This laboratory performs studies of mechanical parameters of agricultural granular materials and food powders and formulates models of basic mechanisms important for storage, handling, and processing to overcome difficulties originating from grains deformation, variation in flowability, and changes of secondary variables with moisture content of the material. New discrete element method is used to simulate granular flows, granular compaction, segregation, convection, avalanches, surface waves, collisions and friction, inelastic collapse, jamming and fluctuations, energy flows, strength properties, anisotropy of packing, stress fluctuation to understand mechanical behavior of plant granular materials: quasi-static processes observed in experimental testing of grain in bulk; particle-plane impact, uniaxial compression, filling and discharge processes.

Several interdisciplinary topics are realized by several departments together as studies of soil filtering and buffering properties to protect water ecosystems against contamination and purification of wastewaters; role of microorganisms in transformation of organic substances in soil and formation of soil aggregates; enzymatic activity of soil to regulate the availability of nutrients for plants; role of soil components and biota in creation of water repellency in soil to regulate soil water retention; processes of carbon and plant nutrients transformations; gas production and emission to the atmosphere from soils to assess their role in global greenhouse effects causing climate change; fast assessment of complex biochemical composition and nutritive value of fresh fruits and vegetables with multispectral biospectroscopy methods with data acquisition systems, computers and optoelectronic devices to introduce widespread and uniform justification system to practice.

Institute of Agrophysics in Lublin: Progress in Agrophysics, Figure 1 A new agrophysical centre, Lublin-Felin from bird's eye view.

New structure

With the support of the E.U. projects, new buildings with well-equipped modern laboratories were created in 2009–2010 within the Institute (Figure 1). They are focused, among others, to the quality control of plant materials processed for food and nonfood products, implementation of innovative solutions in agricultural and food sector, and increase of the natural environment control, renewable energy and biomass acquiring, methane fermentation, biogas analysis, treatment and utilization of post fermentation sludge by recycling and utilization of sludge solid phase for soil improvement. All these activities may serve in developing and diffusion of innovative solutions between science and economy.

Outlook

Recently the Institute creates close interdisciplinary links with other sciences including plant physiology and genetics, molecular biology, nanotechnology, chemical physics, informatics, mathematics, food technology, animal production, and even architecture, veterinary science, or medicine.

INSTITUTE OF AGROPHYSICS IN SAINT-PETERSBURG: ROOTS OF AGROPHYSICS

Igor B. Uskov, Victor P. Yakushev
 Agrophysical Research Institute, Russian Academy of Agricultural Science, St. Petersburg, Russia

Definition of agrophysics

Agrophysics (or agricultural physics) is a science that studies physical, physicochemical, and biophysical processes in the system “the soil – the plants – the active layer of the atmosphere” as well as main principles of the production process, physical properties of the system

components, and of various agricultural products. This science works out scientific foundations, methods, technical and mathematical tools, as well as agricultural techniques of an expedient use of natural resources and improvement of the agricultural ecosystem, arable farming, and crop production. This is a branch of physics that studies physical components of agroecosystems and agricultural landscapes as well as structural and functional patterns of their interaction. Its aim is agroecological optimization of modern farming systems.

Introduction

One of the founders of modern agrophysics was Academician Abram Feodorovich Ioffe (1880–1960). In his fundamental works *Physics and Agriculture* (Ioffe, 1955), and *Physics for Agriculture* (Ioffe, 1959), he pointed out the principal and important points about the time directions of investigations in this new branch of natural and agricultural sciences. These included development of research and measuring tools for agriculture, biology, and agrochemistry, light-physiology and light-culture of plants, artificial soil structure formation, measures against droughts, frosts, and other unfavorable weather conditions, use of polymers in arable farming and plant growing, study of soil hydrophysics and designing methods of active water and heat regulation in soil and plants, and the creation, in the future, of the so-called electronic agronomist.

Institute of agrophysics, its founders, and their achievements

In 1932, the Institute of Physics and Agriculture, later called the Research Institute of Agrophysics, was organized in Leningrad on the initiative of A.F. Ioffe and with the support of the President of the All-Union Academy of Agricultural Sciences N.I. Vavilov. The Institute started its work dealing with the problems indicated by its founder and first director. One of Ioffe's associates and followers was Professor A.F. Chudnovsky (1910–1985). In his studies *Heat Exchange in Disperse Medium* (Chudnovsky, 1954), *Semiconductor Devices in Agriculture* (Chudnovsky and Shlimovich, 1961), and *Thermophysics of the Soil* (Chudnovsky, 1976), he developed the theory and methods of soil heat regulation, suggested ways of farming optimization, and elaborated automatic systems of technology control for irrigated agriculture. He also stated principles of agrophysical instrumentation that served as a basis for many developments, beginning with the creation of the soil radiation constant detector (A.V. Kurtener). The distinguishing feature of agrophysical engineering at the institute was a particular sequence of devising: starting with a laboratory model for studying physical processes which allowed the utmost completeness and precision of measurements but was not very reliable in practice and carrying on with a technological instrument whose precision made it

possible even to nonspecialists to make measurements in field conditions.

