three states – gas, liquid, and solid under the Earth conditions. It is a universal solvent conditioning life. Water is the main component of plant and animal tissues, in which it serves as solvent and reagent. Solid raw materials and liquids usually contain large amounts of water while some processed products are poor in water. In raw materials, the water is constitutive, but in many processes, water is added to obtain special properties of the final product. Water content in raw materials and foods varies from 99.5% in some gels to less than 1% in freeze-dried foods.

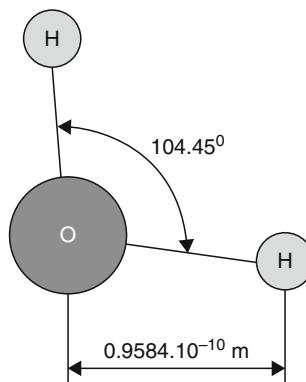

Properties of water

Water is an unusual chemical and its properties differ substantially from other hydrides of the oxygen family. Basic properties of water are collected in [Table 1](#).

Spatial configuration of atoms in the water molecule is well known ([Figure 1](#)). The van der Waals diameter of the water molecule is 0.282 nm. The bonds between

Water Effects on Physical Properties of Raw Materials and Foods, Figure 1 Water molecule.

hydrogen and oxygen are polarized because of high electronegativity of oxygen. Hence, electrons reside often at the oxygen atom than at hydrogen atoms. Because of that, at oxygen atom a partial negative charge occurs, while at hydrogen atoms partial positive charges appear. Bjerrum proposed in 1951 (Siniukow, 1994) to picture water molecule as a regular tetrahedron ([Figure 2](#)). Inside of the solid, there is an atom of oxygen, and in corners, there are either partial charges or hydrogen atoms.

Water molecule, due to partial positive and negative charges located in the tetrahedron corners, behaves as a dipole and interacts with neighboring molecules. A hydrogen bond is formed and its nature is not strictly

Water Effects on Physical Properties of Raw Materials and Foods, Figure 2 Spatial distribution of charges in water molecule.

electrostatic. Molar energy of hydrogen bond is estimated as 20–35 kJ, and the distance between oxygen and hydrogen atoms is from 0.26 nm to 0.30 nm (Franks, 1988). Hydrogen bond is linear, although can be stretched or bent. Hydrogen bond is formed between water molecules, water and solute molecules as well as between solute molecules containing electronegative atoms bonded with hydrogen. All those interactions affect substantially properties of raw materials and foods.

Small ions dissolved in water are surrounded by ordered water molecules, due to intermolecular interactions, and form hydration shell. The surface charge density of the ion affects ordering of water molecules in the hydration shell (Franks, 1988). Ions with large surface charge density are called structure formers because they form well-ordered hydration shells. Ions with small surface charge density are not able to overcome interactions between water molecules but disturb structure of solvent near the ion. These ions are considered as structure breakers.

In macromolecules such as proteins or polysaccharides, besides formation of hydration shell, some water molecules are built in the structure of biopolymers. Hence, structure water and hydration water are associated with biopolymer molecule. Structure water is immobilized in the macromolecule and moves together with biopolymer. On the other hand, hydration shell can be deformed and movement of water molecules is not completely restricted. The number of water molecules associated with macromolecule depends on its energy and ionization state.

In the presence of apolar compounds and groups, degrees of freedom of water are reduced. It stabilizes water molecules in space and the liquid acquires a structure similar to the structure of a solid. This type of interactions is called hydrophobic hydration.

Structure and hydration water arising from hydrophilic interactions as well as hydrophobic interactions all are

responsible, to some extent, for stability and spatial conformation of biopolymers.

Due to all kinds of interactions, with prevailing hydrogen bonding, water in a material occurs in states from completely bound, as structure water, to bulk water. The thermodynamic state of water in a material is expressed by the activity coefficient – a thermodynamic measure of chemical potential of water in the system. Scott (1953, 1957) proposed to express availability of water for microbial growth by the ratio of vapor pressure of water in material p (Pa) to the vapor pressure of pure water p_o (Pa) at the same temperature and total pressure.

$$a_w = \left[\frac{p}{p_o} \right]_{P,T} \quad (1)$$

Water activity calculated from the above equation differs less than 0.5% from the real thermodynamic value. Water activity is from 0 for completely dried materials to 1 for pure water. The lower is the water activity the stronger the water is bound to material constituents.

Water effects

Rheological properties

Water affects rheological properties of liquids and solids. In liquids, the effect is pronounced by changes in viscosity and consistency, while in solids, water affects their response to force. In liquids, increased concentration of solubles, due to structuring of water, increases viscosity of the solution. For Newtonian liquids the relationship is either exponential or a power type (Rao, 1986). The equation of the form

$$\mu = \mu_0 \cdot c^a \quad (2)$$

where μ_0 – viscosity of pure water, Pa·s; c – solubles concentration, %; a – adjustable parameter.

Macromolecules soluble in water cause non-Newtonian behavior of solution and affect strongly its rheological properties. Rheological properties become either time independent or time dependent. Interactions with water molecules are responsible for the size and shape of hydrated macromolecules and their behavior in sheared solution. The weight of solvent associated with a unit weight of solute, called as hydrodynamic hydration, is estimated to be between 0.2 g water g⁻¹ and 0.5 g water g⁻¹ of different proteins. The larger the macromolecule, the larger the friction between hydrated polymer and solvent. Moreover, macromolecules subjected to shearing forces become oriented according to the flow direction and their hydration shell deforms. Shear thinning is observed and consistency of the liquid decreases with increasing shear rate.

Polyelectrolytes are special type of macromolecules, whose size and shape depend on the ionic strength of the solution. In the presence of water, swelling of a polymer occurs and that affects viscosity of the solution. For

polyelectrolytes, the variation of viscosity with concentration is described by empirical equations.

In solids, interactions between water and constituents of the solid, at low water activities, are so strong that water is devoid of solvent properties (Duckworth, 1981). Under these conditions, mobility of small molecules as well as macromolecules is very much reduced and material is regarded as crisp or crunchy.

Increasing water content in solid material causes either plasticization or antiplasticization. Mobility of molecules and polymer chains increases and plasticization of the material occurs. For many brittle materials, there is a narrow range of water activities, within which there is an abrupt change in their mechanical properties (Lewicki and Wolf, 1995; Harris and Peleg, 1996). Further increase in water activity leads to minute changes in mechanical properties of the material. In some cases, increase in moisture causes toughening of the material (Harris and Peleg, 1996; Seow et al., 1999; Marzec and Lewicki, 2006).

Thermal properties

Specific heat of water is high in comparison to other materials. It can be interpreted as the ability of the material to accumulate heat. Hence, even small amount of water strongly affects specific heat of the material. Generally, it is accepted that specific heat obeys the rule of additivity. It means that specific heat of a product is equal to the sum of the fractional specific heats of the main constituents.

Using additivity principle, specific heat can be calculated from the following equation:

$$c_p = c_{pw} \cdot w + c_{pp} \cdot p + c_{pf} \cdot f + c_{pc} \cdot c \quad (3)$$

where c_p is specific heat at constant pressure, $\text{J}(\text{kg}\cdot\text{K})^{-1}$; w, p, f, c – water, protein, fat, and carbohydrate content, respectively, fraction; subscripts w, p, f, c correspond to specific heats of respective constituents. Such models were reviewed by Sweat (1986). In this formula when $w = 1$ the specific heat is equal to the specific heat of pure water.

Thermal conductivity of solid material depends on its structure and chemical composition (Sweat, 1986). At temperatures above freezing, thermal conductivity increases with increasing water content. Thermal conductivity λ , in $\text{W}(\text{m}\cdot\text{K})^{-1}$, of materials with high water content is calculated from the following formula:

$$\lambda = a_1 + a_2 \cdot w \quad (4)$$

where a_1 and a_2 are constants; w – water content, fraction.

Equations 3 and 4 approximate thermal properties of the material with good precision at high water contents; at low water contents differences become marked.

Mass transfer properties

Differences in concentration, strictly speaking in chemical potential, cause molecular mass transfer called diffusion.

The random movement of molecules is expressed by the Fick's first law giving the flux, in $\text{kg}(\text{s m}^2)^{-1}$, of component A diffusing in a stationary component B:

$$n_A = D \cdot \left(-\frac{dc_A}{dx} \right) \quad (5)$$

where c_A is the concentration of component A, kg m^{-3} ; x – the diffusion path, m; D – diffusivity or diffusion coefficient, $\text{m}^2 \text{s}^{-1}$. Diffusing substance undergoes hydration (change in size and shape), and moving collides with neighboring molecules and is subjected to friction (viscosity). In solids, movement of molecules is also affected by collisions with solid matrix and the winding of the path. Hence, diffusion coefficient is affected by interactions between diffusing substance and the surrounding, and becomes intrinsic property of the system.

Electrical properties

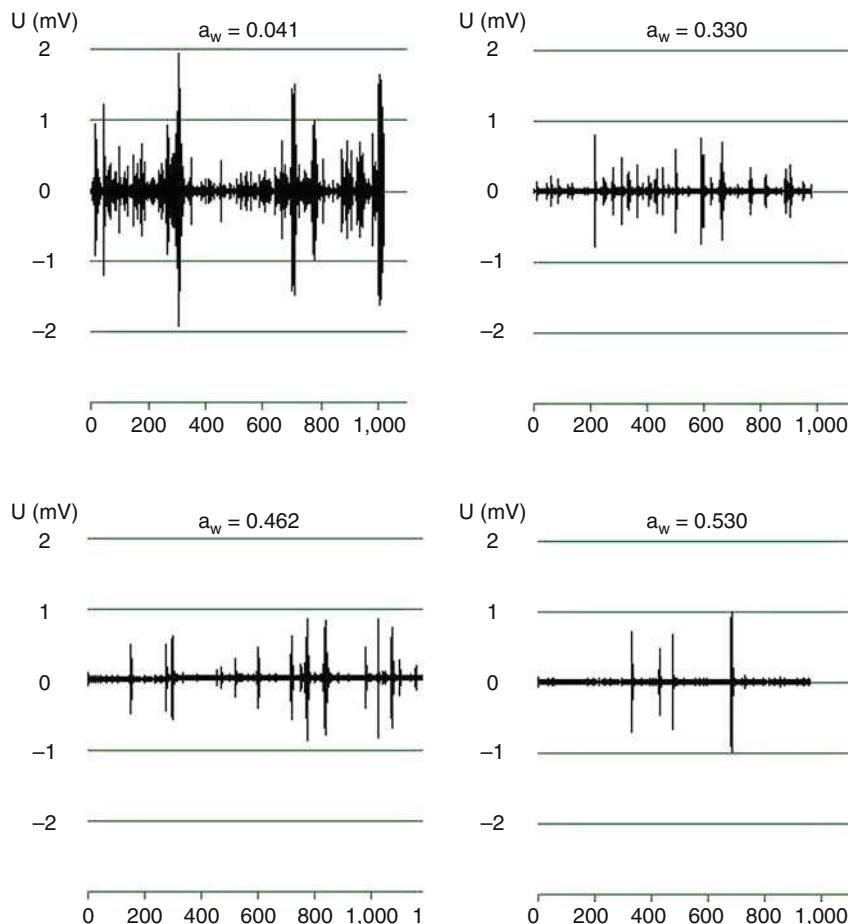

Electrical properties of the material depend primarily on current frequency and temperature, as well as its chemical composition and physical structure (Mudgett, 1987). Dielectric constant and loss factor varies with moisture content. High-moisture materials are generally linear dielectrics. Moreover, the wetter is the material the more its dielectric properties depend on temperature. Dried solids show a little or no variation of dielectric properties with temperature.

Electromagnetic field at radio- and microwave frequencies interacts with material constituents, especially with water. Dipole rotation of free water and conductive migration of charged molecules occur in the material exposed to electromagnetic field. Dipole rotation results in the disruption of tetrahedrally hydrogen bonding patterns.

Electrical conductivity occurs in media that contain electrically charged molecules. Low molecular weight electrolytes and charged macromolecules move in the electric field. This movement is dependent on those events, which are responsible for diffusion of molecules. Hence, increased concentration of ions increases electrical conductivity, but above certain concentration, resistance to movement becomes so large that conductivity decreases. For most solutions, the inflection point in electrical conductivity occurs at concentration between 20% and 30% of solubles.

Optical properties

Infrared radiation reaching surface of a body is partly absorbed and partly reflected. Materials containing water show significant ability to absorb infrared energy. In some products infrared radiation is capable to penetrate the material as deep as 30 mm, and penetration to a depth of 4–5 mm is very common (Ginzburg, 1969). Generally, the shorter the wavelengths the more energy penetrate the material. Hence, in processing of materials with high water content it is recommended to use infrared radiation at wavelength close to the first water maximum, i.e., 1.3–1.4 μm .

Water Effects on Physical Properties of Raw Materials and Foods, Figure 3 Influence of water activity on acoustic emission of flat wheat crisp bread.

Optical properties of materials are responsible for their color and appearance. These include such attributes as translucency and gloss. Free water on the surface of the material often increases its apparent shininess and visual impression of freshness. Treatment of porous materials with water decreases air content in pores, reduces light scattering, and results in more intense color.

Acoustic emission

It has already been mentioned that mechanical properties of solids are strongly influenced by water content (water activity). During breaking of brittle materials a sound is generated, which is perceived by the consumer as the sign of freshness (crisp vegetables) or use of appropriate technology (crackers, biscuits). Decreasing the turgor in fresh fruits or vegetables or increasing water content in crisp products changes their acoustic properties. Influence of water activity on acoustic emission is presented in Figure 3, and was published in numerous papers (Decremont, 1995; Duizer et al., 1998; Roudaut et al., 1998; Gondek et al., 2006; Marzec et al., 2007). It was

shown that each product has a specific frequency pattern for the generated sound and crunchiness disappears at water activities between 0.45 and 0.65.

Conclusions

Water is an important component of raw materials and foods, and affects practically all their physical properties. The influence of water on material properties arises from unusual properties of water per se, and interactions between water molecules and other constituents of the material. The interactions depend on chemical composition, concentration, ionization, surrounding environment, and applied force, and all of them determine the state of water in the material. Hence, many physical properties of food become related to water activity.

WATER EROSION: ENVIRONMENTAL AND ECONOMICAL HAZARD

Jerzy Rejman

Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland

Water erosion

Water erosion is a part of soil erosion process in which water is an erosive force in soil detachment and transport. It finally provides to setting of sediment at footslopes and valley floors or direct delivery of sediment to water courses or reservoirs. During the first phase of water erosion, the impact of raindrops causes soil crusting, that is, limits infiltration and leads to development of runoff, initially in the form of laminar flow and with increase of its depth and velocity – turbulent flow. The change of flow nature is reflected in separation of water erosion into sheet, rill, and gully (ephemeral and permanent). Dynamics of the process is ruled by energy input (rainfall amount and intensity, shear stress of overland flow) and resistance of soil and landscape features. The latter is changing with rainfall duration, providing higher connectivity of the flow system (surface, subsurface) to transport water and sediment during present and next events. Water erosion causes on- and off-site environmental effects, and part of them of significant economical extension.

On-site effects

Soil truncation, redeposition of sediment and nutrients inside fields and catchments, and total soil loss with the development of gullies are the main on-site effects. Soil profile truncation can be quantified as proportion of upper horizons (A/E) that have been removed. These criteria become a basis of separation of four erosion classes (Soil Survey Division Staff, 1993). Whilst upper horizons may range widely in thickness, the absolute amount of erosion cannot be specified by this method. Such division well describes initial phases of soil transformation due to erosion and poorly – larger soil profile changes (that are all put into fourth class). For the latter, separation of erosion classes based on the pedological attitude seems to be more suitable. Such classification was proposed for soils developed from loess (Haplic luvisols), in which lost

Cross-references

[Dielectric Properties of Agricultural Products](#)
[Electrical Properties of Agricultural Products](#)
[Hydrophobicity of Soil](#)

of particular horizon/subhorizon becomes a criteria to separate five classes of erosion (Turski et al., 1992). Availability of this method to assess total amount of erosion is also restricted by the limited presence of non-eroded soil (reference sites). Nevertheless, both attitudes clearly show that in the eroded areas, rate of soil formation is lower than the rate of erosion. Soil truncation generally leads to lowering of soil productivity by lowering SOC content, lowering of infiltration capacity, and decreasing the retention of plant available water. In dependence on soil texture, water erosion affects crop yields also by creation of root barrier and increased compaction. Analyses of Bakker et al. (2004) based on extensive literature review showed 4% decrease of crop yield per 10 cm of lost topsoil. Usually, crop yields on severely eroded soils are reduced by 12–30% in comparison to non-eroded sites (Pimentel et al., 1995). Whilst in well-developed countries, the decrease could be diminished by excessive fertilization, in developing countries – due to limitation of its application (high costs), soil erosion leads to dramatic yield decrease (Boardman, 2006). Soil truncation and accumulation of sediment evoke spatial variation of soil properties over the landscape. The older concept of non-eroded soils on hilltops and eroded – on slopes is rather misleading, especially in the areas of complex landscape (as loess mantles). In these areas, present-day uplands and slopes are covered by mosaic of non-eroded soils, eroded soils, and colluvials (Turski et al., 1992). Spatial variation of soil properties over the landscape affects the intensity of water erosion process. Twofold differences in soil loss between slightly/moderately and very severely (developed directly from parent loess)/colluvial sites located in the same topographical conditions (9% slope) were reported in runoff-plot studies by Rejman et al. (1996). Largest erosion by water took place on bare, temporarily unprotected arable land, overgrazed areas, and badlands. Plot studies in Europe show that this sheet and rill erosion could have the extent of the annual average of 23, 20, and 14 Mg ha⁻¹ for bare soil, vineyards, and maize, respectively (Cerdan et al., 2006). Higher soil erosion rates are estimated for Asia, Africa, and South America with an average of 30–40 Mg ha⁻¹ year⁻¹, and lower for the USA (17 Mg ha⁻¹ year⁻¹), although in some USA regions soil losses reach 30 Mg ha⁻¹ year⁻¹ (Pimentel et al., 1995). Despite these forms, agricultural fields suffer from the formation of ephemeral gullies, and its contributions to total soil loss by water erosion is assessed between 10% and 80%, ranging in dependence on the environmental conditions (Poesen et al., 2006). However, the largest landscape transformation is caused by the development of permanent gullies, which totally exclude land from agricultural land use and lead to badlands evolution (Poesen and Valentin, 2003). The role of water erosion in soil transformation in northern hemisphere is decreasing in comparison to tillage erosion (Van Oost et al., 2005). However, new approach on water erosion shows that during less-intensive rainfalls, soil is transported over limited distance (Wainwright et al., 2008). Thus, sedimentation could take place even on uniform slope in the

case of break of energy input, and magnitude of sheet and rill erosion could be larger than soil losses measured at the plot outlet.

Off-site effects

With breaking of the resistance of landscape elements, overland flow and transported sediment evoke off-site effects (i.e., outside fields or farms). Muddy floods, siltation, and eutrophication of water reservoirs belong to most important effects. Term “muddy flood” was introduced to characterize water flowing from agricultural fields carrying large quantities of soil as suspended sediment or bedload (Boardman et al., 2006). These phenomena usually take place in loess areas, and there appears a close relation between its occurrence and development of ephemeral gullies. Muddy floods can cause serious financial damage to people and public infrastructure being located at the outlet of dry basin systems. It is estimated that each year, muddy floods lead to a total societal cost of 16×10^6 – 172×10^6 € in Central Belgium, depending on the extent and intensity of thunderstorms and monetary values damaged (Evrard et al., 2007). Deposition of sediment within water reservoirs and ponds is the other important off-site consequence of soil erosion by water. Number of these water bodies per unit area (density) is assessed on 0.33, and 0.1–0.2 km⁻², for the USA and Europe, respectively (Verstraeten et al., 2006). At the world scale, the estimation shows that annual loss in storage capacity is around 0.5–1%, and for individual reservoirs these values can be as high as 4–5% (WCD, 2000). For Europe, annual loss of storage capacity is 0.26% which corresponds to 63 hm³ year⁻¹, and the highest annual losses (above 5%) were found for small ponds of loess areas of Belgium. The latter value referred to the catchment areas give sediment yield ranging from 2 to 5 Mg ha⁻¹ year⁻¹ with maximum values of 20–50 Mg ha⁻¹ year⁻¹ (Verstraeten et al., 2006). Estimates for the USA show that about 880×10^6 Mg of agricultural soils are deposited into reservoirs and aquatic systems each year (Pimentel et al., 1995). Together with runoff and sediment, nutrients (C, N, P) and pesticides are transferred to water reservoirs. Subsurface flow is the other pathway of pollutant transfer, especially in the areas of low groundwater table. From the nutrients, phosphorus being considered as the limiting factor for algae growth is the most dangerous for the environment, and its additional load provides to potentially toxic algae blooms, oxygen deficiency, and destruction of wildlife habitats. Amounts of phosphorus discharged through rivers to oceans are estimated between 18.7 and 31.4 Tg year⁻¹, from which 3.1–4 to 10.1 Tg year⁻¹ is potentially biogeochemically reactive (Compton et al., 2000). Usually, it is assumed that the main source of P delivery is agricultural fields, where high inorganic fertilization resulted in its accumulation in topsoil layer, being removed during erosion events. Recent studies of Withers et al. (2009) show however that P sources associated with the functioning of rural communities (impervious surfaces, detergents, and

wastewater) may be more ecologically relevant than those associated with agriculture. Some economical extent of the off-site effects gives estimates for the UK made by Pretty et al. (2000). To the most significant external costs of agriculture belonged pollution of sources of drinking water by pesticides (120), phosphates (55), and nitrates (16), whilst the off-site damage to the soil was assessed on 14, and organic matter and carbon dioxide losses from soil on 82 (all values in millions of pounds).

Water erosion problems in perspective

Environmental and economical effects of water erosion effects are largely connected with changes in agriculture being the result of common acceptance by farmers, the rules of economic efficiency. Characteristic present-day tendencies in worldwide modern agriculture well describes Pimentel et al.'s (1995, p. 1117) description of changes in the US agriculture, "During the past 50 years, the average farm size has more doubled from 90 to 190 ha. To create larger farms and fields, farmers removed the grass strips, shelterbelts, and hedgerows that once protected soil from erosion. Crop specialization has also led to the use of heavier machines that damage the entire ecosystem." To better adopt to market demands, farmers resign from crop rotation, introduce of maize instead of winter wheat, or change meadows into fields, and ignore the off-site impacts of water erosion (Boardman, 2006). The other important factor increasing economical extension of water erosion is an urban sprawl into agricultural land, being one of the components responsible for more frequent occurrence of muddy floods (Evrard et al., 2007). Summarizing, the increase of on- and off-site effects of water erosion is expected to arise in the future, mainly due to improper land use changes from the environmental point of view.

WATER IN FORMING AGRICULTURAL PRODUCTS

Jiří Blahovec

Department of Physics, Czech University of Life Sciences, Prague 6-Suchdol, Czech Republic

Synonyms

Moisture content; Water content

Definition

Moisture content (MC) is defined as the derivative of water mass (m_w) versus the basic mass (m_b) in the matter:

$$MC = \frac{dm_w}{dm_b} \quad (1)$$

MC is a dimensionless quantity, which is sometimes expressed in percent. Two versions of moisture content are used: MC d.b. (dry basis), where m_b is mass of dry matter and MC w.b. (wet basis), where m_b is total mass of the analyzed part of matter.

Introduction

Water represents a fundamental component of agricultural products and organisms (Fennema, 1976). The most important property of a biological product is its nontrivial composition with different components (see *Water Uptake and Transports in Plants Over Long Distances*). Generally, MC of one part of a product differs from the MC of the other parts even if the parts are located in the tight neighborhood. This is typical property of animal or plant tissues (see *Stomatal Conductance, Photosynthesis, and Transpiration, Modeling*) (Oertli, 1976). This is why the MC is defined in Equation 1 as a local differential quantity that can vary in different points. Generally we can find differences in the MC in species, organs, tissues, cells, and cellular substructures, that is, in the whole spectrum of the product structural units. The differences in moisture content are connected with the variability of physical properties (see *Physical Phenomena and Properties Important for Storage of Agricultural Products; Physical Properties as Indicators of Food Quality; Physical Properties of Raw Materials and Agricultural Products*). Water plays the role of plasticizer in the agricultural products (Blahovec, 2007), so that it increases their flowing ability (see *Rheology in Agricultural Products and Foods*).

The lack of water leads to deficiency disease (living organisms – see also *Stomatal Conductance, Photosynthesis, and Transpiration, Modeling*) and/or deterioration (products). On the other hand, too high content of water usually increases the danger of microbial deterioration.

Water properties

Water is the only substance that occurs abundantly in all three basic physical states on this planet. There is mostly in liquid state as in the living organisms but the other two states are also frequent in contact with them. The basic

state constants of water are given in the following table (based on data of Fennema (1976)):

Constant	Value	Unit
Molecular weight	0.01801534	kg mol^{-1}
Phase transition properties		
Melting point (at 101.325 kPa)	0	$^{\circ}\text{C}$
Boiling point (at 101.325 kPa)	100	$^{\circ}\text{C}$
Critical temperature	373.946	$^{\circ}\text{C}$
Critical pressure	22.058	MPa
Triple point temperature	0.0099	$^{\circ}\text{C}$
Pressure	611.73	Pa
Heat of fusion at 0°C	6.010	kJ mol^{-1}
Heat of vaporization	40.62	kJ mol^{-1}
Heat of sublimation at 0°C	50.89	kJ mol^{-1}

Further properties of water and ice are as follows (based on data in Fennema, 1976):

Parameter at normal pressure	Unit	Liquid water		Ice	
		20°C	0°C	0°C	-20°C
Density	kg m^{-3}	998.203	999.841	916.8	919.3
Viscosity	Pa s	0.001002	0.001787	–	–
Surface tension against air	N m^{-1}	0.07275	0.0756	–	–
Vapor pressure	kPa	2.338	0.6105	0.6105	0.1035
Heat capacity	$\text{kJ kg}^{-1} \text{K}^{-1}$	4.114	4.216	2.050	1.943
Thermal conductivity	$\text{W m}^{-1} \text{K}^{-1}$	0.593	0.559	2.22	2.39
Thermal diffusivity	$\text{mm}^2 \text{s}^{-1}$	0.144	0.133	1.18	1.34
Dielectric constant	–				
Static		80.36	88	91 ^a	98 ^a
at 3 GHz		76.7	80.5		3.2 ^a

^aIn direction parallel to crystallographic axis c

Comparing water physical properties with physical properties of substances with molecules of similar molecular weight, like CH_4 , NH_3 , HF , and H_2S , we see that water has unusually high values for melting point, boiling point, surface tension, dielectric constant, heat capacity and heats of fusion, vaporization and sublimation; a moderately low value for density; an unusual density maximum at 3.98°C ; an unusual attribute of expanding upon solidification; and viscosity which, in light of the above, is strangely normal. In addition, the thermal conductivity of water is large compared to other liquids, and the same can be concluded also for ice. Thermal conductivity of ice at 0°C is approximately four times higher than liquid water at the same temperature; the bigger difference was observed at thermal diffusivity that is about nine times higher in ice than in liquid water at the same temperature. These data indicate deep anomalies in the water properties that have to be caused by special properties of the water molecule and its space asymmetry.

Water's large intermolecular attractive forces are caused by its ability to engage in multiple hydrogen

bonding on a three-dimensional basis (see *Adsorption Energy of Water on Biological Materials*). Compared to covalent bonds (bond energy few hundreds of kJ mol^{-1}), hydrogen bonds are weaker (less than 40 kJ mol^{-1}) but of greater and more variable length.

Water as a part of agricultural products

Water exists in different parts of agricultural products where it is more or less bound. Crudely, we can divide the locations into three basic types (see *Microstructure of Plant Tissue*, see also Kollmann et al., 1968 and Hultin, 1976):

Location	State of water	Bond degree
Pores	Soft solution or pure water	Surface and capillary forces
Protoplasm	Solutions of different types	Osmotic forces
Cell walls	Bound	Chemical forces of different kinds

When the content of water in cell walls and the content of solids in water solute solutions can be omitted then unit volume of agricultural product can be expressed as (Blahovec, 2008)

$$1 = v_{\text{DM}} + v_a + v_w = v_{\text{DM}} + v_p \quad (2)$$

where v are relative volumes of basic components of the agricultural products (DM : dry matter, a : air, w : water, and P : pores). Equation 2 well operates in many cases where swelling and shrinkage does not play important role. Porosity P in this case is expressed as

$$P = v_a + w_w = 1 - v_{\text{DM}} \quad (2a)$$

Physical properties of an agricultural (see *Water Effects on Physical Properties of Raw Materials and Foods*) product can be estimated in many cases by superposition of the physical properties of the main components

$$PP = v_{\text{DM}}PP_{\text{DM}} + v_aPP_a + v_wPP_w \quad (3)$$

where PP is physical property of the agricultural product and PP_{DM} , PP_a , PP_w are the same physical properties of dry matter, air, and water, respectively. This principle (the so-called superposition principle, see Blahovec, 2008) can be used, for example, for estimation of density of agricultural materials in cases where swelling and/or shrinkage can be omitted (see *Drying of Agricultural Products*).

In cases where the mass balance is used, the presence of air could be usually omitted due to its low density ($\sim 1.3 \text{ kg m}^{-3}$ exact value depends on temperature and pressure) and the mass of the agricultural product m_{ap} can be expressed as a sum of the mass of water m_w and the mass of dry matter m_{DM} . In this case, a simple relation between different based moisture contents – see Equation 1 – can be expressed (Blahovec, 2008):

$$MC \text{ d.b.} = \frac{MC \text{ w.b.}}{1 - MC \text{ w.b.}} \quad (4)$$

Equation 4 shows that when the theoretical range of 0–1 (0–100%) is accepted for $MC \text{ w.b.}$, the $MC \text{ d.b.}$ moves in the range $0\text{--}\infty$, irrespective of whether it is expressed as a simple ratio or as a percent part.

Moisture content in agricultural products

Moisture content in raw agricultural products is very variable (see *Drying of Agricultural Products; Water Uptake and Transports in Plants Over Long Distances*):

Product	MC w.b. (%)	MC d.b. (%)
Vegetables (Fennema, 1976)		
High MC (asparagus, green beans, cabbage, lettuce, etc.)	90–95	900–1,900
Medium MC (beets, broccoli, carrots, potatoes, etc.)	80–90	400–900
Low MC (avocado, bananas, green peas, etc.)	75–80	300–400
Fruits (Fennema, 1976)		
High MC (rhubarb, strawberries, tomatoes, etc.)	90–95	900–1,900
Medium MC (apples, peaches, oranges, grapefruit, etc.)	85–90	570–900
Low MC (berries cherries, pears, etc.)	80–85	400–570
Grain Crops (in harvest, Haard, 1976)	15–20	18–25
Wood (in time of felling – Kollmann et al., 1968)	44–55	80–120
Meat (Fennema, 1976; Hultin, 1976)		
Fish, muscle proteins	65–81	185–426
Chicken (without skin)	74	285
Beef	70–73	233–270
Pork	68–70	210–233
Milk (Brunner, 1976)	85–88	566–730

The increase in MC of agricultural products leads to an increase in their water activity and a decrease in adsorption energy (see *Adsorption Energy of Water on Biological Materials*).

Conclusion

Water represents one of the three basic components of agricultural products: dry matter, water, and air. With air, water participates in filling of the internal pores. When no important swelling or shrinkage of dry matter accompanies possible changes of water content, the so-called superposition principle can be used, that is, the total volume of the product is the sum of volumes of dry matter, water, and air. In this case, many physical properties of the product can be estimated as a weighted sum of the components. When the composition of the product is given in mass units, the role of air can usually be omitted.

WATER RESERVOIRS, EFFECTS ON SOIL AND GROUNDWATER

Waldemar Mioduszewski

Department of Water Resources, Institute of Technology and Life Sciences, Falenty, Poland

Definition

A *water reservoir* is an artificial pond, formed in a river valley or other basin by a barrier or dam and having controlled or uncontrolled outlets. The rising of surface water level have some impact on the groundwater level in adjacent areas.

Water reservoirs were always an important element in the human environment and for many centuries were built for economic or ornamental purposes. There are many types of water reservoirs. Basic division distinguishes the *dug* and the *dam* reservoirs.

Dug reservoirs, usually named ponds, are formed as a result of digging the natural substratum and filling it with water. The sources of water may be different. Usually dug reservoirs are filled with groundwater. The impact of ponds on soils and groundwaters is small, and hence they are not considered in the further parts of the paper.

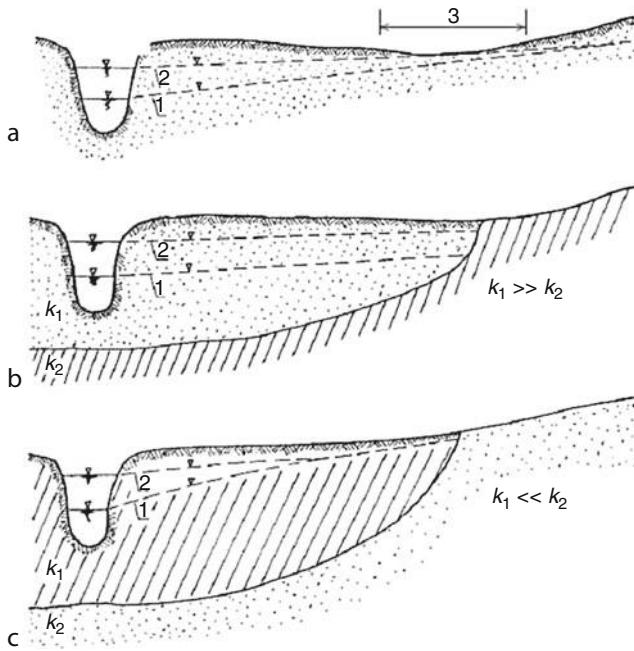

Dam reservoirs are formed as a result of damming the river channel or the whole valley with a water lifting hydraulic structure, usually an earthen dyke with a sluice. After damming, the water level is lifted and the river valley is flooded.

Reservoirs of quite variable sizes are being built worldwide, sometimes huge ones of a volume of several billion cubic meters, heavily affecting many components of the natural environment. This article mainly pertains to small dam reservoirs of a volume less than 0.5 million cubic meters and a water lifting height of 1.5 m.

In practice, every new or reconstructed water reservoir affects soil moisture and the hydrologic regime of a water course, creates favorable conditions for the development of aquatic macrophytes, etc. In most cases, these are positive changes from the biological and economic point of view. Small reservoirs form valuable wetlands with high biological diversity in a monotonous agricultural landscape.

Every dam reservoir that keeps the water level higher than before damming increases the groundwater table and soil moisture in the close vicinity of the reservoir. The range of a reservoir's impact depends not only on land relief and the height of damming but also on the geological structure and hydrogeologic conditions. When the reservoir is surrounded by poorly permeable soils, the range is small – from a few to several dozen meters. In catchments dominated by sandy formations, however, it may reach several hundred meters.

Figure 1 presents an example of the groundwater table depth before and after the construction of a reservoir in

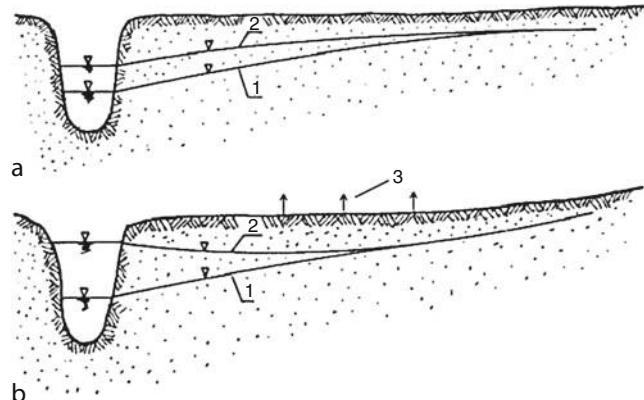

Water Reservoirs, Effects on Soil and Groundwater,
Figure 1 The influence of a reservoir on groundwater level:
 (a) uniform and permeable soil, (b) the erosion valley in
 permeable soil, (c) the valley covered with impermeable soil
 underlying permeable structures; 1: phreatic line before reservoir
 construction, 2: after water level rising, 3: waterlogged area.

relation to geological structure of the valley and uplands. Far range of reservoir's impact may be expected when the upland and valley are built of permeable, uniform formations (Figure 1a). The effect of damming may sometimes manifest itself far from the reservoir by flooding terrain depressions (Figure 1a).

When the erosion valley is made of older, poorly permeable formations (Figure 1b), the range of reservoir's impact is limited by the width of permeable valley. Reservoirs situated in poorly permeable soils exert their impact on groundwaters only in their close vicinity (Figure 1c). It has been estimated that in the soils of a hydraulic coefficient of 10^{-6} to $10^{-7} \text{ cm s}^{-1}$, water lifting by 1 m affects groundwaters not farther than several dozen meters.

The effect of dam reservoirs on soil moisture depends on the depth of groundwaters before and after reservoir construction. At deep groundwater table depths (deeper than the height of capillary rising), water lifting has no effect on soil moisture (Figure 2a). It may, however, cause water logging of terrain depressions as shown in Figure 1a.

When the reservoir is built in relatively flat area and is surrounded by grasslands, which is often the case in localization of small reservoirs, the elevation of groundwater table may be a form of capillary irrigation and may improve water relations in drained wetlands. Increased

Water Reservoirs, Effects on Soil and Groundwater,
Figure 2 The influence of a reservoir on the groundwater level:
 (a) in the winter season, (b) in the growing season; 1:
 groundwater level before the reservoir construction, 2:
 after water rising, 3: evapotranspiration.

soil moisture makes water more available for plants. This leads to increasing biomass production and to increased evapotranspiration. At a high evapotranspiration, the reservoir starts to supply water during the vegetation period (Figure 2b).

Summary

Elevation of groundwater table depth may exert a negative impact on areas used as arable lands. High groundwater table level causes excessive soil moisture and the deficit of air. Some changes of physical and chemical composition of soils can be expected. To maintain agricultural production, it is necessary to construct a draining system in order to discharge excess water and to increase air content in soil pores.

Maintaining high groundwater table makes agricultural utilization impossible and transforms the character of vegetation cover into such typical of hydrogenic habitats. Sometimes such approach is justified since it enlarges wetland areas and increases biological diversity of agricultural landscape.

WATER UPTAKE AND TRANSPORTS IN PLANTS OVER LONG DISTANCES

Marian Kargol
 Independent Department of Environment Protection and Modelling, The Jan Kochanowski University of Humanities and Sciences, Kielce, Poland

Introduction

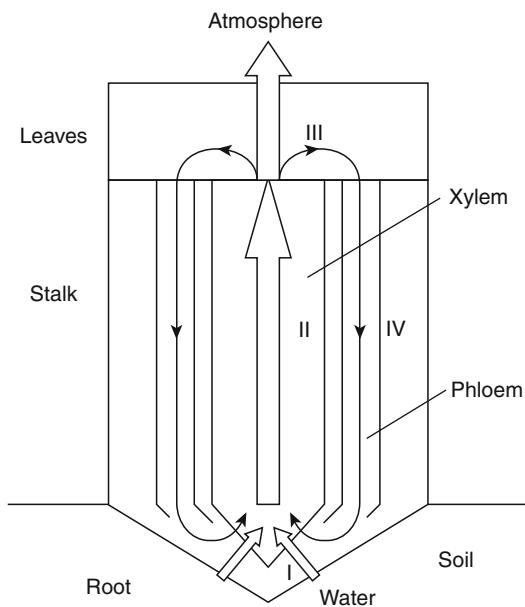

The subject of the present considerations shall be some basic issues pertaining to agrophysical aspects of long-distance water translocation in land plants. We shall be interested in plants with a root system, a stalk, and leaves. These plants take in soil water with the root, and then the water is transported through the root radial route to the xylem of the vascular cylinder. It is then transported through the xylem, along the stalk, to the leaves. Here, its major part transpires (evaporates) into the atmosphere. This is treated as long-distance water transport. Conventional literature also distinguishes another type of long-distance transport in these plants: this is the transport of water and assimilates that occurs through the phloem. Both of these transport types have generally been investigated separately. In several works (Kargol, 1995, 1996, 2007; Kargol and Kargol, 1996; Kargol et al., 2001), we have, however, attempted to formulate long-distance

water transport as part of the so-called integrated water translocation system. It comprises four stages. This idea has been illustrated in [Figure 1](#). At the first stage (I), soil water is taken in and transported from the soil to the xylem of the vascular cylinder. At the second stage (II), translocation occurs through the xylem (most frequently, rising) to the leaves. Next, the water is transported, at the third stage (III), through leaf tissues. From the leaves, the majority of the water evaporates into the atmosphere. The remaining part of the water (relatively small) is taken from the leaf apoplast by sieve tube members, which begin the water routes of the phloem. Next, it is moved (together with assimilates) through the phloem along the plant.

Within phloem water transport (which is the fourth stage [IV] of water translocation), water is – together with the assimilates – delivered to all locations in the plant in which the assimilates are to be used. Our further considerations will pertain to water translocation mechanisms in plants at respective distances. The above shall be done on the basis of the idea, which we have proposed for the integrated water translocation system in plants.

Soil water uptake – theories of xylem water transport in plants

It is believed that the plant root may be, for the sake of a model, treated as an osmometer. It can then be assumed that water intake from the soil and its movement along the radial route (to the xylem of the vascular cylinder) is osmosis-driven. It has also been assumed that osmosis can generate a certain pressure in the root, called root pressure. Due to that, water may also ascend through the xylem to a certain height. This is how the xylem water

Water Uptake and Transports in Plants Over Long Distances, Figure 1 Illustration of the idea for the integrated water translocation system in plants.

ascent theory has been formulated, called *the root pressure theory* (Wilkins, 1969; Zimmermann, 1971; Salisbury and Ross, 1976; Kargol, 1995, 2007). Yet, the most convincing theory of xylem water transport, referred to as *the transpiration-cohesion theory*, has been developed by Dixon and Renner (Wilkins, 1969; Zimmermann and Brown, 1971; Salisbury and Ross, 1976; Kargol, 1992, 2007). A certain amount of attention should also be paid to *the gravi-osmotic idea* of xylem water ascent, formulated by Kargol (1971, 1992, 1995, 2007) and Przestalski and Kargol (1987).

All the above are membrane theories. At this junction, let us explain that membrane transport properties are described by three parameters, that is, the filtration coefficient L_p , the reflection coefficient σ , and the solute permeability coefficients ω and ω_d (Kargol, 1995, 2007; Katchalsky and Kedem, 1965).