The research of Professor F.E. Koliasev (1898–1958) played a key role in laying the foundations of the agricultural theory in agrophysics and in developing it. He advanced the concept of soil differential moisture and methods of soil water content regulation in various soils and climatic zones of the country in his studies *Methods of Artificial Soil Structuring* (Koliasev and Vershinin, 1935) and *Concerning the Soil Differential Moisture Theory* (Koliasev and Melnikova, 1949). The works of Professor P.V. Vershinin (1909–1978) were also of great importance to the development of the soil structuring theory and the control methods; they include *The Basics of the Physical Chemistry of Artificial Soil Structure* (Vershinin and Konstantynova, 1935) and *Soil Structure and Conditions of Its Formation* (Vershinin, 1958). These works treat such theoretical and practical issues as soil structuring and the use of chemical soil stabilizers for protecting the soil from erosion. Professor I.B. Revut (1909–1978) made a great contribution to the development of soil physics. In his studies *Physics in Agriculture* (Revut, 1960), *How to Work the Soil Properly* (Revut, 1966), and *Physics of the Soil* (Revut, 1972), he explains the essentials of soil treatment in different soils and climatic zones.

The corresponding member of the Academy of Agricultural Sciences S.V. Nerpin (1915–1993) was the originator of two branches of agrophysical soil science: soil hydromechanics and theoretical physicochemical soil mechanics. His main works – *Physics of the Soil* (Nerpin and Chudnovsky, 1967) and *Energy and Mass Exchange in the Plant–Soil–Air System* (Nerpin and Chudnovsky, 1975) – have never been equaled in the world scientific literature on the subject. They discuss the theory and the methods of controlling field moisture regime. S.V. Nerpin founded the school of theoretical and computational agrohydrology and laid the groundwork for mathematical modeling in agrophysics. Professor A.M. Globus' fundamental studies *Experimental Hydrophysics of the Soils* (Globus, 1969) and *Physics of Non-isothermal Intrasoil Moisture Exchange* (Globus, 1983) marked, in essence, the beginning of investigations in soil hydrophysics.

Academician E.I. Ermakov (1929–2006) contributed greatly to working out the theory of soil formation in the plant–soil system. He also developed a new direction in science – the use of similarity principles for physical simulation of processes in these systems with the help of vegetation-climatic installations.

The beginning of large-scale investigations in chemical physics of the soils is connected with the name of Professor M.K. Melnikova (1901–1986), the head of the first radiochemical laboratory created to study unknown behavior of uranium and plutonium fission products in the soil and to develop agrotechnical methods of reducing radioactive contamination of agricultural products. These research areas were highly relevant while nuclear weapon testing was going on. Her works *The Foundations of*

Agrophysics (Vershinin et al., 1959), On the Behaviour of Uranium and Plutonium Fission Products in the Soil and Their Absorption by Plants, and The Use of Radioactive Isotopes and Radiation in Agricultural Investigations introduced the method of isotope tracers into soil science. The works of Professor J.A. Kokotov made a very important contribution to the theory of ion exchange in the soil (in acid soils, in particular). They include *Balance and Kinetics of Ion Exchange* (Kokotov and Pasechnik, 1970), *Ion-Exchange Resins and Ion Exchange* (Kokotov, 1980), *The Ion Exchange Theory (Complicated Ion-Exchange Systems)* (Kokotov, 1986). Professor N.F. Batygin (1928–2000) laid down theoretical foundations of agrophysical studies in radiobiology in his work *The Use of Ionizing Radiation in Plant Life Regulation* (Batygin, 1966).

In 1928, an agroclimatology sector was organized at the Institute of Experimental Agriculture. In 1932, the Main Geophysical Observatory (MGO) named after A.I. Voeikov started investigations in the field of agroclimate zoning and climatic resources estimation in agricultural production. In August 1935, the studies at the MGO were stopped but taken up by the Agrophysical Institute (API) founded by A.F. Ioffe. Scientists of API had concentrated their efforts on the physical process investigation that influences the field's microclimate, unlike the geographical climatic approach of the MGO. The goal was to work out the theory, the agrotechnological approaches as well as effective microclimate resources management within the agroecological system under changing physical conditions of plants' habitat, that is, to develop a meliorative agromicroclimatology. The first collection of scientific works of the Institute of Agrophysics (1935) with the participation of B.P. Alexandrov, A.V. Kurtener, and N.N. Banasevich already included articles on heat and water regimes in the soil; the third collection (1941) contained an entire section devoted to microclimate issues. The monographs *Climatic Factors and Heat Regime in Open and Protected Ground and Agricultural Field Microclimate Control* (Kurtener and Uskov, 1982, 1988) were dedicated to the development of theoretical and practical agroclimatology.

The *Physiological Foundations of Plants Drought Resistance* (1926), a world-renowned monograph of Academician N.A. Maksimov (1880–1952), one of the first plant physiologists of the Institute of Agrophysics, marked the beginning of investigations into plant ecological physiology. Professor V.P. Malchevsky (1906–1942) made a major contribution to the creation of the plant light physiology and light culture theory. He developed light culture and light stimulation methods for use in hothouses and closed chambers with artificial light and suggested light stimulation of seeds and seedling for intensifying photosynthesis and reducing vegetation period. The corresponding member of the Academy of Agricultural Sciences B.S. Moshkov (1904–1997) became world famous for his works *Plant Growing under Artificial Light*

(Moshkov, 1953), *Plant Photoperiodism* (1961), *Plant Growing in the Future* (Moshkov, 1962) and *Plant Actinometry* (Moshkov, 1987); he made a significant contribution to the plant light physiology and ontogeny theory and discovered the specific physiological role of the leaf in the photoperiodism. The study of the cellulose ether film properties led to universal replacement of glass with clear plastic films in the protection of the ground in indoor structures (D.A. Fiodorov, I.N. Kotovich). V.G. Karmanov (1913–1997) put forward the theory of plant biological cybernetics as a branch of science dealing with the cybernetic control of physiological processes in plants. The key points of this line of research became phytomonitoring (S.S. Radchenko) as well as the biophysical concept of the transport and heat exchange systems in a whole plant and in cell membranes (Professor O.O. Lialin, 1932–1994).

The studies of Academician N.F. Bondarenko's (1928–2003) promoted agrophysical scientific development and a wide application of the "harvest programming" method; his investigation initiated the development of information technologies in modern agrophysics employing precision agriculture techniques that realized A.F. Ioffe's idea about the creation of an "electronic farmer" (devised by the corresponding member of the Academy of Agricultural Sciences V.P. Yakushev).

Along with the progress in the related branches of physics, geophysics, biophysics, plant physiology, mathematical physics and computational mathematics, some new areas of interest appeared over the years in the structure of agrophysical investigation. They were mostly focused on devising methods of active intervention in the vegetation processes and their regulation by means of measurement, state diagnostics and management technologies. Among these areas are: mathematical modeling of agricultural production (R.A. Poluektov); simulation of agrophysical systems and processes (B.N. Michurin, A.M. Globus, I.B. Uskov, V.G. Onishchenko); interaction of biological objects with different physical fields (light, gravitational, magnetic, electromagnetic, acoustic, electrostatic) (B.S. Moshkov, N.F. Batygin, N.F. Bondarenko, I.S. Lisker, V.N. Lazutin); information technologies of production management in arable farming and plant growing (V.P. Yakushev, I.M. Mikhailenko); agrophysical instrumentation, elaboration of vegetative systems with controlled climate (V.G. Karmanov, A.F. Chudnovsky, J.P. Baryshnev); a new type of coordinate precision agriculture as the first step to the creation of the "electronic farmer" (V.P. Yakushev).

Conclusions

The above-mentioned founders of the agrophysical science believed that their investigations should first and foremost help with the transition from descriptive agronomical science to that based on measurements and calculations of agricultural methods and factors of plant

growth, development and productivity which would control production processes in the field and the formation of harvests in open and protected ground.

INTEGRATED DRAINAGE

A general term for a drainage pattern in which stream systems have developed to the point where all parts of the landscape drain into some part of a stream system, the initial or original surfaces have essentially disappeared and the region drains to a common base level.

INTRINSIC PERMEABILITY

The property of a porous material that expresses the ease with which gases or liquids flow through it. Often symbolized by $k = Kn/pg$, where K is the Darcy hydraulic conductivity, n is the fluid viscosity, p is the fluid density, and g is the acceleration of gravity. Dimensionally, k is an area [L^2].

Synonyms

Regulation of soil water regime

Definition

Irrigation and drainage – artificial application of water to land and artificial removal of excess water from land ([Encyclopedia Britannica](#)).