The Dixon–Renner transpiration-cohesion theory

As already indicated, xylem water transport can be driven by root pressure. Yet, from experimental investigations it follows that this pressure is able to pump water to relatively low heights. How then does water ascend through the xylem to leaves in tall plants? This question was answered by Dixon and Renner, who formulated the transpiration-cohesion theory (Wilkins, 1969; Zimmermann and Brown, 1971; Salisbury and Ross, 1976; Kargol, 1995, 2007). According to this theory, xylem water ascent occurs in unbroken routes of the xylem, which fork as needed along the plant length. In the last phase, water permeates across leaf tissues (mainly via the apoplastic route). From here, its majority evaporates (transpires) into the atmosphere, mostly from the mesophyll and cuticle cell wall surface. To be precise, it is the water contained in the pores of the cell walls that evaporates. In these pores, free water surfaces (from which water evaporates) are formed in concave menisci. Under the circumstances, under these curved surfaces a certain mean pressure is generated (negative with respect to atmospheric pressure). This pressure, called capillary (P_k), may be calculated from the formula:

$$P_k = \rho g h = \frac{2u}{r}, \quad (1)$$

where u is the surface tension, g is the acceleration of gravity, h is the height, and r is the mean pore cross-section radius. This pressure underlies the Dixon–Renner theory. This theory is, as can be seen, very simple. Notwithstanding the above, it very well explains the agrobiophysical bases of xylem water transport.

The Kargol and Przestalski gravi-osmotic hypothesis of xylem vessel water transport

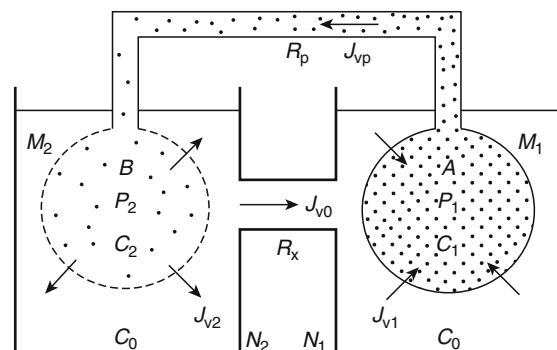

In the year 1971, the so-called gravi-osmotic hypothesis of xylem water transport was proposed (Kargol, 1971). It was subsequently developed by Kargol (1992, 1995, 2007) and Przestalski and Kargol (1987). It postulates that

water may ascend through xylem vessel elements at their respective development phases, with the use of gravi-osmotic mechanisms.

Biophysical theories of phloem transport of water and assimilates

Energy supply to living plant cells occurs by means of assimilates. These high-energy substances are produced in leaves (in photosynthesis processes occurring therein). Next, these assimilates are distributed all over the plant by means of phloem conducting elements, that is, sieve tube members. So far, several hypotheses have been developed pertaining to explanation of the long-distance translocation. They include *the electro-osmotic theory*, *the hypothesis of diffusion and natural cytoplasm movement*, as well as *the Münch pressure-flow theory* (Wilkins, 1969; Zimmermann, 1971; Salisbury and Ross, 1976). We shall focus on the latter as it is the most widely recognized and also because in recent years we have considerably modified and expanded this theory (Kargol, 1996; Kargol and Kargol, 1996; Kargol et al., 2001).

The classic version of *the Münch pressure-flow theory* claims that assimilates are moved through the phloem on the principle of convection in water. This transport, understood as a mass flow, can be best explained with the use of the membrane model as developed by Münch. The classic version of this model consists of two osmometers A and B, joined in opposition by means of the tube R_p . They are plunged in a solution of communicating vessels N_1 and N_2 , which has been more precisely illustrated in Figure 2. The osmometer A of this model, filled with the concentrated solution C_1 , represents a generalization of leaf photosynthesis cells. It is here, as a source effect, that assimilates are created. Hence, their concentration C_1 is high here. If it is also assumed that the membrane M_1 of the osmometer A (which emulates plasmalemmae of the cells at issue) is highly selective, then the osmosis-driven

Water Uptake and Transports in Plants Over Long Distances, Figure 2 The Münch model (classic version): A, B are osmometers; R_p , R_x are tubes emulating the conducting elements of the phloem and the xylem; C_1 , C_2 , and C_0 are concentrations; J_{vp} , J_{vo} are volume flows in the phloem and the xylem; N_1 , N_2 are vessels simulating the leaf apoplast; P_1 , P_2 are mechanical pressures; J_{v1} , J_{v2} are volume flows.

turgor pressure P_1 in these cells will also be high. The osmometer B, in turn, which contains the diluted solution C_2 corresponds to the locations in the plant where assimilates are used. These may be root and fruit cells, or flower buds. The membrane M_2 of this osmometer must be relatively well-permeable, both to water and assimilates. It formulates, for the sake of a model, the cell membranes of the phloem sieve tube members in the locations in the plant where assimilates are used.

It is believed that it is out of these conducting elements of the phloem that the outflow of water and assimilates occurs, driven by reverse osmosis (Wilkins, 1969; Zimmermann and Brown, 1971; Salisbury and Ross, 1976; Kargol, 1995, 1997).

In the presented model, it is also assumed that the tube R_p , which connects both hypothetical osmometers, symbolizes phloem sieve tube members. The containers N_1 and N_2 (together with the concentration C_0) emulate the plant apoplast together with the water and substances dissolved therein contained in it. The tube R_s , in turn, which connects the containers N_1 and N_2 , represents the xylem.

Generally, it may be stated that in the light of the above-presented conventional model of Münch, the phloem mass transport J_{vp} (of water and assimilates), also called pressure transport, occurs under the influence of the mechanical pressure difference $\Delta P = P_1 - P_2$.

On the whole, Münch's theory is essentially very adequate. Yet, since it was published in the year 1930 many significant experimental discoveries have been made, pertaining to long-distance water translocation in plants. As a result, clear possibilities have arisen to introduce to the Münch model significant modifications and additions.

Integrated water translocation system in plants and its modifications

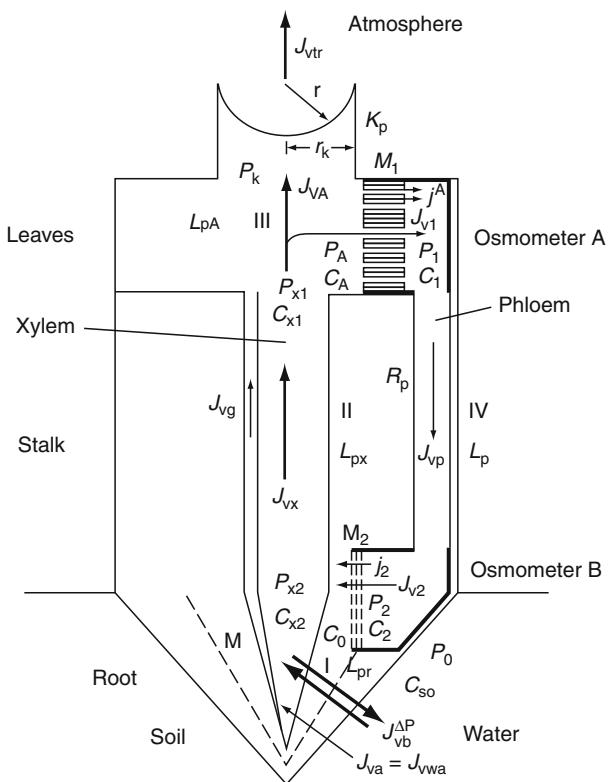

In the light of the conventional Münch model, phloem transport of water is driven by turgor pressure of leaf photosynthesis cells. The value of this pressure is too low, however, for it to be able to transport water and assimilates with sufficient efficiency.

It results mainly from the fact that hydraulic conductivity of the phloem conducting elements (sieve tube members) is relatively small. It also results from the very high viscosity of the phloem sap. Moreover, it has been experimentally demonstrated (with the use of aphids' proboscises) that the phloem sap, contained in leaf sieve tube members, is under very high positive mechanical pressure P_1 . This pressure, calculated with regard to the atmospheric pressure ($P_a = 1,013$ [hPa]), may reach values up to +3 (MPa). It has also been found, through microscope investigations, that pore radius dimensions in the walls of the leaf mesophyll and cuticle cells (from which pore water transpires into the atmosphere) represent the order of magnitude of $r \approx 48 \times 10^{-9}$ (m). On this basis, it has been accurately calculated, from the formula (1), that the negative mechanical pressure P_A in the leaf apoplast may take very high negative values, reaching even $P_A = P_k = -3$ (MPa). The above-quoted

discoveries (Wilkins, 1969; Zimmermann and Brown, 1971; Salisbury and Ross, 1976; Kargol, 1997) have contributed to our developing the long-distance integrated water translocation system in plants (Kargol, 1995, 1996; Kargol and Kargol, 1996; Kargol, 2007; Kargol et al., 2001). They have provided the basis for introducing significant modifications to the Münch model thanks to which that model could become closer to the biological reality.

In this system, as presented in Figure 3, four stages of water translocation have been distinguished (Kargol, 1996; Kargol and Kargol, 1996; Kargol, 2007; Kargol et al., 2001). At the first (I), the flow J_{vr} , which comprises water taken in from the soil, permeates across the root to the xylem of the vascular cylinder. At the second stage (II), the water flow J_{vx} is translocated through the xylem along the plant. Most frequently, water ascent against gravity occurs. The flow J_{vg} is generated by gravi-osmosis. The remaining part of the water that has reached the leaves is, together with the assimilates, transported through the phloem (as the flow J_{vp}), to those locations in the plant where assimilates are used. This translocation of water constitutes the fourth stage (IV) of its long-distance transport.

Agrobiophysical bases of water translocation along the former three distances are well known. Presently, we shall deal with the biophysical interpretation of phloem

Water Uptake and Transports in Plants Over Long Distances,
Figure 3 Long-distance integrated water translocation system in plants (as described).

transport of water and assimilates. This shall be done basing on the Münch model that we have modified, as part of the integrated water translocation system (cf. [Figure 3](#)).

While modifying the Münch model, it has been assumed that the membrane M_1 of the osmometer A emulates the route of water transport from the leaf apoplast to the inside of sieve tube members, which start the phloem water routes in leaves. This route is the tissue which comprises, for example, photosynthesis cells, sieve tube members, and cells adjacent to the tubes. It must be stressed (Kargol, [1995, 2007](#)) that in the leaf apoplast, there occurs negative pressure $P_A = -3$ (MPa). In contrast, in sieve tube members that start the leaf phloem water routes, we deal with positive pressure, which may reach the value of $P_1 = +3$ (MPa).

Under the circumstances, it should be assumed that the inside of the osmometer A emulates the insides of sieve tube members, which start the phloem leaf water routes. In order for the high pressure to originate in the sieve tube members, it should be assumed that transport of assimilates J^A , which occurs across the membrane M_1 , is realized actively. Thanks to that, they have a high concentration of assimilates. Water, when penetrating osmotically from the apoplast to the inside of leaf sieve tube members, is then capable of generating such a high pressure P_1 . The membrane M_1 ought to be ascribed particular properties as well. To be precise, this membrane must be semipermeable (i.e., have the reflection coefficient $\sigma_1 = 1$). To continue the considerations pertaining to the modification of the Münch model, it has to be said that water – together with assimilates contained in the osmometer A – is transported through the tube R_p (which emulates the phloem conducting elements) to the osmometer B. This transport, marked with the symbol J_{vp} , understood as mass transport, is driven by the mechanical pressure difference $\Delta P_f = P_1 - P_2$. In order to make further considerations more precise, let us assume that the osmometer B refers to the root system as the main location of assimilate use. It emulates in a generalized manner sieve tube members, which end the phloem water routes here. Across the membrane M_2 of this osmometer, the volume flow J_{v2} shall permeate, containing water as well as assimilates. This flow is driven by *reverse osmosis* (Kargol, [1995, 2007](#), Kargol and Kargol, [1996](#)). For this to happen, it is justified to assume that the reflection coefficient of the membrane M_2 amounts to $\sigma_2 \approx 0$. Under the considered conditions, water – together with assimilates – is transported (with the flow J_{v2}) to the apoplast of the root vascular cylinder. For particular long distances, the following laws of continuity can be written: $A_x J_{vx} = A_{tr} J_{vtr} + A_1 J_{v1}$ and $A_1 J_{v1} = A_p J_{vp} = A_2 J_{v2}$, where A_x , A_{tr} , A_1 , A_p , and A_2 are surfaces of permeation by the flows: J_{vx} , J_{vtr} , J_{v1} , J_{vp} , and J_{v2} , respectively (cf. [Figure 3](#)).

Conclusions

It must be stressed that solutes, delivered together with the water (through the xylem) to the leaf apoplast, are

absorbed in a completely active manner by the leaf cells where they are then used in metabolic processes, or simply accumulated. If this was not the case, the process of water transpiration would lead to progressive concentration of the leaf apoplastic solution. That would be utterly disadvantageous from the agrobiophysical viewpoint.

The main element of the integrated water translocation system in plants (as well as symptoms of its circulation) is the adequately modified Münch model. As a result of the introduced modifications, it necessarily becomes closer to the biological and agrophysical reality.

The water delivered to the root apoplast may also be removed from it to the soil due to root pressure. Together with this water, redundant (and frequently harmful) products of metabolism in the plant root may be removed to the soil. This aspect has considerable agrophysical significance as the products removed from the root are the food for bacteria. Their removed components may be needed by the plant. It must be noted that water (as the flow J_{v2}) is delivered to the root vascular cylinder. From here, it may be taken over by the xylem and again ascend along the plant.

WATER USE EFFICIENCY IN AGRICULTURE: OPPORTUNITIES FOR IMPROVEMENT

Meni Ben-Hur

Soil Chemistry, Institute of Soil, Water, and Environmental Sciences, The Volcani Center, ARO, Bet Dagan, Israel

Definition

Any concept of efficiency addresses the output obtainable from a given input. According to this concept, the *general water use efficiency* (WUE_g) index in the context of agricultural and environmental activities determines the yield (Y) of the relevant plant attribute (e.g., biomass, grain, fruit, fiber, and merchandisable yield) per unit volume of water (W) (naturally available and added) per unit plant-growing area, according to [Equation 1](#).

$$\text{WUE}_g = \frac{Y}{W} \quad (1)$$

in which WUE_g can be defined as a specific index for a specific context, for example,

1. *Irrigation water use efficiency* (WUE_i), which is defined in [Equation 2](#)

$$\text{WUE}_i = \frac{Y_i}{W_i} \quad (2)$$

in which Y_i is the harvest or merchandisable yield of irrigated crop per unit growing area and W_i is the volume of irrigation water per unit growing area; or

2. *Rainfall water use efficiency* (WUE_r), which is defined in [Equation 3](#)

$$\text{WUE}_r = \frac{Y_r}{W_r} \quad (3)$$

in which Y_r is the harvest or merchandisable crop yield under “rainfed” conditions (farming watered only by rainfall) per unit growing area, and W_r is the seasonal volume of rainfall per unit growing area.

Introduction

With respect to water availability and use, regions can be divided into two main classes: (1) water-limited and (2) water-non-limited. This classification can be applied

by reference to the “aridity index” (AI), defined in [Equation 4](#) (Thornthwaite, 1948).

$$\text{AI} = \frac{P}{ET_p} \quad (4)$$

in which P = annual precipitation in millimeters; ET_p = annual potential evapotranspiration in millimeters. According to this index, regions with $\text{AI} \geq 1$ are considered to be water-non-limited regions and those with $\text{AI} < 1$ to be water-limited. In some regions, water-limited conditions could be temporary, because of high variability of the rainfall during the year. In regions under permanent or temporary water-limited conditions, in order to increase food production, on the one hand, and to relieve pressure on the earth’s natural ecosystems, on the other hand, it is important to increase water use efficiency (WUE) in agriculture.

Factors affecting water use efficiency

Plants absorb water mostly from the soil, via their root systems, therefore soil water content (water weight or volume per unit of weight or volume of soil) and soil water potential (the energy state of the water in the soil) are important factors in controlling the water availability for plants. The main sources of soil water are rainfall, irrigation water that is supplied by various irrigation systems, and upward movement of water into the root zone from shallow groundwater reservoirs. Four major factors can affect the WUE:

1. Environmental conditions in the vicinity (underground and aboveground) of the plant: plant growth, yield, and reproduction (plant production) depend on environmental factors such as soil fertility and structure, nutrients availability, soil and atmosphere aeration, and solar radiation, in the vicinity of the plant. Absence or deficiency of any of these factors could impair plant production, even under optimal water conditions, and could also decrease the water absorption capability of the plant.
2. Water status in the soil – the soil water can be characterized in terms of its energy state, called the “water potential.” Two main components of soil water potential can affect water uptake by the plant. (a) *The matric potential* (Ψ_m), which expresses the water-retaining strength of the soil matrix, and which is functionally related to the soil water content. In practice, when soil is saturated, that is, all soil pores are filled with water, the water $\Psi_m = 0$; as the soil water content decreases, also the value of water Ψ_m decreases, that is, becomes more negative. For soil solution with given electrolyte concentration, the lower the Ψ_m , the more the energy the plant needs to invest to extract the water from the soil matrix. (b) *The osmotic potential* (Ψ_p) of the water, which depends on the differences between the electrolyte concentrations in the solutions in the soil and in the root tissues: solutions that are separated by the root membrane which acts as a semipermeable membrane. For low and moderate ranges of electrical

conductivity (EC) values, the Ψ_p can be related to the EC of the saturated soil-extracted paste according to [Equation 5](#)

$$\Psi_p(\text{bar}) = -0.36 \cdot EC(\text{dS} \cdot m^{-1}) \quad (5)$$

The Ψ_p value is negative, and the more negative its value, the less the availability of soil water to the plant.

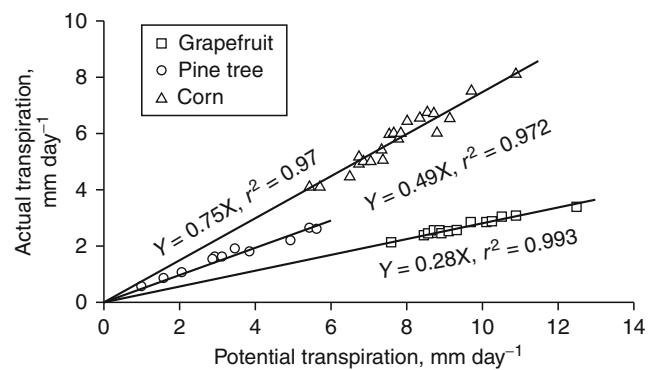

3. Plant properties – the effects of plant properties on WUE are discussed in detail below.
4. Water losses – from the standpoint of WUE, water loss can be classified into two main types. (a) *Internal losses*, that is, losses from soil water in the root zone, examples of which include deep water percolation below the root zone, and direct water evaporation from the soil surface. (b) *External losses*, that is, losses from water supplies before their infiltration into the soil, examples of which include water intercepted by foliage, following overhead sprinkler irrigation or rainfall, and which evaporates without entering either the soil or the plant; water that leaks from the irrigation system and is not used by the plant; and the fraction of the rainfall and irrigation water that is removed by surface runoff.

Plant water requirement

The plant water requirement is the amount of water needed by a plant for its production under any given climatic conditions. However, most of the water taken up by a plant (e.g., 99% in open fields in arid regions) is transpired in order to meet the climatic demand. Under arid and semi-arid climates, that is, climates with a high percentage of bright sunshine, the dry biomass yield of the plant (Y_b) tends to increase linearly with increasing transpiration, according to [Equation 6](#) (de Wit, 1958):

$$Y_b = m \frac{E_a}{E_p} \quad (6)$$

in which m is an empirical coefficient, E_a is the actual transpiration, and E_p is the potential transpiration. Under conditions of unlimited supplies of water, nutrients, and CO₂ to the plant (desirable conditions), and under any given climatic conditions, the plant E_a attains its maximal value, which is the maximum plant water requirement (E_r) for these specific climatic conditions. Values of E_r are presented as functions of E_p in [Figure 1](#), for grapefruit (*Citrus paradisi*), pine (*Pinus halepensis*), and corn (*Zea mays*). For these three plants, the E_r values increased linearly and significantly with increasing E_p , but with differing slopes, which indicates that water requirement depends on both climatic conditions and plant characteristics. In this case, the slope of each regression line ([Figure 1](#)), which expresses the plant water requirement per unit of potential transpiration, could be defined as the plant specific water requirement (SWR), which is an inherent plant characteristic that depends on the genetic properties of the plant: the values of SWR for grapefruit, pine, and corn are 0.28, 0.49, and 0.75, respectively

Water Use Efficiency in Agriculture: Opportunities for Improvement, Figure 1 The actual transpiration values as functions of potential transpiration values for three different crops (Data were taken from Cohen, 1992).

([Figure 1](#)). Under these conditions, [Equation 1](#) can be converted to

$$\text{WUE}_p = \frac{Y_u}{\text{SWR}} \quad (7)$$

in which WUE_p is the WUE of a specific plant, and Y_u is the plant yield of interest under desirable conditions. Thus, WUE_p could be considered as an inherent plant characteristic that indicates the crop productivity per unit volume of transpiration.

Approaches and methods to increase water use efficiency

In the following sections we discuss some major approaches and methods that can be used to increase WUE in agriculture.