Introduction

Most of the material transport processes in soils are closely related to the water movement. The water regime type of a soil depends on the meteorological and hydrological conditions of the region where the soil is located and on the chemical and physical properties of the soil. Soil with leaching characteristic (decreasing water soluble salt content in the top layer) can develop in areas where the natural or natural + artificial water input on the soil surface exceeds the evapotranspiration from the soil surface in a longer period of the year. Soil profiles with accumulation of soluble salts can be found in areas where the amount of natural precipitation is not high enough to leach the weathering products, or the level of salty groundwater

table is high enough to reach the top layer of soil through capillary rise.

Irrigation and drainage are the most important means to modify the water regime properties of soils.

Irrigation

Advantages

Irrigation covers several essential agricultural requirements in the arid areas of the world:

- Water supply for plant growth, nutrient transport
- A flow of water to leach or dilute the salt content of the soil
- It is one of the most effective means of mitigation of wind erosion
 - by maintaining a protective vegetation cover
 - by maintaining a higher moisture content of the soil

Disadvantages

Soil salinization is a major threat to irrigated agriculture. Salt accumulation can be directly caused by the capillary rise from saline groundwater or by the irrigation water itself, because of the high salt content of the water and limited leaching in the soil. The two types of salt accumulation in soils can be distinguished by taking into account the place of the accumulation in most cases. If the salinization or sodication is caused by the irrigation of poor quality water, the increasing salt content can be measured in the surface layer. The salinization caused by the rising saline water table affects the deeper layers and can only be diagnosed by measuring the salt content of the deeper layers. The latent character makes this process even more dangerous. If the rising groundwater contains Na_2CO_3 too, the salt accumulation can hardly be reversed by leaching because – as Várallyay (1981) figured out – the water conductivity is much more limited by Na_2CO_3 in the low suction range (case of leaching) than in the higher suction range (e.g., capillary rise).

Salt accumulation on the soil surface can be prevented by keeping the irrigation water standards. In well-drained soils, where salinity is caused by neutral sodium salts, the accumulated amount can be leached by applying more water than that lost by evaporation and by the consumption of plants. The amount of excess water was defined as the leaching requirement (LR) by the US Salinity Laboratory (Richards, 1954). LR depends on the salinity tolerance of the cultivated plants.

Salinity problems caused by rising groundwater can be controlled by keeping the groundwater table below a critical level at which salt accumulation cannot be expended. A calculation method based on salt balance, ground water quality and water regime properties of the soils was elaborated by Szabolcs et al. (1969).

Recently, several computer models have started being used for predicting the salt accumulation, for example, DRANMOD (Abdel-Dayem and Skaggs, 1990),

LEACHMS (Wagenet and Hutson, 1992), and UNSATCHEM (Simunek and Suarez, 1994).

Field studies (Tóth and Blaskó, 1998) showed that seepage from unlined channels can be one of the main man-made causes of the rising groundwater in an irrigated area.

The possible soil physical disadvantage of sprinkling irrigation with high intensity is surface sealing and crusting. Summer and Stewart (1992) edited a synthetic work about the tendency of dispersion and crusting on the soils pointing out the main causes of structural deterioration. Blaskó et al. (1998) found that dispersion occurred most frequently in soils with unfavorable chemical properties containing swelling clay minerals and high amount of clay fraction with exchangeable sodium. Examining the inclination toward crust formation, it was revealed that soils with the most unfavorable hydraulic conductivity were the most sensitive to become crusty.

Drainage

Advantages

Subsurface and surface drainage systems are the most effective means of soil water regime regulation. The main function of the subsurface drainage is keeping the groundwater level below a critical level and to let the water moving out by gravitation from the top layers to the pipes. The purpose of surface drainage is to let the excess water out from the soil surface. These functions prevent the soil from overwetted state.

Beside the regulation of soil moisture content on areas affected by salty groundwater, drainage systems can control the salt accumulation and leaching processes as well.

In a long-term amelioration experiment on a salt-effected soil with structural B-horizon, the salts leached from the topsoil in case of non-drained variants remained in the layers close to the surface, involving the risk of resalinization due to the rise of groundwater table, while in case of drained soil there was a significant decrease of sodium in the whole layer above the drainage system (Blaskó, 2004).

Disadvantages

In drained areas, the typical characteristic is the accelerated material movement in correlation with a faster water movement.

Studying the chemical composition of drain waters, the nitrogen was proved to be the most threatened material in the order of leaching (Armstrong et al., 1983; Blaskó and Juhász, 1989).

The amount of nitrogen loss depends on the depth of the drainage system, as well.

N leaching has been studied in lysimeters, and it was found (Rézegyi and Heltai, 1984; Nyiri and Karuczka, 1989; Karuczka and Zsembeli, 1999) that N leaching was more severe in soils where a shallow drainage system (1–1.5 m depth) had been applied.

Natural streams or rivers can be the outlets for drainage systems. Nutrients carried in drainage water can cause eutrophysisation of “living” waters.

The nitrogen loss can only be mitigated by split application of the mineral fertilizer, but the loss caused by heavy rains in time of intensive nitrification cannot be avoided (Juhász et al., 1997).

The drainage waters coming from salt-affected areas may increase the salt content of streams, rivers, and lakes, so an excessive drainage of salt-affected areas can cause the export of the salinity problem on other territories.

Summary

Irrigation and drainage are the most effective means of water regime regulation in soil–water systems. In addition to influencing the water supply of plants, they have a strong influence on the accumulation and leaching processes in the soils as well.

The main advantages of drainage and irrigation are the regulation of water regime of soils, maintaining the available moisture content and letting the excess water out from overmoistened soil. Besides, they control the salt accumulation processes. The “leaching requirement” (LR) of irrigation water washes out the salts from the rooting zone until the tolerance level of a given plant. The subsurface drainage system prevents the top layers from salt accumulation which would be caused by capillary rise from the groundwater.

The potential disadvantages of the irrigation are salt accumulation caused by irrigation water of poor quality or by rising groundwater level caused by seepage from unlined irrigation channels. The main disadvantage of a drainage system can be the accelerated leaching out of nitrogen and other salts, causing eutrophysation or the increase of the salt content of streams and rivers. Usually, the disadvantages can be avoided by using proper irrigation methods and keeping the irrigation water standards. The nitrogen loss can only be mitigated by split application of nitrogen fertilizers.

IRRIGATION WITH TREATED WASTEWATER, EFFECTS ON SOIL STRUCTURE

Guy J. Levy

Institute of Soil, Water and Environmental Sciences,
The Volcani Center, Agricultural Research Organization,
Bet Dagan, Israel

Definition

Treated waste water (TWW) is referred to in the context of the current presentation as raw sewage water, originating mainly from domestic sources, that has been subjected to a number of treatment processes, making the water suitable for irrigation of arable land.

Introduction

The use of TWW for irrigation of cultivated fields has increased considerably in recent years, especially in areas suffering from shortage of freshwater (e.g., arid and semi-arid regions). With this increased necessity to use TWW for irrigation, farmers are faced with unique and unfamiliar problems among which is the possible degradation in soil structure and stability.

Soil structure is commonly referred to as the size, shape, and arrangement of solids and voids, as well as the continuity of pores and voids. Soil structure directly affects the soil's capacity to retain and transport water, and organic and inorganic constituents, thereby influencing important field-scale phenomena such as soil water movement and retention, erosion, crusting, nutrient recycling, root penetration, and crop yield (Lal, 1991). Hence, favorable soil structure and stable aggregates are important for improving soil quality, increasing agronomic productivity and sustainability, and decreasing soil erodibility.

The current presentation attempts to summarize existing knowledge on the impact of irrigation with TWW on some soil determinants that are closely associated with soil structure and stability.

Characteristics of TWW

Raw sewage water can be subjected to different treatments. Secondary (biological) treatment is generally required when the TWW is intended for irrigation of cultivated land (Feigin et al., 1991). Some typical properties of TWW from Israel after a secondary treatment and those of its freshwater (FW) of origin are presented in Table 1. TWW contains significantly higher levels of beneficial components for agricultural use such as nitrogen, phosphorus, potassium, and possibly some other beneficial elements in minimal concentrations. The concentration of boron (an essential microelement for crops that has a small concentration window between deficiency and toxicity) in TWW may often be in the toxic range.

TWW also exhibits higher loads than FW of suspended solids and dissolved organic matter (DOM), commonly

Irrigation with Treated Wastewater, Effects on Soil Structure, Table 1 Chemical characteristics of secondary treated wastewater (TWW) and freshwater (FW) used for irrigation in the Bet She'an Valley, Israel. Average values for 4 years (2002–2005) (Adapted from Bhardwaj et al., 2007)

Water quality parameter ^a	Irrigation water	
	TWW	FW
SAR	5.12 (0.95) ^b	3.12 (0.37)
EC (dS m ⁻¹)	1.91 (0.23)	1.23 (0.10)
pH	7.58 (0.27)	7.60 (0.32)
N-NH ₄ ⁺ (mg L ⁻¹)	35.1 (11.0)	0.00 (0.00)
N-NO ₃ ⁻ (mg L ⁻¹)	0.14 (0.24)	0.06 (0.12)

TSS (mg L ⁻¹)	170.4 (69.8)	0.00 (0.00)
BOD (mg L ⁻¹)	86.8 (52.7)	0.00 (0.00)
COD (mg L ⁻¹)	136.2 (37.1)	0.00 (0.00)

^aSAR sodium adsorption ratio, EC electrical conductivity, TSS total suspended solids, BOD biochemical oxygen demand, COD chemical oxygen demand

^bNumbers in parenthesis are one standard deviation

expressed in terms of BOD or COD (Table 1). TWW is more saline and has a higher sodium adsorption ratio (SAR) than its FW of origin. TWW may contain some trace elements but generally at concentrations that are suitable for long-term irrigation (Feigin et al., 1991).