Improving irrigation techniques and management

Under rainfed conditions, sporadic, low precipitation, with even short dry spells, often reduces crop production, and a prolonged drought can cause total crop failure. In contrast, irrigation involves supplying water artificially to permit farming during dry periods and droughts, therefore it can increase the WUE, because the potential productivity of irrigated land per unit volume of supplied water (i.e., from rainfall + irrigation) generally exceeds that of rainfed land. The old, traditional irrigation management practice involved repeated, infrequent but massive applications of water that were intended to replenish the soil water reservoir to its field capacity. Each irrigation event was followed by a prolonged period of depletion, nearly to the point of permanent wilting, before the next irrigation event. The concept behind this irrigation management was that the availability of water for plants is constant within the range between field capacity and wilting point. However, it was found that plants responded with a pronounced increase in production when irrigation was provided in sufficient quantity and frequency to prevent the occurrence of moisture stress during the growing

season. However, this favorable water condition in the root zone is difficult to achieve with the traditional surface and sprinkler irrigation methods.

Drip or trickle and microsprayer irrigation systems – collectively called microirrigation systems – currently are being introduced in many irrigated areas. The major advantages of microirrigation systems with respect to WUE are (Hillel, 1997; Coelho and Or, 1999; Assouline et al., 2006):

1. Ability to maintain favorable moisture conditions in the root zone, in accordance with the plant requirements, while still maintaining unsaturated conditions, so that the gas exchange capability between soil air and the atmosphere is high. Under irrigation with microirrigation systems, these favorable moisture conditions in the root zone can be maintained even in problematic soils.
2. Microirrigation systems wet the soil only in the immediate vicinity of the plants. As a result, a large proportion of the field, especially the inter-row areas, remains dry, which, in turn, makes the field less prone to weed infestation and to water evaporation directly from the soil surface.
3. Because microirrigation systems generally apply the water underneath the plant canopy, water loss through interception and the hazards of leaf scorch and fungal diseases are avoided.
4. They enable incorporation of equipment such as fertilizer injectors, filters, timers, and metering valves into the irrigation system. These complementary devices can enable optimization of the water, nutrients, and air regimes in the root zone, and thereby, in turn enable enhancement of the WUE (Nadler and Tyree, 2008).
5. Under saline conditions, the continuous supply of water by microirrigation systems ensures that the Ψ_p of the soil solution remains relatively high (less negative) in the root zone, which increases water availability and plant production.

Preventing surface runoff

Surface runoff is formed when the rainfall intensity or the application rate of the irrigation system exceeds the soil infiltration rate and the water-holding capacity of the field surface. According to the field characteristics, the runoff may flow out of the field and/or accumulate in small depressions within the field. Runoff can affect crop production in three main ways: (a) runoff from a cultivated field usually is lost for plant production; (b) local runoff within a cultivated field leads to poor water distribution within the field; and (c) runoff accelerates erosion of fertile soil out of the field, and depletion of fertilizer and pesticides from the field. Ben-Hur (2008) indicated that when soils with unstable structures are exposed to water-drop impact under rainfall or sprinkler irrigation, seal formation at the soil surface could lead to a drastic decrease in infiltration. Soils in many parts of the world – such as arid and semiarid regions – are characterized by relatively low organic matter

content, high levels of salinity and sodicity, high percentages of expandable clay minerals, and low vegetative cover, all of which decrease the stability of the soil structure (Ben-Hur et al., 2009). Consequently, high surface runoff is expected in these regions (Ben-Hur, 2008).

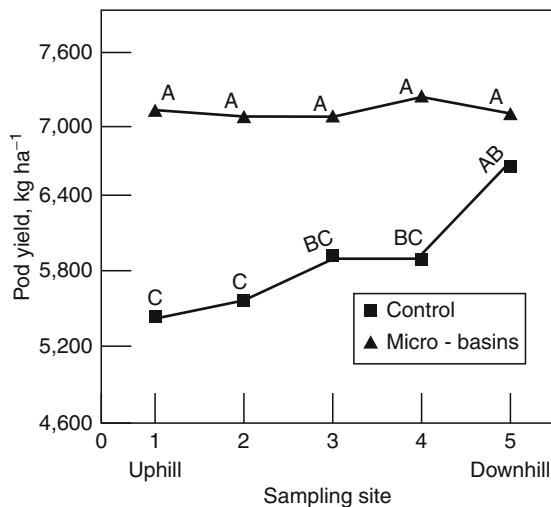

Advantages of self-propelled moving sprinkler irrigation systems (MSISs) include automation, wide-area coverage, ability to operate on relatively rough terrain, and reduced labor requirements; thus, the MSIS has become increasingly popular in recent years. However, since MSISs are designed to apply controlled amounts of water within relatively short periods, the instantaneous rate of water application rate of an MSIS with spray-nozzle emitters might be as high as 300 mm h^{-1} , compared with about 10 mm h^{-1} under traditional sprinkler irrigation. Consequently, this high water application rate increases the expectation of runoff during irrigation, particularly in soils with low infiltration rates (Stern et al., 1992; Ben-Hur, 2008).

Surface soil tillage practices

Field-surface tillage practices involve means such as microbasins (pits) and dikes across the furrows (Figure 2, lower), which can be formed by special

Water Use Efficiency in Agriculture: Opportunities for Improvement, Figure 2 Microbasin cultivator (upper) and microbasins (lower) in field irrigated by moving sprinkler irrigation system (Pictured by M. Ben-Hur).

Water Use Efficiency in Agriculture: Opportunities for Improvement, Figure 3 Peanut pod yields for two tillage treatments and five sampling sites along a slope. Within sites, symbols labeled with different letters indicate significant differences between the yields ($p < 0.05$).

machinery (Figure 2, upper). These tillage practices can increase the surface storage capacity of the field and, in turn, decrease the runoff flow within and out of the field under rainfall and irrigation with MSIS (Morin et al. 1984; Ben-Hur and Assouline, 2002). In a field experiment with peanut (*Arachis hypogaea* L.) and a slope of 3%, which was irrigated with a lateral MSIS with an average application rate of $\sim 100 \text{ mm h}^{-1}$, it was found that pod yield in plots with microbasin treatment were fairly uniform along the slope (Figure 3) whereas, in contrast, in control (without microbasin) plots pod yield increased in the downhill direction (Figure 3). Preventing runoff decreased water loss and improved the distribution uniformity of available water in the field, which, in turn, increased average pod yield by 880 kg ha^{-1} .

Soil amendments

Increased aggregate stability and prevention of seal formation, runoff, and soil erosion can be achieved by spraying soil amendments, such as gypsum or synthetic polymers, over the soil surface before a rainstorm or irrigation event (Levy and Sumner, 1998; Ben-Hur, 2006). The polymer molecules are adsorbed on the surfaces of soil particles, where they act as cement, holding particles together against the destructive forces of water drops, and preventing seal formation and runoff development (Ben-Hur, 2006). Ben-Hur (2001) studied the effects of spraying a low-molecular-weight, nonionic polymer (P-101) at 40 kg ha^{-1} on the soil surface in a field in the western Negev, Israel on runoff and potato (cv. Chloster) yield. The field was routinely irrigated with a linear MSIS fitted with three different emitters, Sprayer No. 1, Spinner, and Super Spray, with discharges of

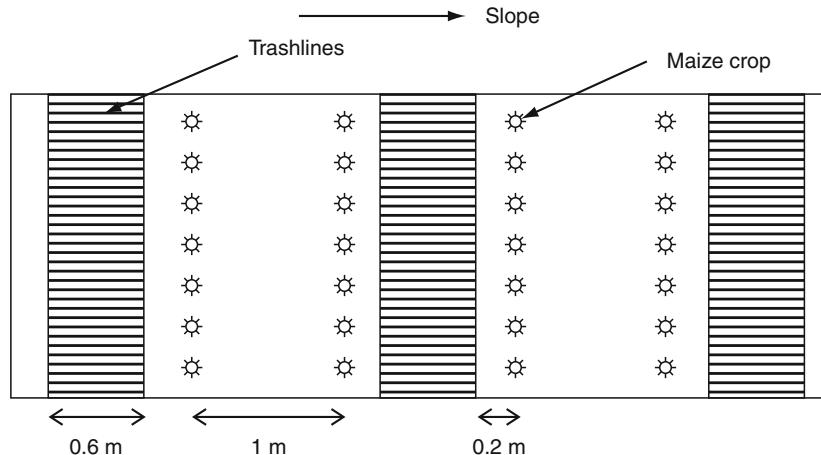

$1,254$, $2,713$, and $1,777 \text{ l h}^{-1}$, respectively. Ben-Hur (2001) found that the polymer reduced runoff by 75%, 60%, and 65% compared with the control treatment (untreated soil), for the Sprayer No. 1, Spinner, and Super Spray emitters, respectively, and the WUE_i values achieved with the MSIS fitted with these emitters were 56 , 31 , and 43 kg mm^{-1} , respectively, on untreated soil, and 66 , 49 , and 65 kg mm^{-1} , respectively, under the 40-kg ha^{-1} polymer treatment.

Soil mulching

To combat the massive problems of runoff and erosion, and the resulting low yields, poor smallholder farmers in arid and semiarid regions often use inexpensive, indigenous soil- and water-conservation techniques. The trash lines technique is among the most common and popular methods of conserving land in many areas of semiarid Africa, and is particularly valued for its positive effect on soil fertility. Wakindiki and Ben-Hur (2002) modified the traditional trash lines technique as the close-space trash lines (CSTL) technique (Figure 4). In this technique, the spacing between the trash lines was reduced to 2 m, and the plants, which are sown between the trash lines, could optimize the benefits from the water that infiltrates in the trash-covered area (Figure 4). Wakindiki and Ben-Hur (2002) studied the effects of a CSTL technique with 0.6-m-wide trash lines on runoff and soil loss, and on corn (*Zea mays* L.) and cowpea (*Vigna unguiculata*) production in semiarid Tunyai, Kenya, during five rainy seasons. The seasonal, average rainfall runoff percentage decreased significantly from 9% in untreated plots to 4% in CSTL-treated plots, and the seasonal, average soil loss decreased significantly from 3.35 Mg ha^{-1} in untreated plots to 1.17 Mg ha^{-1} in CSTL plots. These decreases in runoff and soil loss in the CSTL plots led to significant increases in the seasonal dry biomass (grain + stover) yield of corn, from 1.48 Mg ha^{-1} in the untreated plots to 3.63 Mg ha^{-1} in the CSTL plots.

Increasing crop productivity per unit transpiration, and plant selection

A different approach to increasing WUE is through increasing crop productivity per unit transpiration. To obtain progress via this approach, the closely linked processes of transpiration and yield formation need to be uncoupled, which involves two main, distinct objectives: (1) to achieve a substantial reduction of crop transpiration without a corresponding decrease in yield; and (2) to substantially increase crop yield without incurring a corresponding increase in transpiration. However, because little progress has been made toward the first objective, it is not discussed in this chapter. In contrast, much progress has already been achieved towards the second objective, by increasing the proportion of total dry matter in the harvested crop yield. For example, in some modern wheat varieties, which are grown today, the dry matter content of the grain is half of the plant total dry

Water Use Efficiency in Agriculture: Opportunities for Improvement, Figure 4 Schematic layout of the close-space trash lines technique.

matter, as compared with one-third or less in the wheat varieties that were grown at the beginning of the twentieth century (Stanhill, 1992). The modern varieties have a smaller leaf area and shorter height, and also a shorter crop cycle. All of these improvements decrease transpiration and increase WUE values by 1.5-fold compared with the values that were achieved 100 years ago (Stanhill, 1992). The potential for further progress in this direction is expected to be realized by transferring the carbon metabolism that is responsible for the high net dry matter production of C₄ plants to C₃ crop species (Ting, 1976). This would enable major increases in yields of many agricultural crops to be achieved without significant increases in transpiration. Increasing the crop productivity per unit transpiration by means of plant breeding and genetic engineering, and by growing selected crop varieties with high WUE_p, would enable substantial increases in WUE in agriculture.

Conclusions

In order to increase food production and to relieve pressure on the earth's natural ecosystems in water-limited regions, it is important to increase the WUE in agriculture. Four major factors can affect the WUE: (1) environmental conditions in the vicinity of the plant; (2) the availability of the soil water to the plant; (3) plant properties; and (4) water losses in the field. Some major approaches and methods that can be used to increase WUE in agriculture are: (1) using microirrigation systems for irrigation and improving the irrigation management; (2) preventing surface runoff in cultivated fields by using appropriate surface soil tillage practices, using soil amendments and mulching; and (3) increasing crop productivity per unit transpiration by means of plant breeding and genetic engineering. Using the above means and growing selected crop varieties with high WUE_p would enable substantial increases in WUE in agriculture.

Resistant to penetration by water but not entirely waterproof.

WATERLOGGED SOIL

A soil that is nearly saturated with water much of the time, such that its air phase is restricted and anaerobic conditions prevail. In extreme cases of prolonged waterlogging, anaerobiosis occurs, the roots of mesophytes suffer, and chemical reduction processes occur (including denitrification, methangensis, and the reduction of iron and manganese oxides).

WEATHER, EFFECTS ON PLANTS

Vlasta Štekauerová

Institute of Hydrology, Slovak Academy of Sciences,
 Bratislava 3, Slovakia

Definition

Weather is the state of the atmosphere on a particular place and at a defined time or a defined time interval. It is characterized by a set of data of the meteorological elements and phenomena, as precipitation, sunshine duration, air temperature, air pressure, wind velocity, air humidity, cloudiness, or other characteristics. The weather impact upon the vegetation can be evaluated either directly through its particular components (i.e., meteorological elements) or through transpiration impact upon the biomass production.

Introduction

Weather is influencing the environment permanently. Its course throughout the year is influencing both, the qualitative and quantitative properties of plants. For some production branches, weather presents in relation to vegetation, an objective production factor. For ecosystems, it is a factor on which the life can depend, at extreme, long-lasting conditions, even the plant's some species survival can depend.

Weather conditions are one of the factors influencing biomass production and its variability. Weather impact manifests differently on various species of the vegetation cover.

To determine weather impact upon the vegetation cover is fairly difficult; namely, weather in its effect should be understood as a multicomponent characteristic. It should also be noted that vegetation belongs to the atmosphere–plant–soil system, and that the biomass production depends upon all these three system components.

Long-term weather regime represents the climate representing an average weather state of a particular region. This state is derived from time courses of the meteorological elements, of a long-term period. Climate, differently from the weather, is influencing permanently on the vegetation cover structure and its biomass production. Based on this, it is possible to optimize the plant production structure, in various production regions.

Weather, and its dynamic in particular years, often differs expressively in relation to long-year mean values. Factors influencing the biomass production in a great extent are the weather extremes.

Solar radiation

For weather formation, the most important is the energy transfer from the Sun to the Earth through the cosmic

space, in the form of electromagnetic waves. Solar radiation is only slightly influenced by the cosmic space. It changes only when passing through the atmosphere. There it comes to its reflection, absorption, and dispersion, by clouds, water vapor, molecules of gases, and dust particles.

Electromagnetic spectrum of the solar radiation expands within a broad wavelength interval. Only a negligible part of it (400–760 nm) is noted for physiological effects (photosynthetically active radiation [FAR]), which condition the growth and the development of the green plants. This part of the energetic spectrum is also called the light. It is a part of the plant's photosynthesis.

Physiological radiation effect (photochemical) is materialized in process of the photosynthetic assimilation. Physical result of radiation is the plant's warming and consequent acceleration or deceleration of several physiological processes. Appearance of the plant depends upon the ratio of particular spectrum components. According to the plant's demands for light, we divide them into demanding light, demanding shade, and indifferent.

Photosynthesis is a decisive process for the plant production. Through it, the substances originate basic for the plant's body, and the energy needed for the physiological processes and reactions in the plant's mass exchange.

Portion of FAR in all radiation amount is not constant. It is influenced by the sun's elevation above the horizon, by the cloudiness, by the precipitation intensity, etc. The highest FAR portion in total global radiation was detected at cloudless sky, immediately prior to sunrise (70%), and the lowest at cloudless sky at noon hours (40%). Based upon the observation results, it was agreed internationally that this ratio be constant and equal to 45% of the global energy radiation. This means that the photosynthesis consumes only a small part of it. Photosynthetic efficiency of the real agricultural plants, forests, and marshes, as a rule does not exceed 2.5% of the global radiation energy, in the vegetational period.

Thus the plant production substance is the accumulation of the transformed energy of the sun into yield, and the amount of this energy upon the soil unit area is quasi constant. From it follows, that to achieve the maximum biomass production, it is necessary to utilize maximum ratio of the total solar radiation energy used for photosynthesis, during the production period on the area covered with vegetation.

Maximum biomass production (U_{\max}) is possible to express by [Equation 1](#), where G_{vo} (kWh m^{-2}) is the total global radiation falling during the vegetation period in the given conditions, and ε_{\max} is the maximum utilization degree of the radiation energy for photosynthesis, for a particular plant.

$$U_{\max} = \frac{G_{vo}\varepsilon_{\max}}{100Q} [\text{kg m}^{-2}] \quad (1)$$

Q is energy equivalent needed for the production of 1 kg of organic matter dry substance. Photosynthesis integral part is the transpiration, i.e., the water transfer from soil

through the plant into the atmosphere. Part of water flowing through the plant becomes a part of the transpiration and simultaneously is transporting to plant the nutrients. Transpiration is subordinated to the solar energy inflow. Its substantial part is consumed for the water phase change from liquid to water vapor, and simultaneously for cooling of the surrounding environment and adjusting it for vegetational living conditions.

There is another important process – evaporation. It also depends upon the solar energy input and upon its transformation into heat. The sum of evaporation and transpiration is evapotranspiration, the important water balance component and is also an important thermoregulatory element.

Sunshine

Sunshine duration and thus the solar energy input is governed by regular natural laws and shows a cyclic influence upon the vegetation cover – the yearly seasons. Depending on them directly is the vegetation transpiration.

Temperature

Air temperature is the state quantity determined by the mean kinetic energy of the chaotic air molecules motion.

When passing through the clean atmosphere, the solar radiation takes only a negligible role in the air warming up. The mean source of heat for the earth air enfold is the earth surface, called as active surface. There the sun's short-wave radiation is being transformed, increasing the earth surface temperature, which on the other hand, radiates the long-wave radiation, warming up the atmosphere.

It is surface of the earth, snow cover, rock, vegetation, or arbitrary body, which absorbs, transfers, and radiates energy. This all is of importance even for deeper soil layers.

Among the most important atmospheric processes belongs the heat exchange, forming the atmospheric thermal regime. Heat exchange takes part between the atmosphere, the active earth surface, vertical and horizontal transport of water, and energy.

Temperature presents one of the basic living conditions of plants. It is the base and is inevitable for life and its functions, as the nutrients receipt, transpiration, photosynthesis, breathing, and others. Plants can grow only at a particular temperature interval. Its lower and upper limits are called the critical temperatures. Dependence of the photosynthesis intensity upon the air temperature has form of the normal probability distribution, limited by the minimum air temperatures (biological temperature minimum), within the limits 2–5°C. It is also limited by the high air temperatures (lethal temperature), at which plants are dying in consequence of decay of their tissues (45–50°C). The maximum photosynthesis efficiency takes part at the optimum temperature, depending on the plant species. Optimum air temperature for potatoes is around 30°C, for warm-living plants (tomatoes, cucumbers) it is approximately 35°C. With the air temperature rise, the photosynthesis intensity is dropping down fast, until it stops at the critical air temperatures.

Air pressure

Air pressure is defined as the force, by which the air column (from the earth surface up to the upper atmosphere limit) is acting upon the surface unit.

Irregular air pressure distribution and its changes are due to irregular earth surface warming up. This irregular air pressure distribution results in horizontal and vertical airflow (wind). The air pressure changes cause, in most cases, the weather extremes.

Air pressure depends upon the altitude above sea level, acceleration gravity, and temperature. Neither its direct influence upon plants nor its changes have been detected so far. Its indirect influence is manifested through the weather change, depending directly upon the air pressure changes.

Air pressure changes are also manifested in the unsaturated soil zone, in its water retention and flow. This soil zone is one of the decisive factors influencing the plant's growth. Air pressure is affecting also the groundwater level. It is decreasing (lowering) at the air pressure rise, and vice versa, rising at pressure drop. These changes can make up to tens of centimeters, thus influencing the soil water regime.

Air humidity

Through air humidity the air water vapor content is expressed. A dry air does not exist at natural conditions. Water vapor has a decisive importance for the meteorological phenomena related to the water physical phase changes. The air water vapor content is changing continuously within particular limits, in consequence of the water phase changes. Depending on the temperature, the air can contain only a particular amount of water vapor. It is an equilibrium state, when the air is saturated with water vapor at a given temperature. At this state, that amount of water vapor molecules condensate into water, same molecules amount of water will evaporate at this temperature.

Air humidity is influencing the transpiration intensity and thus indirectly, the vegetation cover. The lower the air humidity, the higher is the transpiration. When the air is saturated with water vapor, the transpiration is zero. Air humidity is of the highest importance in periods when evaporation is of such intensity, that water inflow from soil is not sufficient for the plants water consumption. Vegetation then wilts and fades away inevitably.

Direct effect of air humidity upon the plant production can be observed also at incidence of plant diseases and insects. Many plant diseases and incidence of insects, except the air temperature, depend also upon the air humidity.

Cloudiness

Degree of the sky coverage by clouds is called cloudiness, expressed by the ratio of the sky covered by clouds, e.g., within the range from 0 to 10, or in percent (%).

Cloudiness plays an important role in view of the earth energy balance. Clouds absorb and reflect the direct solar

radiation and increase its dispersion. Thus, it decreases the positive balance of the long-wave radiation falling on the earth surface, and through this, it changes the conditions of its illumination.