Presence of pathogenic microorganisms (e.g., viruses, bacteria, protozoa) in the TWW represents the most common threat to the agricultural use of wastewater, both for workers and end consumers of crops, but not necessarily to the soil.

TWW impact on mechanisms affecting soil structure

Processes that may harm soil structure and stability include clay swelling and dispersion, and aggregate breakdown through slaking or impact of water drops of high kinetic energy (e.g., rain or overhead sprinkler irrigation systems). These processes are expected to occur mainly in winter when the soil is leached with rain water (i.e., water free of electrolytes). Under these conditions, the sensitivity of the soil clay to swelling and dispersion is high (Shainberg and Letey, 1984), as is the susceptibility of aggregates to slaking (Levy et al., 2003).

Irrigation with TWW is likely to enhance the processes of clay swelling and dispersion in comparison to irrigation with FW because of the higher SAR and the presence of DOM in the TWW. Sodic conditions, especially in the absence of electrolytes, render soil clays greater sensitivity to swelling and dispersion (Shainberg and Letey, 1984) and lead to weakening of soil aggregates (Abu Sharar et al., 1987). In addition, the presence of dissolved humic

substances in the TWW may enhance clay dispersivity (e.g., Tarchitzky et al., 1993). This effect is attributed to the interaction of the negatively charged organic molecules with the positively charged edges of the clay, which prevents the edge-to-face association of clay particles responsible for flocculation (Tarchitzky et al., 1993). The presence of DOM in the TWW could have an additional indirect effect on the soil via its effect on the SAR; the effective SAR of the TWW is expected to be greater than that commonly calculated based on the total concentration of cations in the solution (Halliwell et al., 2001). The difference between the commonly calculated SAR and the effective one could reach up to 50% due to the great affinity of the divalent cations to organic ligands (Fotovat et al., 1996).

Aggregate stability

The term soil-structure stability is often considered synonymous with aggregate stability, especially in cases where aggregates break down by water (Kay and Angers, 1999). In general, organic substances are considered as cementing agents that improve aggregate stability (e.g., Bronick and Lal, 2005). However, humic substances have been observed to have a dual role as aggregating and disaggregating agents (Oades, 1984). Some studies have indicated that the aforementioned duality is related to the concentration of humic substances; at low concentrations ($<0.05\text{--}0.10\text{ g kg}^{-1}$) the humic substances stabilize aggregates, while at higher concentrations they have a dispersive effect (Piccolo et al., 1996).

Studies of aggregate slaking (i.e., aggregate breakdown caused by compression of entrapped air during fast wetting) revealed that for soils having *a priori* unstable aggregates (coarse- and medium-textured soils, $<25\%$ clay), sensitivity to slaking of aggregates taken from TWW-irrigated fields was comparable to that of aggregates taken from FW-irrigated fields (Levy and Mamedov, 2002; Levy et al., 2003). In such soils, irrigation with TWW, which induces conditions favoring clay dispersion via increased sodicity, seems to play a minor role in determining aggregate stability. Conversely, in fine-textured soils ($>40\%$ clay) having *a priori* stable aggregates, aggregates from TWW-irrigated soils were more sensitive to slaking (i.e., less stable) than those taken from FW-irrigated soils (Levy and Mamedov, 2002; Levy et al., 2003). Evidently, in clay soils where the clay stabilizes the aggregates (Kemper and Koch, 1966), conditions favoring dispersive behavior of clay (high sodicity and the presence of humic substances in the TWW) adversely affect aggregate resistance to slaking.

The impact of irrigation with TWW on aggregate stability seems to depend also on the intensity of cultivation. In aggregates taken from intensively cultivated fields (e.g., field crops) aggregates from TWW-irrigated land were less stable than those taken from FW-irrigated land (Levy et al., 2006). In samples taken from orchards where soil cultivation is minimal and the aggregates are not subjected

to frequent disturbance, stability of aggregates from TWW- and FW-irrigated samples was comparable (Levy et al., 2006; Bhardwaj et al., 2007).

Saturated hydraulic conductivity

During the irrigation season it is mainly the presence of suspended solids in the TWW, especially in poorly treated wastewater, that could adversely affect soil physical and hydraulic properties. Suspended solids present in the TWW may accumulate and physically block water conducting pores, thereby leading to a sharp decrease in soil HC. Blocking of the pores depends on (1) the load of suspended solids in the wastewater (Rice, 1974), (2) the environmental conditions prevailing in the soil, which determine the rate of breakdown of the suspended solids (DeVries, 1972), and (3) soil texture; the finer the soil texture, the greater the decrease in the HC (Levy et al., 1999; Lado and Ben-Hur, 2009).

In cases where TWW that had been subjected to a high level of treatment is used and a reduction in the HC following irrigation with TWW is observed, the reduction could be ascribed to clay swelling and dispersion that are enhanced by the higher SAR of the TWW (Mace and Amrhein, 2001) and/or the presence of DOM in the TWW (Tarchitzky et al., 1999). In addition, a decrease in HC during leaching with TWW of good quality, but of high C to N ratio, could arise from the growth of microorganisms in the soil, which can partially clog water-conducting pores (Magesan et al., 1999).

The impact of irrigation with TWW on soil HC during the subsequent rainy season, i.e., when the soil is exposed to water nearly free of electrolytes seems to depend on soil texture and conditions prevailing in the soil (e.g., intensity of cultivation, rate of wetting, method of irrigation), and to vary seasonally.

For instance, in a sandy clay, no differences were noted between the HC of TWW- and FW-irrigated samples taken from both intensely and non-intensely cultivated fields. By comparison, in a clay soil, for both types of the aforementioned fields, the HC of the TWW-irrigated samples was significantly lower than that of the FW-irrigated samples (Levy et al., 2006).

Preventing aggregate slaking (i.e., by ensuring aggregate wetting at a slow rate) prior to measuring the HC, significantly reduced the adverse impact of long-term irrigation with TWW on the reduction in HC, compared to conditions where aggregate slaking was allowed (Shainberg et al., 2001; Mandal et al., 2008). However, when the HC of intact cores (i.e., no destruction of soil structure) of a clay soil collected from an orchard at locations in close proximity to micro-sprinklers or dripers was studied, the results showed that the method of irrigation (drip vs. microsprinkler), rather than irrigation water quality (TWW vs. FW), determined the response of the soil to leaching with deionized water (Bhardwaj et al., 2007).

A study that compared the HC of intact cores taken in spring (after the rainy season) to those taken in autumn (at the end of the irrigation season) from a silty clay irrigated with TWW showed that the HC of the spring samples was nearly sixfold higher than that of the autumn samples (Bhardwaj et al., 2008). It was postulated that the lower HC in the autumn samples was associated with the partial blocking of soil pores by suspended solids present in the TWW. It was further suggested that the suspended solids that accumulated in the soil during the irrigation season broke down in the course of the rainy season (DeVries, 1972), leading to the observed increase in the HC of the samples taken in spring (Bhardwaj et al., 2008).

Infiltration rate (IR), runoff, and soil loss

Most studies that evaluated the impact of irrigation with TWW on soil permeability, runoff, and erosion concentrated on soil sensitivity to those determinants under simulated or natural rain conditions.

Laboratory studies with rainfall simulators (where deionized water was used) showed that for TWW-irrigated soils the infiltration rate (IR) values were lower (Mamedov et al., 2000a) and runoff levels were higher (Mamedov et al., 2001b) than those obtained in FW-irrigated samples. However, the reported differences were relatively small, especially for rain with kinetic energy typical of Mediterranean-type rainstorms (15.9 kJ m^{-3}). It appears that, despite the relatively higher ESPs of the TWW-irrigated soils, which enhance clay dispersion, the raindrop impact energy (in the case of the high kinetic energy rain) causes aggregate breakdown and compaction and controls the process of seal formation at the soil surface, resulting in subsequent low IR and high runoff levels.

A field study on two calcareous soils showed that runoff levels from FW- and TWW-irrigated fields were comparable (Agassi et al., 2003). The rapid decrease in the exchangeable sodium percentage (ESP) of the upper soil layer in the TWW-irrigated field (the layer where seal development occurs) during the rainy season, from 5 to 6 at the end of summer to its natural level of ~ 2 , as found in the FW-irrigated field, attributed to the presence of lime in the soil, was held responsible for the observed similarity in the IR and runoff recorded for the soils from the FW- and TWW-irrigated fields (Agassi et al., 2003). These findings also explain the observed adverse effects of irrigation with TWW on soil permeability and runoff production in a non-calcareous sandy soil used in the studies of Mamedov et al. (2001a, b) and Lado et al. (2005).