Formation of clouds is due to irregular air water vapor distribution. Existence of the condensation nuclei is inevitable for that, together with saturation of the air by water vapor around the nuclei. Regardless of the cloud origin conditions, it is always formed either by tiny water droplets or by very small ice crystals. For vegetation are important those clouds bringing precipitation.

Precipitation

From meteorological elements or phenomena influencing most the plant's nutrients intake, belongs the precipitation amount. It influences primarily its water regime as well as that of the soil. Water as a base of the soil water solution and the plant nutrients carrier is influencing nutrients reception by a dominant way.

Precipitation deposited from the clouds is falling on the earth surface in a liquid or solid phase. The liquid precipitation is rain, which can be either of a long-term character (regional rain) or of a short-term one (short-term downpour). Important is also snow precipitation of a solid phase. It supplies water to soil in sufficient amount at the beginning of the vegetation season, and also protects vegetation against freezing out. Water is a basic building component of the plant complexes, where it plays important vital functions. Precipitation belongs to the natural water resource, in many cases only single supplying vegetation by water. In order to secure in plant cells normal vital functions, these cells must be sufficiently saturated by water – hydrated. Hydration level is not a stable quantity, because each cell, each plant organ, and the whole plant has its own water balance, i.e., its inflow and outflow.

The plant water content is not static, it is dynamic. The receipt and release water balance components in the same time interval are not the same. The balance can be positive at water saturation or negative when water deficit originates, and the plant suffers with lack of water. The water deficit can be of a permanent character, caused by a low soil moisture (by prevailing transpiration), or transient caused by a transient passive water balance, e.g., during daily time course.

In general, plants utilize water mostly from the soil resources. Soil water storage is formed by the precipitation and does not have the properties of free water. It is held in soil mainly by the capillary soil forces. So the soil water resources magnitude, except precipitation, depends upon the soil water type and its retention storage capacity. Whether this storage will be satisfactory for the production process during the vegetation season depends upon the soil hydrophysical properties and upon the plant characteristics. There exist such moisture soil states, according to which it is possible to determine whether the soil water is able to supply plant by it. Such soil moisture states can be expressed by the basic hydrophysical

soil characteristic – moisture retention curve. The field water capacity is characterizing by moisture lasting in soil profile a relatively longer time, when simultaneously the soil aeration zone is sufficient for the vegetation cover development. The point decreased soil water availability is characterizing the state of soil water when vegetation cover physiological processes are limited by water shortage. In case of the soil moisture increase (e.g., by precipitation), the plant is developing and growing further on. The soil moisture wilting point is characterizing the state when vegetation cover is not sufficiently supplied by water, and the plant is in stress and it is permanently wilting, perishing. This state is usually irreversible. The latest research shows that plants are able to use water from soil also in case when soil moisture is lower than soil moisture subsistent to wilting point, if they can adapt to the stressed conditions. (Ritchie and Burnett, 1971).

When extreme precipitation occurs, the soil can be flooded, soil aeration is low (anaerobiosis range of soil moisture), and not suitable for vegetation cover further development. Similarly, at longer precipitation absence, the dried soil is not able to supply vegetation by water. To what extent these extremes will show up upon the plant production decrease depends on their durations and on their occurrence frequency during the vegetation season, respectively.

Conclusions

It is rather complicated to express impacts of weather upon the vegetation. The weather is a multicomponent system, where individual components are mutually influencing each other. Impact of these components upon vegetation can be expressed also individually, but it should be kept in mind that they all act together influencing the weather in a complex way.

Weather and its changes show up in change of the vegetation cover production. It can be expressed in relation to the plant dry matter production Y_d , and to the total transpiration E_t during the whole vegetation season, according to Equation 2:

$$Y_d = nE_t \quad (2)$$

where n is water efficiency coefficient.

The total transpiration is a function of weather as a whole. The Penman–Monteith equation (Penman, 1948; Monteith, 1965) based on the transpiration model is using the above-described weather components as the model input variables. These weather components, either directly or indirectly, influence the transpiration or evapotranspiration velocity, respectively.

The weather manifests specifically by its extremes, like flooding, long periods of droughts (periods without precipitation), strong windstorms, etc. These extreme events usually influence the vegetation cover production only once in a way.

WETLANDS, MANAGEMENT, DEGRADATION AND RESTORATION

Kathrin Kiehl

University of Applied Sciences Osnabrück, Osnabrück, Germany

Definition of wetlands

For wetlands many definitions exist, which are generally based on three components: hydrology, physicochemical environment, and biota (Mitsch and Gosselink, 2000). The most comprehensive definition of wetlands was presented by the U.S. Fish and Wildlife Service (Cowardin et al., 1979):

Wetlands are lands transitional between terrestrial and aquatic systems, where the water table is usually at or near the surface or the land is covered by shallow water. [...] Wetlands must have one or more of the following three attributes: (1) at least periodically the land supports predominantly hydrophytes; (2) the substrate is predominantly undrained hydric soil; and (3) the substrate is [...] saturated with water or covered by shallow water at some time during the growing season of each year.

This definition covers both coastal and freshwater wetlands. The following text will focus on freshwater wetlands such as shallow lakes, ponds, freshwater marshes, swamps, and riparian ecosystems. Peatlands such as bogs and fens are another type of freshwater wetlands characterized by the accumulation of peat under wet conditions. Environmental

functions of peatlands are described by Vasander ([Peatlands: Environmental Functions](#)) and physical properties by Szajdak ([Peats and Peatlands, Physical Properties](#)).

Functions of wetland ecosystems

Both in natural and in cultural landscapes, wetland ecosystems play a major role in the ecological functioning of watersheds as they are often located in transition zones between terrestrial and open-water aquatic ecosystems. Their morphology and hydrologic conditions influence not only the retention and release of water but also biogeochemical transformations of carbon, nutrients, and pollutants and the availability of habitats for specialized plant and animal species (Bobbink et al., 2006; van der Valk, 2006).

Water budget and water retention

Wetlands can be characterized by their hydroperiod and their water budget ([Ecohydrology, Water Budget in Soil](#)). The hydroperiod is defined as the seasonal pattern of the water level (Mitsch and Gosselink, 2000). Examples for freshwater wetlands with different hydroperiods are permanently flooded wetlands (e.g., ponds, shallow lakes), seasonally flooded wetlands (e.g., riparian wetlands and freshwater marshes affected by floodings), and wetlands with water-saturated substrates but without surface water during most of the year (e.g., fens and bogs, see [Peatlands: Environmental Functions; Surface and Subsurface Waters](#)).

The water budget of a freshwater wetland is affected by precipitation and “evapotranspiration” as well as by inflow, outflow, and storage of water as a result of geomorphological and geological conditions. The balance between water storage, inflow, and outflow can be expressed as

$$\frac{\Delta V}{\Delta t} = P_n + S_i + G_i + ET + S_o + G_o$$

where

V = Volume of water stored in the wetland

$\Delta V/\Delta t$ = Change of volume of water stored in the wetland per time unit t

P_n = Net precipitation

S_i = Surface inflows (incl. flooding by streams)

G_i = Groundwater inflows

ET = Evapotranspiration

S_o = Surface outflows

G_o = Groundwater outflows

(modified for freshwater wetlands after Mitsch and Gosselink, 2000)

The capacity of wetlands to store water is one of their main ecosystem functions (Davidsson et al., 2000; Zedler, 2003; McAlpine and Wotton, 2009). There is strong evidence that water retention in wetlands located in floodplains or in headwaters of rivers can significantly reduce or delay floods and therefore reduce flood damage downstreams (Bullock and Acreman, 2003; Zedler and Kercher, 2005; Brody et al., 2007; Ming et al., 2007). Only in few cases, an increase of downstream flood flows has been

reported for saturated headwater wetlands (Bullock and Acreman, 2003).

Transformation and retention of nutrients and pollutants

The improvement of water quality during the flow through wetlands is another ecosystem function of both ecological and economical significance (Zedler, 2003; McAlpine and Wotton, 2009). All over the world, constructed wetlands are used for the treatment of wastewater (Vymazal et al., 2006; Lee et al., 2009; Zhang et al., 2009). Natural and seminatural wetlands, however, have also a high potential for removing nutrients from surface waters and groundwater, for example, in agricultural landscapes with high nutrient discharges (Jansson et al., 1994; Kronvang et al., 1999; Saunders and Kalff, 2001; Hoffmann and Baattrup-Pedersen, 2007; Bavor and Waters, 2008).

As human activities (e.g., agricultural fertilization and burning of fossil fuels) have altered the global nitrogen cycle, the nitrogen load to freshwaters has strongly increased, especially in industrialized and agriculturally used areas (Vitousek et al., 1997). It has been shown that diffuse nitrogen discharges from agricultural land can be lowered by a reduction of fertilizer application, by nitrogen uptake of crops, and by nitrogen removal in natural and constructed wetlands (Saunders and Kalff, 2001; Verhoeven et al., 2006; Lee et al., 2009).

In wetlands, three processes contribute to nitrogen retention: denitrification, sedimentation, and uptake by aquatic plants. During denitrification, facultative anaerobic bacteria in sediments or in biofilms on the surface of aquatic plants transform nitrate finally to gaseous atmospheric nitrogen (N_2):

The efficiency of nitrogen removal is affected by the nitrate concentration, the availability of organic carbon, the presence and type of wetland vegetation, and the retention time of the water within the wetland (Davidsson, 1997; Lee et al., 2009). Under certain conditions (e.g., at high temperatures or in partly aerated wetland soils), the intermediate product nitrous oxide (N_2O), instead of the end product N_2 , may be released to the atmosphere during denitrification (Vymazal et al., 2006), which is problematic because N_2O is one of the greenhouse gases contributing to global warming (see [Greenhouse Gas Fluxes: Effects of Physical Conditions](#)). For constructed wetlands, however, which generally receive the highest nitrogen loads, the contribution to global warming potential is usually neglectable due to their small scale (Stadmark and Leonardson, 2005; Vymazal et al., 2006). In natural wetlands, the production of greenhouse gases can be reduced by careful management of the water table (see below).

Phosphorus discharges from agricultural areas to surface waters are mostly due to soil erosion because phosphorus is bound to soil particles (Blume et al., 2002; see [Water Erosion: Environmental and Economical Hazard](#)).

The processes for the removal of phosphorus from surface waters are sedimentation of P bound to soil particles, soil adsorption, plant uptake, and microbial uptake (Uusi-Kämppä et al., 2000; Hogan et al., 2004; Hoffmann et al., 2009). In contrast to nitrogen, phosphorus cannot be totally eliminated from wetlands by bacteria. It can be accumulated in wetland sediments or released later depending on the interactions between groundwater and surface water. In riparian buffer zones and other temporarily or permanently flooded wetlands, P-retention by sedimentation can reach high rates, while immobilization rates by plant uptake are much lower (Kronvang et al., 1999; Hoffmann et al., 2009). Particle-bound phosphorus can be released from wetlands, however, when sediments are remobilized and washed out, for example, due to high flow velocity of flooding water. Furthermore, dissolved P can be released from wetland soils or sediments due to interactions with iron and aluminum oxides or other minerals under anaerobic conditions (Hoffmann et al., 2009). The sorption, precipitation, and release of different P-fractions under changing redox potentials (see *Oxidation-Reduction Reactions in the Environment*) is a complex field that still needs further research.

Apart from nutrient retention, constructed wetlands have also been used successfully for the removal of industrial pollutants such as heavy metals or organic compounds from wastewater (Yang et al., 2006; Haberl et al., 2008; Vymazal and Kröpfelová, 2009).

Wetlands as habitats for native plants and animals

Worldwide, wetlands are important habitats for specialized plant and animal species (Mitsch and Gosselink, 2000). Wetland plants such as hydrophytes (water plants) or helophytes (semiaquatic plants with aboveground organs above the water table) need special morphological and physiological adaptations to cope with temporal or permanent submergence and anoxic conditions in the root zone (Jackson, 2006; van der Valk, 2006; *Aeration of Soils and Plants*).

Many invertebrates such as aquatic insects, crustaceans, or mollusks depend on wetland habitats (van der Valk, 2006). Typical wetland vertebrates include amphibians (e.g., frogs and newts), reptiles (e.g., alligators and crocodiles), birds (e.g., ducks, waders, herons), mammals (e.g., beavers, otters, moose), and fish species typical for shallow water.

Apart from some widespread species, many native wetland plant and animal species have become rare due to wetland loss and degradation (see below). Today, a high proportion of species typical for wetlands and other freshwater ecosystems is even threatened with extinction (Bobbink et al., 2006).

Wetland degradation and loss

With increasing human activity, in particular since the nineteenth century, large areas of natural wetlands have been degraded or destroyed by drainage and

intensification of land use (e.g., Wolff, 1993; Finlayson and Rea, 1999; van der Valk, 2006). Especially in industrialized countries, natural wetlands declined due to reclamation of floodplains, poldering, river regulation, peat mining, and drainage for agriculture and forestry. Worldwide, the dramatic loss of wetlands has reached 50%; in densely populated regions of Europe, North America, or East Asia even more than 80% of wetlands are lost or severely degraded (Bobbink et al., 2006).

Many natural wetlands are degraded due to drainage by artificial ditches or restricted flooding regimes, which can change the soil structure (see *Physical Degradation of Soils, Risks and Threats*) and the whole biogeochemical cycling of nutrients and other chemicals in soils and sediments and hence affect the quality of resident and outflowing water (Updegraff et al., 1995; Olde Venterink et al., 2002; Hoffmann et al., 2009). Furthermore, the drainage and cultivation of wetland soils with high contents of accumulated organic matter (especially in peatlands; see *Peatlands: Environmental Functions*) leads to tremendous losses of CO₂, N₂O, and other greenhouse gases (Zedler and Kercher, 2005; see *Greenhouse Gas Fluxes: Effects of Physical Conditions*).

Although wetlands show a high capacity for retention and transformation of nutrients (see above), nutrient loads to natural wetlands have reached a critical level in many parts of the world with negative effects on wetland biodiversity and ecosystem functioning (Khan and Ansari, 2005; Lamers et al., 2006; Hogan and Walbridge, 2009). Therefore, wetland management and restoration have to consider the conflict between the optimization of nutrient retention and the optimal conservation of species-rich wetland communities adapted to oligo- and mesotrophic conditions (Verhoeven et al., 2006).

Wetland management

Natural wetlands are often unmanaged but in many parts of the world, both, natural and especially constructed wetlands are managed for nature conservation, environmental protection, and recreation or for the production of food and renewable resources (Mitsch and Gosselink, 2000; Zedler and Kercher, 2005; Welcomme et al., 2006; see *Nature Conservation Management*). Management practices differ strongly between different types of wetlands depending on desirable ecosystem services and other management goals.

In constructed wetlands, the management of floods and nutrient retention includes the optimization of wetland topography in order to control the water table, the in- and outflow as well as the retention time of the water (Trepel and Opitz 2000; Vymazal et al., 2006). Periodic removal (“harvest”) of vegetation and organic detritus or sediments (if necessary) enhances the water flow through the wetland and removes nutrients that cannot be eliminated by bacterial transformations (e.g., phosphorus, see above). Furthermore, the removal of vegetation and detritus can have a positive effect on wetland biodiversity

because the dominance of competitive species is reduced and conditions for early successional plants (like many threatened water plants) are improved.

Due to the fact that water and nutrient budgets of wetlands within one catchment area are often related and biocenoses are linked to each other, it is advisable to develop management concepts for whole watersheds (Kronvang et al., 1999; Zedler, 2003; Pittock et al., 2006). For a sustainable management of natural and seminatural wetlands, it is a challenge to take into account conflicting interests of biodiversity conservation and agricultural or industrial land use as well as ecosystem services (Maltby, 2006; Verhoeven et al., 2006).

Wetland restoration

Although damages to natural wetlands are often not reversible (e.g., loss of organic matter and soil compaction due to drainage), many projects have shown that it is possible to restore at least part of the ecosystem functions of degraded wetlands (Zedler and Kercher, 2005). For the restoration of drained wetlands, it is essential to improve the water balance (see above) by rewetting and to restore the hydroperiod, for example, by filling up ditches, inflow of surface water or restoration of natural flooding regimes (e.g., Pfadenhauer and Grootjans, 1999; Hoffmann and Baattrup-Pedersen, 2007). However, not only the quantity but also the quality of the water used for rewetting has to be considered in order to avoid negative effects of high loads of nutrients and pollutants on species-rich oligo- and mesotrophic ecosystems (Lamers et al., 2006; Verhoeven et al., 2006). In areas with high nutrient discharges from agricultural fields, it is recommendable to use series of consecutive wetlands. First, nutrient-rich water can be cleaned, for example, in constructed wetlands optimized for nutrient retention (e.g., Vymazal et al., 2006) or in (semi) natural wetlands with high productive but species-poor vegetation like reed (*Phragmites australis*) with high potential for nutrient retention. Afterwards, the cleaned discharge water can be used for rewetting of oligo- and mesotrophic wetlands with high value for biodiversity.

In rewetting projects, it has to be considered that soil physical properties and the biogeochemical cycling of nutrients in formerly drained wetland soils can be changed dramatically by drying and rewetting (Olde Venterink et al., 2002; Lamers et al., 2006; see *Wetting and Drying, Effect on Soil Physical Properties*). Under certain conditions, rewetting can, for example, induce phosphorus discharges from eutrophied wetland soils (Hoffmann et al., 2009) or enhance the production of greenhouse gases if water tables are not carefully adjusted (Verhoeven et al., 2006).

Wetland restoration can be limited not only by abiotic but also by biotic constraints (Zedler and Kercher, 2005). As many alien invasive species spread easily along watercourses, the restoration of natural or seminatural wetlands can be hampered by dominant invasive species (Zedler and Kercher, 2004). On the other hand, wetland target

species, which have disappeared from the wetland and its surroundings due to drainage or changed land use, often show a limited dispersal in fragmented landscapes (e.g., Klimkowska et al., 2007). Recent studies indicate, however, that dispersal limitation can be overcome by measures of target species introduction (Pfadenhauer and Grootjans, 1999; Zedler and Kercher, 2005).

Summary

Freshwater wetlands as transitional ecosystems between terrestrial and aquatic systems have important ecological functions in watersheds. Calculations of water budgets have shown that the capacity of wetlands to store water is generally high. The quality of water loaded with nutrients or pollutants can be strongly improved during the flow through wetlands due to sedimentation and nutrient transformation processes (e.g., denitrification). Therefore, constructed wetlands can be used for wastewater treatment. Natural wetlands as habitats of many specialized plant and animal species and globally important sinks for carbon have dramatically declined all over the world. Furthermore, drainage and restricted flooding regimes have led to tremendous carbon losses from wetlands and often changed the biogeochemical cycling of nutrients and other chemicals in soils and sediments. Management and restoration concepts for the improvement of the retention and habitat function of wetlands should be developed for whole watersheds. They have to consider the conflicting interests of biodiversity conservation and agricultural or industrial land use as well as the ecosystem services of wetlands.

WETNESS

Water content of soil solids per unit mass (mass-wetness); or per unit bulk volume of the soil (volume-wetness).

WETTABILITY

The tendency of a soil to accept water (in contrast with the opposite tendency of some soils to repel water, called “hydrophobicity”). Water applied to a wettable soil typically forms an acute contact angle, and is drawn into the soil’s pores.

Definitions

Wetting is defined as the process leading to increase in water content of an unsaturated soil upon ingress of water.

Drying is defined as the process leading to reduction in water content and degree of saturation of a soil due to evaporation or evapotranspiration.

Introduction

Residual soils often exist where the climate is characterized by alternate wet and dry seasons. During dry period, the soil zone located above the water table and near the ground surface (up to depths of 6 m or more) begins to dry out with concomitant reduction in degree of saturation (S_r) in the soil mass. The loss in water by evaporation causes water to flow from the deeper regions of the soil mass toward the surface by capillary action. During drying process, capillary menisci form between adjacent soil particles at the air-water interface, with the pore water pressure (u_w) in the convex inner side being lower than the atmospheric pressure (u_a) on the concave outer side of the menisci (Yong and Warkentin, 1975). This pressure difference ($u_a - u_w$) constitutes the matric suction in unsaturated ($S_r < 1$) soils (Fredlund and Rahardjo, 1993). It has been suggested that the matric suction acts as a “modified” effective stress and increases the shear strength of unsaturated soils that mainly manifests as the apparent cohesion (Brand, 1982; Ho and Fredlund, 1982). The matric suction contribution to effective stress can be represented through a suction stress component, $\chi(u_a - u_w)$, where χ is a material property (Bishop and Blight, 1963; Lu and Likos, 2004) that depends on the degree of saturation, varying between zero (perfectly dry soil) to unity (saturated soil). According to Burland (1961), Jennings and Burland (1962), the high curvature capillary menisci formed at the grain contact points during drying tend to glue or bond the particles. These bonded particles offer considerable resistance to local shear stresses induced by addition of loads. Consequently, soils develop larger shear strength and resistance to volumetric deformations in the unsaturated state. However, infiltration of water causes loss of matric suction strength component and the soil mass responds by experiencing shear failure or swell/collapse strains when subjected to K_0 loading condition (i.e., the soil cannot experience lateral strains).

Effect on strength

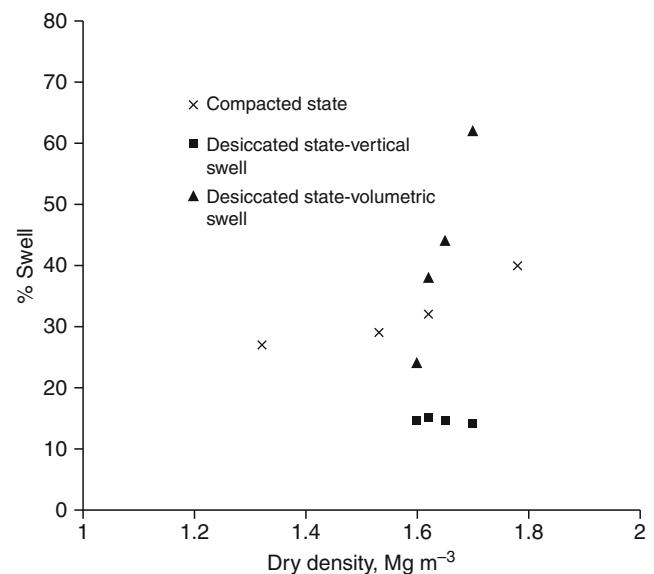

The influence of cyclic wetting and drying on certain engineering properties of residual soils has been investigated. Blight (1966) observed that repeated wetting and drying of residual soils produced an irreversible and significant increase in shear strength of the desiccated clay. The effect of intense wetting and drying appears to be equivalent to those produced by heavy overconsolidation. Grant (1974) investigating lateritic soils of Australia found that lightly tamped specimens subjected to cyclic wetting and drying mobilized unconfined compressive strength of the order of 50–100 kPa starting from a negligible strength at the beginning of the experiment. Grant (1974) attributed this gain in strength to creation of cementation bonds. Allam (1977), Allam and Sridharan (1981), Allam and Sridharan (1984) and Sridharan and Allam (1982) had

investigated the effect of repeated wetting and drying on the shear strength and consolidation characteristics of red soils from Bangalore District. Their results suggested that a microstructure was created on repeated wetting and drying of the red soil specimens due to cementation of the soil particles by chemical compounds. The generated microstructure in turn increased the shear strength, made the soil less compressible and more porous.

Swell behavior of expansive soils

Several researchers have performed laboratory investigations to understand the swelling behavior of expansive soils subjected to cycles of wetting and drying. The laboratory studies broadly categorize in two groups depending on the amount of drying experienced by the expansive soil specimens during the wetting–drying cycles. Repeated cycles of full wetting and partial drying are observed to reduce the vertical swell potentials of compacted soil specimens (Chu and Mou, 1973; Chen and Ma, 1987; Subba Rao and Satyadas, 1987; Al-Homoud et al., 1995). Comparatively, exposure of expansive soils to full wetting–drying cycles can almost double their vertical swell potentials (Popesco, 1980; Osipov et al., 1987; Dif and Bluemel, 1991; Day, 1994). In both the cases, the vertical swell potentials reached an equilibrium state after about three to five cycles. The reduction in swell potential in the first case is attributed to aggregation of clay particles during full wetting – partial drying cycles leading to reduction in clay content and hence swell potential of the specimens (Al-Homoud et al., 1995). The increase in swell potential in case two is attributed to destruction and disorientation of the soil elements during full wetting and drying cycles (Osipov et al., 1987); equilibrium in particle orientation and fabric is apparently reached after three to four cycles as illustrated by equilibrium swell potentials of the soil specimens.

Variations in initial dry density and compaction water content are known to significantly influence the swell potentials of compacted expansive soils (Chen, 1988). Subba Rao et al. (1998) and Subba Rao et al. (2000) have examined the role of the initial compaction conditions (dry density, water content) on the swell potential of expansive clay specimens subjected to four cycles of full wetting and drying. Figure 1 illustrates their results for an expansive soil (liquid limit = 75%, plasticity index = 44%, clay content = 55%) subjected to four cycles of wetting and drying at 40 °C at vertical stress of 6.25 kPa in odometer cells. The clay specimens develop greater vertical swell magnitudes with increase in dry density ρ_d (from 1.32 $Mg\ m^{-3}$ to 1.78 $Mg\ m^{-3}$) in the compacted state (Figure 1). However, near identical vertical swell potentials (defined as $\Delta h/H \times 100\%$, where Δh is increase in sample thickness on swelling and H is initial thickness of the specimen) of 15% are developed by the specimens after four wetting–drying cycles irrespective of the compaction dry density values (Figure 1). Further, following the cyclic wetting drying process, the dry densities of the

Wetting and Drying, Effect on Soil Physical Properties,
Figure 1 Dry density-swell magnitude relations for compacted and desiccated specimens

clay specimens were observed to vary in a narrow band of 1.6 $Mg\ m^{-3}$ to 1.7 $Mg\ m^{-3}$ (Figure 1). Unlike mobilization of near unique vertical swell potentials, the clay specimens subjected to cyclic wetting and drying process developed volumetric swell potentials (defined as $\Delta e/1 + e \times 100\%$, where Δe is increase in sample void ratio on swelling and e is initial void ratio of the compacted specimen) that vary from 24% to 62%. The volumetric swell potentials of the desiccated clay specimens (specimens subjected repeated wetting–drying cycles) were observed to linearly vary with volumetric shrinkage strains (Figure 2); the volumetric shrinkage strain is defined as

$$\Delta e_{\text{shrinkage}} = e_{\text{compacted}} - e_{\text{shrinkage}}, \quad (1)$$

In Equation 1, $e_{\text{compacted}}$ and $e_{\text{shrinkage}}$ represent the void ratios of clay specimens in the compacted state and at the end of four cycles of wetting and drying (termed desiccated state) respectively. The linear relation in Figure 2 suggests that specimens experiencing larger shrinkage strain or larger reduction in void ratio on wetting and drying are liable to develop larger volumetric swell potentials.

Figure 3 explores the role of initial void ratio in influencing the shrinkage strain magnitudes of expansive soil specimens subjected to wetting and drying cycles by plotting $\Delta e_{\text{shrinkage}}$ versus compaction density of the expansive soil specimens. The plot reveals that densely compacted specimens tend to shrink less upon cyclic wetting and drying. Further, the plot reveals that specimens compacted to dry density of 1.66 $Mg\ m^{-3}$ (point A in Figure 3, termed optimum dry density) would not experience any change in void ratio even after repeated wetting and drying under vertical stress of 6.25 kPa. Collating the

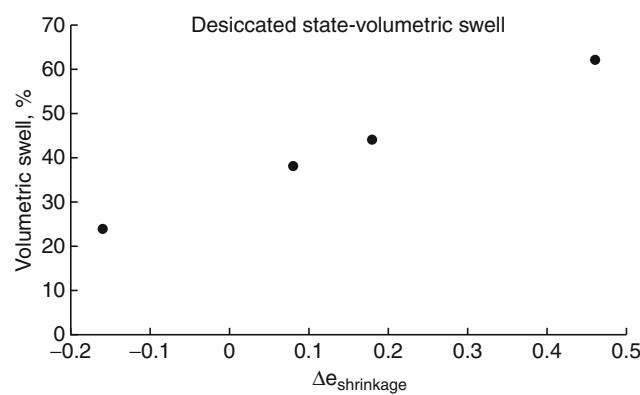

results in Figures 1 and 3 it follows that tendency of compacted clay specimens to experience increase in volumetric swell potential upon wetting and drying reduces as their initial dry density increases; volumetric swell potentials of clay specimens compacted at optimum dry density appear to be immune to the influence of cycles of wetting and drying. The optimum dry density is expected to be function of (a) the surcharge pressure at which the unsaturated soil is wetted and dried and (b) the amount of shrinkage (partial or complete) permitted during each drying cycle.

Swell behavior of lime-stabilized expansive soils

Table 1 presents the swell potential values of compacted expansive soil specimen (liquid limit = 65%, plasticity index = 46%, clay content = 40%) prior to and after lime

stabilization (lime content ranges from 2% to 7% on dry soil mass basis). The table also includes the swell potentials of the lime-stabilized specimens subjected to four cycles of wetting and drying (drying temperature = 40 °C) in odometer cells at vertical stress of 6.25 kPa (Rao et al., 2001). Lime addition modifies the swelling soil (swell potential = 10%) to mildly collapsing soil (collapse potential = -0.02 to -0.1%) brought about by the lime modification and pozzolanic reactions (Herrin and Mitchell, 1961; Bell, 1993).

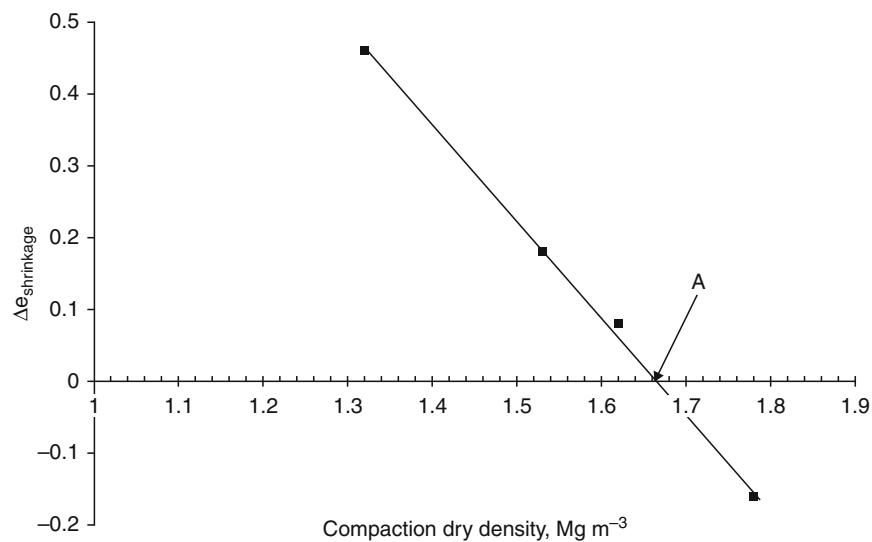

Cyclic wetting and drying degrades the cementation bonds in the lime-stabilized specimens causing them to exhibit vertical swell potentials of 1.2% to 4.2%. The initial consumption of lime (ICL) of the expansive soil corresponds to 3% (Rao et al., 2001). The vertical swell potentials in **Table 1** imply that inadequate lime addition (lime additions below ICL, e.g., 2% lime treated specimen) makes the treated soil more vulnerable to the effects of wetting and drying. Addition of lime in excess of ICL value (e.g., 4% and 7% lime-treated specimens) minimizes the destabilizing influence of wetting-drying cycles on the swelling behavior of lime-stabilized clays.

Wetting and Drying, Effect on Soil Physical Properties, Figure 2 Variation of volumetric swell of desiccated specimen with $\Delta\epsilon_{\text{shrinkage}}$

Collapse behavior

Table 2 examines the influence of cyclic wetting and drying on the swell/collapse behavior of the compacted red soil specimens (liquid limit = 37%, plasticity index = 18 %, clay content = 32%) at vertical stress of 6.25 kPa and 100 kPa (Rao and Revanasiddappa, 2006). The clay fraction of red soils is generally dominated by kaolinite and hydrous oxides of iron and aluminum with some amount of smectite. The compacted red soil specimens were subjected to four cycles of complete wetting and drying at 40 °C in odometer cells at vertical stresses of 6.25 kPa and 100 kPa. The table

Wetting and Drying, Effect on Soil Physical Properties, Figure 3 Influence of compaction density on $\Delta\epsilon_{\text{shrinkage}}$

Wetting and Drying, Effect on Soil Physical Properties, Table 1 Influence of wetting and drying on axial deformations of lime-stabilized soil

Soil state	Vertical swell potential/Collapse potential, %			
	Compacted	2% lime treated specimen	4% lime treated specimen	7% lime treated specimen
Compacted	10	-0.02	-0.04	-0.10
Subjected to four wetting-drying cycles	13	4.16	1.88	1.16

Wetting and Drying, Effect on Soil Physical Properties, Table 2 Index properties of compacted and desiccated specimens

Series	Specimen state	ρ_d ($Mg\ m^{-3}$)	w (%)	Void ratio	% swell at vertical stress of 6.25 kPa	% collapse at vertical stress of 100 kPa
1	Compacted	1.49	10.6	0.81	1	-5.2
1	Desiccated	1.51	2.0	0.78	2.2	-1.8
2	Compacted	1.49	17.6	0.81	0	-3
2	Desiccated	1.54	3.5	0.74	2	-1
3	Compacted	1.49	26.4	0.81	0	0
3	Desiccated	1.66	5.5	0.62	1	-0.5

illustrates that the wetting–drying process causes larger reduction in void ratio for an initially wetter specimen.

Since the swelling tendency of compacted soils increase, while, their tendency to collapse decrease with reduction in void ratio (Popescu, 1986), the wetting–drying process differently impacts the swell and collapse potential of the red soil specimens (Table 2). At a given compaction water content, the reduction in void ratio from wetting–drying process therefore increases the swell magnitude of the soil specimen at the vertical stress of 6.25 kPa but reduces the collapse magnitude at the vertical stress of 100 kPa.

Summary

Cyclic wetting and drying impacts the strength, swell, and collapse behavior of soil specimens. Cyclic wetting and drying increase the strength of natural soil specimens from growth of bonds. Though dry density impacts the vertical swell magnitude of expansive soils in the compacted state, it is unable to control the vertical swell magnitude of expansive soils subjected to repeated wetting and drying. The compaction dry density plays a significant role in the volumetric swell magnitudes of expansive specimens subjected to cycles of wetting and drying. Densely compacted specimens experience lesser shrinkage and therefore develop smaller volumetric swell potential upon subject to wetting–drying cycles. Wetting–drying processes degrade the cementation bonds in lime-stabilized specimens. Expansive soils treated with lime contents that are below the ICL value are more vulnerable to the wetting–drying effects. Soils that can experience both swelling and collapse strains on saturation (example red soils) react differently to wetting–drying effects. The reduction in void ratio from cyclic wetting and drying increases the swelling tendency but reduces the collapse tendency of the red soils.

WILDFIRES, IMPACT ON SOIL PHYSICAL PROPERTIES

Henryk Czachor
 Institute of Agrophysics, Polish Academy of Sciences,
 Lublin, Poland

Definition

Wildfire is a raging, rapidly spreading fire.

The overall effects of wildfire on forest ecosystems cause the reduction or elimination of aboveground biomass and impact belowground soil physical, chemical, and microbial properties. Low-impact burning can promote a herbaceous flora, increase plant available nutrients, and thin overcrowded forests, all of which can foster healthy systems. Severe fires can often cause changes in successional rates, alter above- and below-ground species composition, generate volatilization of nutrients and ash entrainment in smoke columns, produce rapid or decreased mineralization rates, alter C:N ratios, and result in subsequent nutrient losses through accelerated runoff and erosion, leaching, and denitrification. In addition, changes in soil hydrologic functioning, degradation of soil physical properties, decreases in micro- and macrofauna, and alterations in microbial populations and associated processes can occur. The direct effect of fire on belowground systems is a result of the burning severity, which integrates aboveground fuel loading (live and dead), soil moisture and subsequent soil temperatures, and duration of the burn (Neary et al., 1999). Soil erosion limited only by post-fire rainfall intensity and quantity, or until bedrock is exposed, might be expected after wildfire on steep slopes in the forests, given the noncohesive sandy soils and their water repellent character (Shakesby et al., 2007).

The transfer of heat downward in the upper part of the soil combined with the vaporization and movement of water and organic compounds enhances the formation of a highly water-repellent soil condition during fire (DeBano, 2000; Wang et al., 1978).

WILTING POINT

The point when soil water content (usually at soil water potential of -1.5 MPa) is insufficient to meet a plants need due to use water from its own tissues for transpiration.

WIND EROSION

Christof Gromke, Katrin Burri
WSL Institute for Snow and Avalanche Research SLF,
Davos Dorf, Switzerland

Synonyms

Aeolian erosion; Aeolian particle transport

Definition

Erosion. Removal of surface material by any fluid motion.
Wind Erosion. Wind-induced removal of surface material like soil aggregates, grains, and snow.

Introduction

The implications of wind erosion on the Earth's surface are exemplified by several phenomena. Among them are such spectacular events as sand and dust storms or the relatively slow but persistent movement of shifting sand dunes in deserts, desert-like areas, or along coastlines (Schwämmle and Hermann, 2003). In many parts of the world, wind erosion causes substantial soil loss, leading to land degradation and desertification. Cornice formations due to intense snow deposition near ridge locations (Mott and Lehning, 2009), sastrugi and ripples are products of the erosive power of wind in alpine terrain and polar regions, respectively (Clifton et al., 2006).

The examples above show that wind erosion has the power to form the Earth's surface. Moreover, it affects the global dust particle concentration in the atmosphere,

which in turn influences the Earth's climate via the global radiation balance. Implications for human health, in particular respiratory diseases, are also evident as well as for agricultural land use and settling practices. Thus, wind erosion profoundly influences the natural environment and consequently human behavior and society.

Starting from a rather global perspective, the general conditions and prerequisites for wind erosion are introduced in the next section. The physical mechanisms on the particle scale are dealt with in the paragraph [Processes](#). Reference and relevance to agriculture is provided in the next two sections [Interaction with Agriculture](#) and [Mitigation Measures](#), before the conclusions are given.

Background

The occurrence of wind erosion is generally the result of a complex interplay between several factors including surface properties, topography, climate, and atmospheric conditions. The intensity of wind erosion depends on the erodibility of a surface on the one hand and on the erosivity of a wind event on the other. Erodibility is the potential of the surface to be eroded, while erosivity is the potential of the fluid to cause erosion (Shao, 2008). From this, it becomes clear that dry, less cohesive soils are especially susceptible to wind erosion. Large erosion events involving transport of soil material usually take place in arid and semi-arid regions with little or no vegetation cover since the surface erodibility is intrinsically high there. Besides desert areas in the lower latitudes, elevated plains (e.g., Tibetan Plateau) embedded in mountain ranges located in the temperate latitudes are often prone to wind erosion. This is because the local orography favors wind erosion friendly climatic conditions. Air masses approaching a mountain range are forced to elevate and to rain out when the condensation level is reached. The low humidity wind on the ridge's lee side warms up during the descent and dries out the soil surface, increasing its erodibility. Relatively strong winds can now easily cause wind erosion events.

Processes

Looking more closely at the processes occurring during a wind erosion event at the scale of a single particle (soil aggregate, grain, snow particle), three different states can be distinguished: particle entrainment, transport, and deposition. Particle entrainment is the state when the particle becomes mobile, leaves the surface, and becomes airborne. Entrainment can be caused either by aerodynamic forces (aerodynamic entrainment) or by impact with other airborne particles (splash or bombardment entrainment). Transport is the state in which spatial displacements are accomplished by the particle. Three modes of particle transport are generally distinguished: surface creep (also known as rolling, reptation, or surface traction), saltation, and suspension (also turbulent suspension). Surface creep is when the moving particles jostle and roll over the

surface in direct contact with the ground. Saltation is a hopping motion of the particles in which they follow almost parabolic trajectories. Typical saltation distances of sand grains are in the order of a few meters with maximum trajectory heights of 0.1–0.2 m. Suspension is a long-range transport mechanism and occurs when particles get caught by turbulent eddies, which lift them up into higher air streams. Some authors also distinguish a fourth mode of transport: modified saltation (Nishimura and Hunt, 2000). This mode is when a saltating particle gets slightly affected by turbulent eddies and shows a parabolic trajectory superimposed by a fluctuating motion. Deposition is when the moving particle hits the surface or stops rolling and remains at a fixed location.

The most likely transport mode, creep, saltation, or suspension, depends primarily on particle size. Larger-sized particles (>1 mm) preferentially move by creeping. Saltation is the typical transport mode for most sand-sized particles (0.1–0.5 mm). Dust particles (<0.02 mm) are susceptible to suspension because of their low terminal fall velocity. Once entrained, they are transported for long distances (some 1,000 km).

Each transport mode is the result of a certain balance of forces acting on the particle. Six types of forces are distinguished: gravitational force F_G , aerodynamic drag force F_D , aerodynamic lift force F_L , Magnus force F_M , electric force F_E , and cohesive force F_C . Forces originating from particle–particle interactions in the air such as collisions are generally not considered to be important as the particle number density in air is rather low and direct collisions are very rare.

When it comes to overall mass transport by wind erosion, saltation is the most important transport mode. A key parameter for understanding and quantifying saltation is the friction velocity u_* , which is a measure of the shear stress transported downward to the surface by the wind. The friction velocity u_* is the square root of the correlation of the fluctuating velocity parts $u'(t)$ and $w'(t)$ of the streamwise horizontal and vertical wind velocity components, respectively, i.e., $u_* = \sqrt{\langle u'(t) w'(t) \rangle^{1/2}}$. Here, the brackets denote the averaging operation and t denotes time. A rough estimate for the friction velocity is given by $u_* = 0.05 \dots 0.1 U_\delta$, where U_δ is the wind velocity at the top of the atmospheric boundary layer. Typical values for u_* range from 0.1 m s^{-1} to 2 m s^{-1} for normal, average atmospheric conditions. A particle is entrained and starts to saltate when a certain friction velocity, the so-called threshold friction velocity $u_{*,f}$, is exceeded. It is further distinguished between a fluid and an impact threshold. The fluid threshold $u_{*,f}$ is the value that needs to be exceeded for aerodynamic particle entrainment, whereas the impact threshold $u_{*,i}$ is required to maintain saltation when surface particles get ejected by splash and bombardment entrainment and is smaller than $u_{*,f}$ ($u_{*,i} \approx 0.8 u_{*,f}$). Owen (1964) hypothesized saltation to be a self-balancing process, meaning that the concentration of saltating particles in the air is governed by the momentum exchange, i.e., shear stress partitioning between the particle and the fluid phase. In the case of low concentration, only a small

fraction of the momentum of the fluid phase is absorbed by the airborne particles, but the shear stress acting directly on the surface is high and causes large entrainment rates. With increasing concentration, more momentum is absorbed by the airborne particles and consequently less shear stress acts on the ground. When the concentration increases further, the momentum transfer to each single airborne particle is too low to maintain the entrainment of surface particles by impact, leading to reduced entrainment rates. According to this argument, the airborne particle concentration adjusts itself to an equilibrium state.

In the following, simple equations for estimating the threshold friction velocity $u_{*,f}$, the total sediment mass flux Q , the vertical profile of sediment mass flux $q(z)$, and the saltation layer height h_s are provided. The equations were mostly derived by the pioneer of wind erosion studies – Ralph Alger Bagnold (1896–1990). His book “The Physics of Blown Sand and Desert Dunes” is the standard work in wind erosion science (Bagnold, 1941). Assuming the saltation process to be a balance of the aerodynamic drag force F_D and gravitational force F_G only, Bagnold (1941) derived for the threshold friction velocities $u_{*,f}$ and $u_{*,i}$:

$$(u_{*,f}, u_{*,i}) = (A_{t,f}, A_{t,i}) \sqrt{\frac{\rho_p}{\rho_a} g d} \quad (1)$$

with indices f and i indicating the fluid and impact threshold quantities, respectively, ρ_p the particle density, ρ_a the air density, g the gravitation constant and d the particle diameter. The values for $A_{t,f}$ and $A_{t,i}$ were empirically found to lie in the range between 0.1 and 0.2, with lower values corresponding to larger particles (for $d > 0.2$ mm $A_{t,f}=0.1$). The density ratio ρ_p/ρ_a is typically of order 2.5.

For the total sediment mass flux Q including creep and saltation Bagnold (1941) gives

$$Q = C \sqrt{\frac{d \rho_a}{d_s g}} \left(1 - \frac{u_{*,f}^2}{u_*^2} \right) u_*^3 \quad (2)$$

Here, C is a dimensionless coefficient depending on the particle size distribution ($C = 1.5$ for nearly uniform sand, $C = 1.8$ for naturally graded sand, and $C = 2.8$ for poorly sorted sand). d_s is Bagnold’s “standard” grain diameter of 0.25 mm. Equation 2 satisfactorily agrees with experimental results for sand particles of diameter $d > 0.1$ mm, but shows rather poor agreement for smaller particles, e.g., for dust.

The variation of the sediment mass flux with height, i.e., the vertical profile of mass flux $q(z)$ is generally assumed to a first approximation to be exponential. Nishimura and Hunt (2000) suggest

$$q(z) = \rho_a u_* \lambda C \sqrt{\frac{d}{d_s}} \exp(-\lambda/(u_*^2/g) z) \quad (3)$$

where λ is a dimensionless parameter, which typically but not necessarily decreases as the particle diameter

d increases. Wind tunnel saltation experiments with various kinds of particles of different shapes, diameters, and densities suggest $\lambda = 0.15\text{--}1.5$ (Nalpanis et al., 1993; Nishimura and Hunt, 2000).

Finally, an estimate for the saltation layer height h_s is provided. The idea is that the component of vertical kinetic energy, which is transferred to a surface particle in the entrainment state is converted into potential energy. Assuming the vertical lift-off velocity is proportional to the friction velocity u_* , implies $E_{\text{kin}} \sim \frac{1}{2} m u_*^2$ (m is particle mass). The potential energy of a particle in the highest point of its trajectory h_s is $E_{\text{pot}} = m g h_s$. This gives an estimate for the saltation layer height h_s :

$$h_s = \alpha \frac{u_*^2}{2g} \quad (4)$$

Values for the dimensionless parameter α range typically between 1 and 2.5.

The equations for saltation given above should be considered as estimates rather than exact mathematical formulations. However, they involve the basic physical principles of saltation and show fairly good agreement with experimental observations of saltating sand particles. More recent and sophisticated models and estimates can be found in the literature (Greeley and Iversen, 1985; Shao, 2008). These models can be seen as enhancements of the ideas presented above. They also contain empirical parts requiring input parameters, but are often applicable for broader particle size ranges including dust.

Interaction with agriculture

Wind erosion is influenced by agriculture and agriculture is simultaneously affected by wind erosion. For example, plowing activities break up larger soil aggregates into smaller ones and thus considerably increase the surface erodibility at least for some time. On the other hand, cultivation of crops, vegetables, and fruits shelters the ground from direct exposure to atmospheric wind. By absorbing fluid momentum (shear stress partitioning), vegetation reduces the wind erosivity. Additionally, since the soil structure is reinforced by the roots, the surface erodibility is reduced. Vegetation can also trap particles in motion, thus reducing the total sediment mass flux. Overgrazing, leading to lower grass covers or sometimes even to the destruction of low-rise vegetation by trampling also has a negative impact on the surface erodibility. The implications of wind erosion for agriculture and the multifaceted interactions involved are illustrated by the following example. The entrainment and suspension of dust particles often initiates a gradual degradation of the land. This is because fine particles contain most of the soil's organic matter and nutrients. Without artificial fertilizing, less, or in extreme cases, no vegetation will grow on the eroded ground, and the vegetation sheltering effect described above will become diminished and eventually vanish giving rise to increased wind erosion activity. Tegen and Fung (1995) estimate that 30–50% of the total atmospheric dust

loading originates from human disturbed soil surfaces to which activities like cultivation and deforestation contribute a major part.

Mitigation measures

According to the following five basic principles, wind erosion can be controlled by either reducing the wind force at the soil surface or by making the soil more resistant to the wind force (Tibke, 1988):

- (1) Reduce field widths along the prevailing wind direction by strip cropping or establishing wind barriers and thereby reduce wind velocity and erosivity. Wind barriers can either be planted, e.g., trees, shrubs, grasses, or constructed from inert materials, e.g., earth and rock walls, wooden fences, straw rows (Frank and Ruck, 2005).
- (2) Establish and maintain vegetation or vegetative residues to protect the soil, e.g., by stubble mulch tillage, no-till farming, or cover crops. In situations where it is not feasible to protect the soil with a vegetation cover, gravel, crushed rock, and various chemical surface films are used alternatively.
- (3) Produce, or bring to the soil surface, stable aggregates or clods large enough to resist the wind force.
- (4) Roughen the land surface, e.g., by tillage ridges, to reduce the wind velocity and trap drifting soils.
- (5) Level or bench land to reduce effective field widths and erosion rates on slopes and hilltops where converging streamlines of wind flow cause increased velocities and wind forces.

These measures are primarily targeted at cultivated land. However, wind erosion control is a major issue also on grazing land and in severely degraded areas with drifting sand. Trampling damages on grazing land can be avoided by proper management such as rotational grazing, limiting of livestock numbers, and fencing of highly erosive areas. On severely degraded bare land, the objective is to establish permanent vegetation. Vegetation can directly shelter the soil from the wind by reducing its erosive force on the surface, by trapping windborne particles, and by providing locations for sediment deposition (Wolfe and Nickling, 1993; Burri et al., 2009). Furthermore, plants affect wind erosion by altering soil and climatic characteristics, such as soil structural stability and near-surface soil moisture. However, revegetation practices often face major difficulties with low rates of plant establishment and survival. In areas with drifting sand dunes, stabilization by artificial barriers or covers and irrigation are usually required before seeding or planting vegetation. Reclamation success in limiting habitats can also be improved by applying symbiotic mycorrhizal fungi, as they are able to improve both plant growth and soil structure (Graf et al., 2006). Furthermore, it is important to consider native, adapted plant species and natural succession patterns.

Conclusions

Wind erosion processes and their effects are apparent all over the world, ranging from long time land forming

processes to spectacular short time events such as sand or dust storms. They have a direct impact on human society by affecting public health and imposing constraints on our habits and opportunities. Since world climate change is expected to favor wind erosion, it is considered to be among the most serious environmental problems the world is facing today and in the near future. Agricultural cultivation can have positive and negative effects on wind erosion. Appropriate agricultural measures help to stop and reverse land degradation and desertification.

The vivid imagery of a beginning sand storm given by Ondaatje (1992, p. 137) in his famous book “The English Patient” when citing the Egyptian explorer Ahmed Hassanein Pasha shall conclude this article on wind erosion:

It is as though the surface were underlaid with steam-pipes, with thousands of orifices through which tiny jets of steam are puffing out. The sand leaps in little spurts and whirls. Inch by inch the disturbance rises as if the desert were rising in obedience to some upthrusting force beneath. Larger pebbles strike against the skins, the knees, the thighs. The sand-grains climb the body till it strikes the face and goes over the head. The sky is shut out, all but the nearest objects fade from view, the universe is filled.

WINDBREAK AND SHELTERBELT FUNCTIONS

Andrzej Kędziora

Institute for Agricultural and Forest Environment,
Polish Academy of Sciences, Poznań, Poland

Definition

A *windbreak* or *shelterbelt* is a plantation usually made up of one or more rows of trees or shrubs planted around the edges of fields on farms, down the roads and ditches, and across big fields, improving the structure of landscape toward maintaining and enhancing ecosystem services.

History

Living windbreaks (trees and hedgerows) have been used for thousands of years. Some of the oldest shelterbelts were planted in England at the end of the eighteenth century, in Poland in Wielkopolska region in the early years of the nineteenth century, and in Russia in steep region at the same time. Some of the first serious windbreak research started in the dustbowl years in the US Midwest. Years of removing trees and of finely tilling the soil had created a classic wind erosion problem.

In the early 1980s, the kiwifruit boom created a need for artificial windbreaks. The first kiwifruit needed to be sheltered because the hairs on the fruit were rubbed off if the vines were shaken by the wind. This devalued the fruit. Scientists then discovered that the growth and fruit production of the vines were very sensitive to wind speed too, so windbreaks were quickly accepted as an essential part of a viable kiwifruit orchard.

First, the windbreaks were used mainly to protect the fields against erosion and give shelter to animals against

very high temperature in summer and low ones in winter. But the recent investigation on windbreaks has showed new functions of the shelterbelt which are very important for sustainable development of agricultural landscape and rural areas.

Introduction

The knowledge on processes underpinning ecosystem services opened new frontiers for the management of landscapes' structures toward enhancing their capacities to deliver requested services. Forests and shelterbelts show similar functions in the landscape, but a network of shelterbelts perform many similar services like forests growing on smaller part of landscape area. According to the studies carried out by the Institute for Agricultural and Forest Environment in Poland, the following functions of shelterbelts are similar to those shown by forests when 4–5% of the landscape area is under the network of shelterbelts:

- Modify the microclimatic conditions and heat and water balances
- Control the water chemistry composition (control of diffuse pollution)
- Limit water and wind erosion
- Protect the biodiversity
- Increase the survival of the game animals
- Enhance recreational value of the region
- Provide wood and other products
- Promote aesthetic values of the countryside

The first four of these functions are most important for functioning of the landscape as a whole, so they will be

presented in more detail below. The paradigm for proper use of shelterbelts in agricultural landscape must be an aspiration for the creation of the net of shelterbelts instead of planted individual windbreaks ([Figure 1](#)). Shelterbelt networks can better improve water and wind conditions and reduce diffuse pollution in agricultural areas. They should approximately run perpendicular to the direction of dominating winds and cross fields transverse to the directions of water runoff. Tree species composition in shelterbelts should be adapted to local habitat conditions. Shelterbelts should preferably be located on marginal lands and areas of low agricultural utility. This condition is usually fulfilled by connecting their networks with infrastructure elements in fields (roadsides, canals, streams, swamps, etc.). The distance between wind protective belts should generally be 500–700 m, while optimal distances for water quality protection are 400–500 m.

Modification of microclimatic conditions and heat and water balances

The shelterbelts introduced into grain monoculture landscape change the microclimatic conditions of the field as well as aerodynamic characteristics of an active surface. Shelterbelts reducing wind speed ([Jansz, 1959](#)), stomatal resistance, and increasing the humidity ([Rosenberg, 1974](#)), turbulence, and net radiation cause a little increase of actual evapotranspiration of landscape taken as a whole but decrease it from the cultivated field lying between shelterbelts ([Kędziora and Olejnik, 2002](#)). The various ecosystems use net radiation energy in different ways. The shelterbelt uses about 40% more energy for evapotranspiration than does the wheat field. There are two main

Windbreak and Shelterbelt Functions, Figure 1 Net of shelterbelts in the agricultural landscape, Turew, Poland.

reasons for this difference. First, there is a difference in the structure of plant cover. Trees have much longer roots than wheat, which allows them to absorb water from deeper layers of the soil. In effect, more water is within reach of the tree roots. Since trees have greater amounts of water available for their use than cereals, tree leaves have smaller stomatal resistance than cereal leaves. Shelterbelts also have a greater canopy roughness than wheat, which together with a higher wind speed in the shelterbelt canopy, results in more intensive turbulent exchange over shelterbelt.

In the landscape composed of cultivated fields and shelterbelts, one can observe two opposite tendencies in water cycling (Kędziora, 1996). The trees increase evapotranspiration rates. At the same time, the protecting effects of trees stimulate a decrease in wind speed and a lower saturation of vapor pressure deficits which decrease evapotranspiration. It is for this reason that fields between shelterbelts conserve moisture which can increase yields (Ryszkowski and Karg, 1976; Grace, 1988; Brandle et al., 2004).

Controlling the water chemistry composition (control of diffuse pollution)

The increasing use of artificial fertilizers, as well as liquid manure from big farms, usually applied in one dose, and the increasing use of pesticides together with simplification of agricultural landscape structure led to very high pollution of environment. Shelterbelts and stretches of meadows located in upland parts of watersheds also influence the chemistry of water flowing within the reach of plant's root systems. It was observed that nitrate concentrations were decreasing substantially when the groundwater carrying them from under fields passed

under biogeochemical barriers. Both, shelterbelts or small mid-field forests could decrease concentrations of incoming N-NO₃ from fields in range of 63–98%. In meadows the detected decrease of nitrate concentrations was similar and ranged from 79% to 98% of the input (Ryszkowski et al., 2002). The decrease of phosphate concentration under the biological barriers is also clearly evident although not in cases when plant residues underwent rapid decomposition and release phosphorus compounds (Hillbricht-Ilkowska et al., 1995). When the waterborne migration of mineral compounds from the mosaic watershed was compared with their outputs from uniform drainage basin, more than tenfold lower outputs of inorganic ions were detected (Lowrance et al., 1983; Peterjohn and Correll, 1984; Kędziora et al., 1995; Haycock et al., 1997).

Controlling of water and wind erosion

One of the major threats for agricultural activity is water or wind erosions which destroy the soil structure and fertility. Water erosion is a danger in regions with high precipitation and silty soil, while wind erosion usually occurs in dry regions with strong wind. But sometimes, especially in a uniform landscape, after removing all shelterbelts and strips of bushes, erosion can be a substantial threat for ploughed soil layers (Figure 2). Wind erosion can occur in early spring under special weather conditions. At this time, there are many bare fields in the agricultural landscape. When under such conditions the cold weather is accompanied by very intensive solar radiation and very high wind speed, very high water vapor saturation deficit in the near surface air layer is observed. It is generated by intensive heating of soil aggregates surface and very low concentration of water vapor in the cold air. It, in turn,

Windbreak and Shelterbelt Functions, Figure 2 Wind erosion in open landscape in the dry and windy spring, Turew, Poland.

brings to extremely intensive evapotranspiration from the soil aggregated. In such conditions, the hydraulic conductivity within soil aggregates is too low to ensure enough water flux density from inside of aggregates to its surface to cover the needs of evapotranspiration. This process leads to the drying up of the surface of the aggregates and its crumbling. These small mineral particles as well as organic matter are intensively blown away bringing to real silt-storm. One of the best measures to counteract the wind and water erosion is introduction of net of shelterbelt into uniform landscape. Suitable dens of shelterbelt net can reduce the wind speed up to 60% of this in open landscape (Jansz, 1959) and reduce runoff up to 10% in comparison with open landscape (Kędziora and Olejnik, 2002). The reduction of wind up to 60% brings to reduction of wind erosion tenfold.

Biodiversity protection and enhance

Conversion of pristine ecosystems into cultivated fields and intensification of agricultural production brought an impoverishment of biological diversity which was recognized not only by scientists (e.g., Wilson, 1992; Collins and Qualset, 1999; Loreau et al., 2002) but also by politicians (Convention on Biological Diversity opened in 1992 at the Earth Summit in Rio de Janeiro for endorsing; COM 1999 and many other documents).

The results of long-term studies on above ground insect show that more insect families were found in mosaic landscapes with shelterbelts and their recurrent detections were more frequent in consecutive years. The distribution of insect families along a distance gradient from a refuge site (shelterbelts) was well described by a negative exponential equation. An increase in cereal share in crop patterns as well as changes in precipitation had a much smaller impact on insect diversity than mosaic of perennial vegetation patches. The main factors counteracting the decline of biodiversity in agroecosystems are the mosaic structure of the landscapes, reach in shelterbelts. The negative impacts of various agrotechnologies on biodiversity are well documented, but refuges in mosaic landscapes counterbalance the loss of insect biodiversity due to intensification of agriculture production. It was found that a number of families and diversification of the residual families depend on the distance from the shelterbelts,

Summary

Diversification of agricultural landscape structure formed by the introduction of shelterbelts changes evapotranspiration and water runoff rates and therefore influences water cycling in the region. The reported cleansing effects of shelterbelts on groundwater chemistry enable to use higher doses of fertilizers and by that token to achieve higher crop production without stimulation of water pollution by chemicals leached from fields than this will happen

in agricultural landscape consisting of large cultivated fields only. Thus, the introduction of shelterbelts into the agricultural landscape will help to develop new environment-friendly agrotechnologies which at the same time allow intensive production balanced with the ability of agricultural landscape to absorb the side effects of agriculture without being damaged. Landscape, agronomic, and technical methods should mutually support themselves in order to achieve effective and economical system of water management in rural areas.

Definition

X-ray is the electromagnetic waves in which energy of photons on a power scale is between ultraviolet and gamma radiation. X-ray is a key element of a method of nondestructive diagnostics of grain and seeds.

Introduction

Quality of grain is estimated by indicators of over 20 of its physical, biochemical, and technological properties. X-ray method (XRM) occupies more than a modest place among approximately three tens of methods to estimate the quality of grain. It is included into the standard as a method to estimate a contamination and insects' colonization of grain including the quarantine species. Not destroying an object, XRM enables to reveal its internal structure and make it observable and accessible for qualitative and quantitative estimation. This method distinguishes many defects of an internal structure of kernel that affect significantly the quality of kernel:

1. Endosperm cracks caused by natural and anthropogenic reasons
2. Damage caused by Sunn pest (*Eurygaster integriceps* Put.)
3. The enzyomo-mycotic exhaustion
4. The damage of a germ of the various origin and level
5. The hidden insect colonization including early stages of larvae development
6. The internal germination had still begun in the field or in a heap and then stopped by drying
7. Contamination and damage caused by fungi

All these defects reduce the quality of kernel both as seed and as technological raw material. In some cases it makes kernel suitable (the presence of an insect, the beaten out germ) neither for crops nor for processing.

The physical parameters of a separate kernel and grains in weight or in heaps such as the kernel size, grain nature, impurities, etc., are evaluated by XRM. The other possibilities in demand of X-ray method applications for the analysis of grain quality have recently come to light.

X-ray is defined as an electromagnetic radiation with wavelength from 0.001 to 50 nm located in a spectrum between areas of gamma- and ultraviolet radiations. These rays were discovered by Roentgen (1895); later in 1901, he was awarded the Nobel Prize for this discovery – the first award in history in the area of physics. The opportunities of the discovered phenomenon have demonstrated their inexhaustibility until now. The area of its application continues to broaden. The most desirable X-ray property for use is its ability to penetrate through objects being partially absorbed by them in proportion depended on density or thickness of matter. Due to this property radiation penetrating through the complex body consisting of many parts of different size, form, and density displays a shadow "portrait" of body internal structure on the fluorescing screen revealing its defects. X-ray films and now – CCD-matrices can be used instead of the

fluorescing screen. Roentgen tubes are used for emission of X-rays.

It is known from the history that the first features that attracted attention on the X-ray pictures of seeds were the signs of the content absence in the seed coat ("empty seeds") or the signs of the obvious morphological deviations of a germ meaning non-viability of a seed.

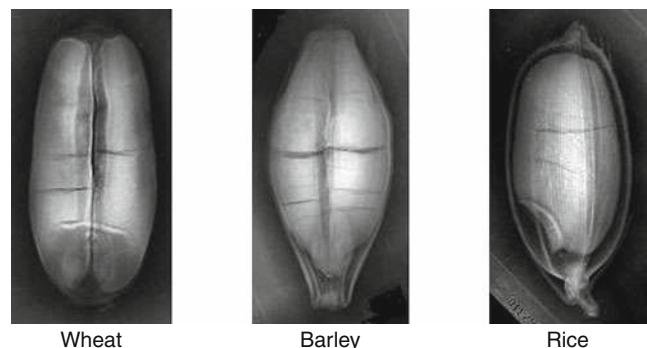

For the first time the radiographic analysis of seeds has found practical application in 50th years of the twentieth century. It was used for quarantine entomological examinations of seeds (Varshalovich, 1958). However, the method has not received development because of low productivity and labor content. It should be taken into account that there was no special equipment, and medical or technical ones were used instead of it. The later did not fit structurally and did not satisfy the needed radiation parameters. At a later stage X-ray radiation has been studied at the Institute for Agrophysics. Firstly, these studies were focused on mutagenic and suppressing growth of plants factor, then its classic application has been studied as well. These works gave an impetus to design special equipment for the analysis of grain and seeds. The microfocus soft-ray X-ray device "Elektronika-25" specially designed for X-ray shooting of seeds and grain was made. It consisted of a monoblock in which the X-ray radiator and a power unit were placed as well as of a film-making chamber and a control panel. It was used to receive the radiation generated under 15–25 kV and tube current up to 100 μ A and expositions from 1 to 16 min on a flat film of sensitivity equaled approximately to 100 on ISO scale. The focus spot sized from 40 to 100 μ m was observed. The chamber had side wall grooves into which the objective frame with grains could be inserted on different heights; the cartridge with X-ray sensitive film was placed under the frame.

The device enabled to shoot with direct X-ray enlargement that could be up to ten times as large. The experiments proved the fact that the shooting with twofold to threefold enlargement was needed to reveal the defects of grain structure (kernel) considering its small size. During 20 years in the past the device had been serving as the main tool for the radiographic analysis of grain and seeds in Russia and Poland (Grundas and Velikanov, 1998; Grundas et al., 1999; Nawrocka et al., 2010; Velikanov et al., 1994, 2008; Yakushev et al., 2002).

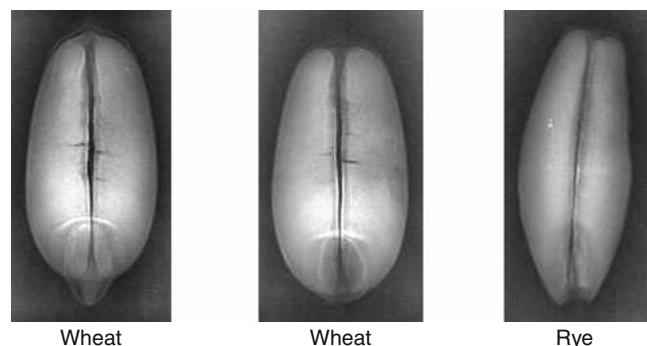

The used range of wavelengths (0.05–0.1 μ m) at specified tube current, expositions, sensitivity of a film, size of a focus spot made possible to distinguish steadily enough contours of a based germ and its details while internal germination has begun. The local irregular changes of optical density (dimness) of an image allowed to judge about presence or absence and also about damages of a germ and endosperm. Considering a character of dimness and its localization it was possible to conclude on the nature of damages.

Examples of X-ray images of cereal grain

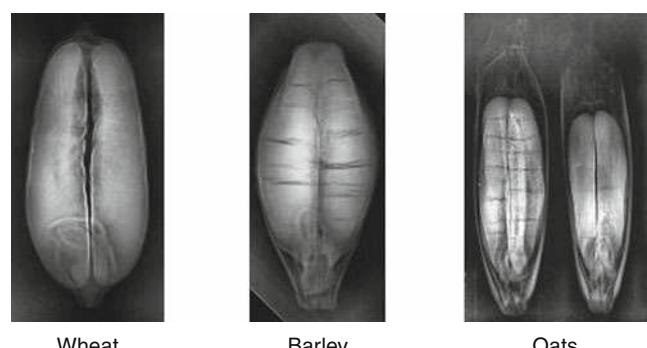

Some examples of X-ray images of kernels of basic cereals with internal defects of various origins are shown below and commented (Figures 1–6).

X-ray Method to Evaluate Grain Quality, Figure 1 Cracking of endosperm in wheat, barley, and rice. (Collection from authors.)

X-ray Method to Evaluate Grain Quality, Figure 2 Full or partial loss of a germ. (Collection from authors.)

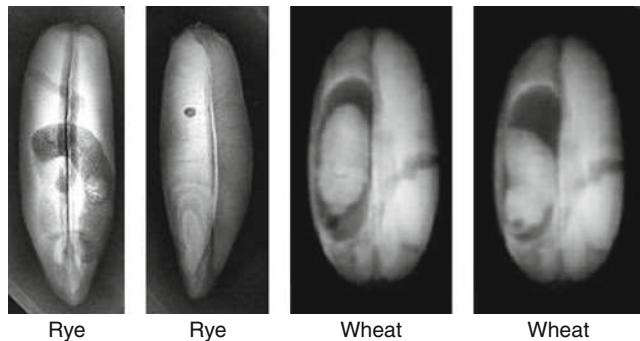

X-ray Method to Evaluate Grain Quality, Figure 3 The latent germination (wheat, barley, oats). (Collection from authors.)

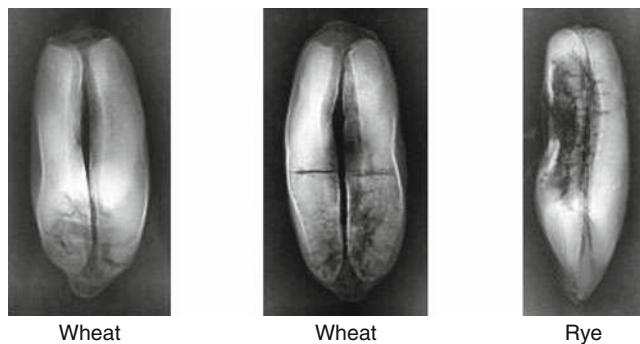

Endosperm of grain's kernel can get cracking while maturing in a field due to drops in air temperature and humidity as well as while drying, preprocessing, and transportation of grain. Strongly expressed cracking reduces both sowing properties of seeds and technological properties of grain (oxidation of spare substances,

reduction of admissible periods of storage, impossibility of getting the whole grits).

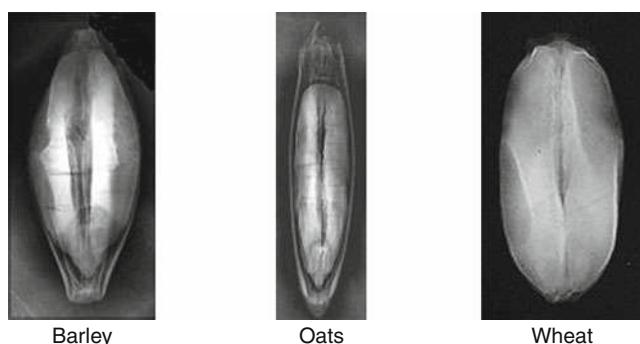

Full or partial loss of a germ at a kernel of any cereal (examples for wheat and a rye are shown in [Figure 2](#); the left picture demonstrates a kernel of wheat with a normal germ) leads toward a nonemergence of seeds and an

X-ray Method to Evaluate Grain Quality, Figure 4 Infestation and colonization of grain by insects.

X-ray Method to Evaluate Grain Quality, Figure 5 Damage of grain by a Sunn pest bug (*Eurygaster integriceps*).
(Collection from authors.)

X-ray Method to Evaluate Grain Quality, Figure 6 The enzymo-mycotic exhaustion of grain (barley, oats, wheat).
(Collection from authors.)

encapsulation of grains, i.e., the opening for air and malicious agents access if the later is not made specially due to the technological requirements just before grinding.

It is known that grain can sprout in the field in standing, in heaps, and while storage. The initial stages of germination revealed in X-ray pictures ([Figure 3](#)) cannot be found out visually, however biochemical and morphogenetic changes in grains reduce their sowing and technological properties. In the case of glumiferous even the advanced internal germination can be not noticed visually (in the right picture two oat kernels are shown in a smaller scale: the length of the sprout of the left kernel hidden by a film is almost equal to the length of endosperm).

The cavities inside the kernel that have been eaten away by larvae of insects can be easily seen in pictures ([Figure 4](#)) as a specific dimming irrespective of their size (two pictures of rye kernels at the left). The reshoot made in some seconds gives possibility to identify live insects in grain (pictures of two wheat kernels at the right). Presence of insects in grain is inadmissible. The selective visual analysis is unreliable. Only separation can guarantee the absence of infected kernels.

Specific moiré dimming in pictures of kernels in a unique manner indicates on decondensation of endosperm as the result of active hydrolytic enzymes introduction by bugs ([Figure 5](#)). If 2–3% of kernels with signs of such damages are presented in a sample it transfers grain of hard wheat into the category of soft weak. The visual analysis results in an underestimation or overestimation. The X-ray analysis gives a possibility of more accurate quantitative estimation of damages.

The pictures ([Figure 6](#)) demonstrate the loss of density of a kernel tissue in lateral parts and along a groove as a result of own enzyme activity under the increased air humidity in the field, and then of fungi enzymes, which have developed on a kernel surface with appeared hydrolyzates.

Visual estimation is difficult especially for glumiferous kernels. The X-ray analysis is accurate; the quantitative estimation of damage is possible. Sowing and technological parameters of kernels with signs of enzymo-mycotic exhaustion are decreased.

Discussion

The digital technologies have been recently widespread. The focus spot of produced X-ray tubes was reduced from 40–100 μm for tubes made in 1980–1990s to several microns that considerably increased the quality of image. Quality of X-ray images was improved by using the phenomenon of phase contrast (Zernike, 1935). Zernike the Nobel Prize in 1953 for, opening of a method of contrast of a phase and construction of the first contrast phase microscope has been awarded.

The method of phase contrast provides a high spatial resolution visualization of an internal structure of low absorbing objects with small gradients of substance density.

In spite of considerable progress in development of XRM, its use for diagnostics of seeds and grain quality remains significantly restricted. Concerning the problem of seeds and grains quality, what can be said about the situation in a whole?

Huge grain masses are estimated for their sowing and technological properties on the basis of the smallest samples. The previous studies proved that the size of these samples (2 kg) is sufficient for correct estimation of material state. It means the great risk especially for the minimum acceptability features such as a presence of insects or part damaged by a Sunn pest bug (*Eurygaster integriceps*). The quantitative estimation of kernels with these signs can be overestimated or underestimated while the decision about the whole party is made. Now the diagnosis itself if the state of grain party is concerned is not a reason to change this state in case if it is bad. On the basis of such diagnosis the price can be lowered, the decision on its processing by insecticides is made, as well as customer may decide to use this grain after applying additives to improve, but quality of initial party has no prospects for improvement. The situation can be significantly changed only by separation by critical feature, for example, by insect presence. However, such separation is impossible because the initial material is destroyed for diagnostics.

The big number of the parameters that are confidently found out by XRM allocates this method among others even at present time. In spite of indisputable advantages, X-rays are limited by two reasons. First, the control of protein and other grain biochemistry is required. Secondly, technologies should allow the total control. Today there are all premises to solve these problems.

Still in 1953, Watson and Crick were awarded the Nobel Prize for the discovering of the structure of double DNA helix by means of comparison of X-ray analysis data with the cardboard model proposed by them. The biochemical diagnostics required for an estimation of grain and seeds quality can be carried on by methods of the X-ray structural analysis. It is determined by possibility to study an atomic structure of substance by means of diffraction of X-rays. Considering the diffractive picture an electronic density of substance is estimated, then using the latter a sort of atoms and their arrangement are determined in its turn. The X-ray structural analysis is used to find out the structure of crystals, liquids, protein molecules, etc. To receive the images of the large molecules with the atomic resolution the rays with shorter wavelengths are used, i.e., not soft but hard X-ray is applied.

To solve the second problem the fast analysis of great volumes of a grain material is required. Usually to provide sharpness of the image at X-ray shooting object is illuminated during the exposing of a frame only. To gain it a switch linked to the mechanism of movie camera sends impulses of a current to the control grid of an X-ray tube of the X-ray device. In such a way using X-ray tube with cold emission 10^{-7} s exposition at frequency of shooting 100 shots per second is reached. Now it has reached the frequency of filming in a range from 1 to 100,000 frames

per second with a frame exposition up to 15 ns. The adaptation of these technologies to the needs of the diagnostics of cereals makes possible to exclude almost completely a poor-quality material by separation. The start of industrial application of X-ray separation that means the moving from diagnostics of several kilograms in hour to diagnostics of several tons in hour initiates the revision of a number of concepts. To solve the arbitrage problems it is not enough to declare that we observe signs of quality and its grade as well as deficiency. The limits of features should be defined quantitatively and proved to be true by specially developed standard documents. It means that modern problems of X-ray application demand the radical revision of the existing quality standards for cereals. It will allow the move to the full control of parameters for seeds rating and grain quality. It will require the obligatory introduction of elements of fast separation in the systems of X-ray diagnostics.

Conclusion

As shown, the XRM is unique for instant recognition of internal kernel defects. In parallel it allows to identify specific both high-quality features and fractional grain composition. The biochemical analysis of grain is also possible at use of more short-wave part of X-ray radiation spectrum. Thus, XRM may be potentially treated as a universal method of diagnostics and processing of initial parties of grain to the quality of high standards.

Subject Index

A

- Absorption, 1
 - energy, 7
 - isotherms, 7
- Adhesion, 1
- Adsorbate, 4
- Adsorption, 2, 5
 - energy, 3, 4
- Adsorption hysteresis, 843
- Advection-dispersion equation (ADE), 876–877
- Aeration, 12
 - air-filled porosity, 8
 - airflow rates, 8
 - air permeability, 9
 - grain, 8
 - plants, 8
 - silo, 8
 - soils, 8
- Aerodynamic characteristics
 - coefficient of aerodynamics, 328
 - coefficient of fineness, 328
 - critical velocity, 328
- Aerodynamic properties, 328
- After harvest technology, 461
- Aggregated bio-materials, 697–698
- Aggregate formation, soils, 448–449
- Agricultural landscape, 271
 - heat balance, 270
 - radiation balance, 270
 - water balance, 270
- Agricultural management
 - biochemical activity, 63
 - conservation tillage, 63
 - no-tillage, 63
 - reduced tillage, 63
- Agricultural material
 - brittleness, 569–570
 - elasticity, 569
 - hardness, 569
 - plasticity, 569
 - strength, 569
 - toughness, 569
- Agricultural plant products
 - porosity, 568
 - shape and size, 568
 - surface area, 568–569
 - volume and density, 568

Agricultural products, 207–212, 231–232, 237–241, 699

- aeration, 7
- airflow, 48
- anisotropy, 407–408
- color measurements, 585
- compression tests, 583
- degree of elasticity, 694
- density, 972
- dielectric properties, 208
- drying/dehydration, 232
- electrical properties, 237, 240, 241
- electric conductivity, 238
- firmness, 583
- force-displacement curve, 694
- heat transfer, 572
- hysteresis loss, 694
- isotropy, 407
- length, 189
- loading/unloading test, 694
- Magness-Taylor puncture, 583
- measurement of texture, 582–583
- moisture content, 972
- permittivity, 238
- physical condition, 669
- physical properties, 579–587
- production, 580
- quality, 669
- raw materials, 579, 580
- resistivity, 240
- rheological functions, 695
- rheology, 693
- shrinkage, 730–733, 972
- specific heat, 572
- storage, 6, 232, 567–572
- stress relaxation, 694
- swelling, 730–733, 972
- tensile measurement, 583
- thermal conductivity, 572
- thermal diffusivity, 572
- thickness, 189
- water, 971–972
- width, 189

Agriculture

- and environment, monitoring, 490
- irrigation water, 979
- machine vision, 433–436

rainfall water, 979

- wind erosion, 999

Agro-food products

- colour, 571
- gloss, 571
- thermal properties, 571–572
- translucency, 571

Agroforestry, 123, 124

- alley cropping, 27
- biodiversity, 27, 29
- environmental services, 29
- forest farming, 28
- riparian buffers, 28
- silvopasture, 27
- windbreaks or shelterbelts, 28

Agrogeology, 29

- agricultural science, 31

Agrophysical objects

- agricultural plants, 34
- agricultural products, 34
- foods, 34
- soils, 34

Agrophysics, 16, 37, 610

- agrophysical objects, 36
- agrophysical processes and properties, 36
- conferences, 38
- definition, 35
- fractal analysis, 309–315
- fractal geometry, 315
- history, 36
- image analysis, 387–389
- journals, 38
- neural networks, 505–508
- properties, 36
- research, 38
- scale dependence, 313
- standardization, 854

Air capacity

- classification, 872
- modeling, 872

Algae, source of fuel, 49

Alkalinity, soils, 50

Amplitude sweep test, 703

Animal burrowing, soil penetrability, 754

Anisotropy, 8, 335, 407–408

- description, 408
- granular solid, 408

Archie's empirical law, 243
Arrhenius formula, 240

B

Backscattering, physical forms, 59
Bacteria
 retention, 69
 transport, 69
Beer-Lambert law, 424

Biocolloids
 retention, 67
 soils, 67
 transport, 67

Biofilms
 bacteria, 76
 control, 76
 exopolymers (EPS), 75
 formation, 75
 microorganisms, 75
 pathogens, 76
 removal, 77
 soil, 69
Biological materials, 5, 7
 cooling, 8
 heating, 8

 solar drying, 816

Biomass
 availability, 79
 charcoal, 80
 clearing land, 83, 84
 crops, 85
 energy, 80, 87
 energy source, 78
 energy value, 79
 environmentally benign, 87
 fuels, 79–81
 greenhouse gases (GHG), 81
 hydrogen, 80
 income, 84
 renewable energy, 52, 81

Biosphere, 31
 soil, 32

Biotechnology
 biomass, 89
 bioreactors, 89
 chemical processes, 90
 enzyme biocatalysis, 90
 physical processes, 89

Boltzmann's law, 440

Bread
 crumb, 91
 crust, 92, 93
 mechanical properties, 92
 physical properties, 93
 quality, 91
 raw material quality, 91
 raw materials, 91
 storage, 92

Breeding, 611
 physical characteristics, 610–621

Brightness temperature
 emissivity, 94
 microwave radiometers, 94
 soil, 94

Brooks and Corey hydraulic conductivity
 expression, 300

Brooks–Corey equation, 556

Bruise susceptibility
 citrus fruit, 320
 kiwifruit, 320
 pome fruit, 319
 stone fruit, 319–320
 tomato, 320

Brunauer, Emmett, and Teller (BET), 3, 840
Buffer capacity
 soil, 94
 sorption, 94
Bulk density, 190
 compaction, 96
 tillage, 96
Bypass flow
 cracks, 100
 funnel flow, 100
 macropore flow, 100
 macropores, 103
 preferential flow, 100
 water movement, 100

C

Campbell equation, 257
Capillary rise, 881
Carbon dioxide, 11, 13
 greenhouse gases, 12
 oxygen, 12
Cartesian coordinates, 2

Cation exchange capacity (CEC)
 plant roots, 885
 soil, 885

Cellular rheology, 699

Cereals, 324
 falling number, 112
 flour, 111
 flour milling, 111
 grain hardness, 111
 sedimentation test, 112
 utility values, 112
 wheat, 111, 112

Chemical imaging
 agriculture, 113
 image processing, 113–114
 techniques, 113

Chemical potential, 5, 6
Chemical time bomb (CTB), 116–117
 concept, 116

Clay minerals, 882

Claypan soils, 183
 agrichemical leaching, 124
 agrichemical runoff, 123–124
 best management practices (BMPs), 125
 erosion, 123–125
 permeability, 122
 plant productivity, 124
 preferential flow, 124
 saturated hydraulic conductivity (K_{sat}), 122, 123

structure, 122
texture, 122
tillage, 122–124

Cleavage plane, 125

Climate change
 aerosol concentration, 133
 aerosols, 129–130, 132, 133
 albedo, 129, 131, 132
 atmospheric CO₂, 131, 133, 134
 deforestation, 130

desertification, 134
environmental effects, 125–134
geologic history, 130–133

glaciers, 133

global aridization, 134
global cooling, 133

global warming, 134
greenhouse effect, 134
greenhouse gases, 128–130

mechanisms, 131

Milankovich cycles, 128, 133
seawater level, 126, 133

snow cover, 126
solar activity, 133
solar radiation, 128, 130
temperature, 126, 127, 129–131
thermohaline circulation, 129, 133
vegetation cover, 130
volcanic activity, 133
volcanoes, 129–130, 133
warming, 127
weather changes, 133

Clod, 135

Clusters, 310

absorption of heavy organic matter, 137
adsorption of heavy metals, 137
formation, 135–136
functions, 136
life time, 136
parent rock, 137
properties, 136
structures, 137
weathering, 137

Coherency spectra

clay content, 836
corn yield, 836
soil water storage, 836

Cohesion, 138

Colloidal particles

dispersed particles, 938–939
dispersion, 938
flocculation, 938

Colloids

aggregation, 67, 266
coagulation, 266
flocculation, 67, 266–267
peptization, 267
retention, 67
soils, 67
transport, 67

Color

CIELAB color space, 139–141
CIELAB system, 142, 143
CIE system, 142
color variation, 140
food, 140
fruit, 140
HSI color space, 139
HSV color space, 139
indices, 143
measurement, 140

Color composite (multiband photography), 138

Colored images

machine vision, 605
plant disease, 605–608

Compaction

bulk density, 334
of soil, 145
soil bulk density, 149, 218

Compressibility indices

compression and swelling index, 744
compression curve, 744
cyclic compressibility, 745
void ratios, 744

Conditioners

characteristics, 146
classification, 146
organic substances, 145
soil physical properties, 145
synthetic agents, 146

Conductivity, 148

Consistency, 148

Consolidation, 148

Contact area

inflation pressure, 148, 151
penetration resistance, 151