Soil susceptibility to sealing and runoff production depends on the conditions prevailing at the soil surface prior to exposing the soil to rain. Allowing the surface aggregates to slake (using fast wetting) before exposing the soil to rain enhances the development of a seal with low permeability and subsequently the production of high

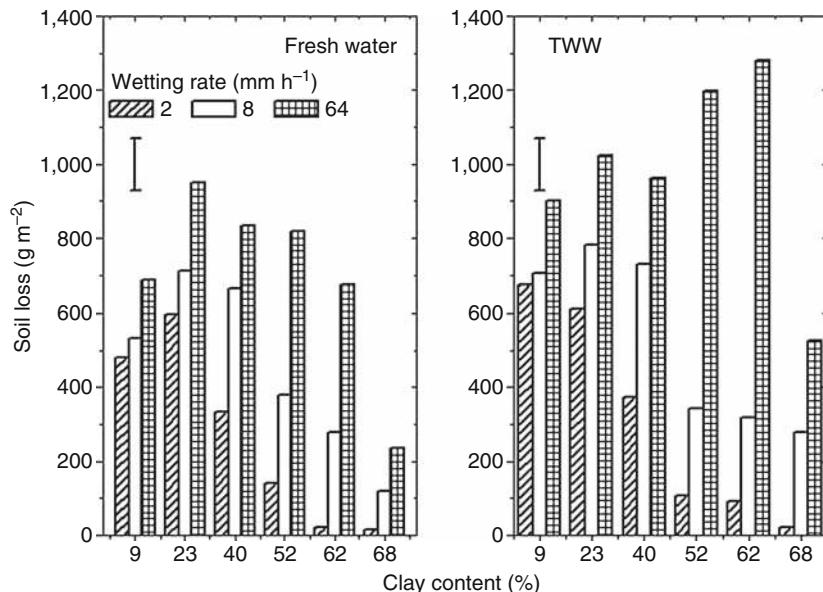

levels of runoff (Levy et al., 1997). However, but for a sandy soil, comparable runoff levels were observed for TWW- and FW-irrigated medium- and fine-textured soils irrespective of the initial conditions (i.e., degree of aggregate slaking) that existed at the soil surface prior to applying rain (Mamedov et al., 2001a; Lado et al., 2005).

Comparison of soil loss from FW- and TWW-irrigated soils, subjected to different levels of rain kinetic energy, showed that soil loss from the TWW-irrigated soils was always significantly higher (Mamedov et al., 2000b), while respective IR levels did not differ significantly between soils irrigated with the two water qualities (Mamedov et al., 2000a).

Under circumstances where soil surface conditions were manipulated by using different wetting rates prior to applying rain, it was observed that under conditions of fast wetting (sever aggregate slaking), the TWW-irrigation soils yielded higher soil loss levels compared with the FW-irrigated samples (Figure 1). This observations for soil loss, combined with the similar level of runoff in the two types of samples (Mamedov et al., 2001a), suggested that once the surface aggregates are slaked by fast wetting, the slaked particles are more readily detached and removed from the soil by the runoff water in the TWW-irrigated samples than in the FW-irrigated ones, resulting in a higher soil loss load. When non-slaked aggregates (i.e., slowly wetted aggregates) were exposed to the impact of rain drops, irrigation with TWW had no additional adverse effect on soil susceptibility to sealing, runoff, and soil loss production beyond that of FW (Mamedov et al., 2001a; Mamedov et al., 2001b). More recently, Lado et al. (2005) suggested that for non-calcareous sandy soils, TWW-irrigated samples are more susceptible to runoff and soil loss production than FW-irrigated ones, irrespective of initial conditions of slaked or non-slaked surface aggregates.

Summary

Examination of numerous studies that evaluated the impact of long-term irrigation with TWW on different indices representing soil structure and stability revealed that the effects of using TWW for irrigation are inconsistent. The observed inconsistencies may stem from (1) the fact that different mechanisms (clay swelling and dispersion, aggregate slaking) control in different ways the response of the determinants tested, (2) variability in soil properties (mainly clay content and presence of lime) affecting soil stability, and (3) disparity in the conditions prevailing in the soil (e.g., intensity of tillage, rate of wetting). It emerges that under conditions where either aggregate slaking is prevented or aggregates are subjected to only minor disturbance (non-intensive tillage), the use of TWW for irrigation has almost no adverse effects on soil structure and stability, especially in calcareous soils. In cases where long-term irrigation with TWW had led to some deterioration in determinants associated with

Irrigation with Treated Wastewater, Effects on Soil Structure, Figure 1 Effects of water quality and rate of wetting on soil loss from soils with different clay content exposed to simulated deionized rain water. Bars indicate a single confidence interval value at $\alpha = 0.001$. (Adapted from Mamedov et al., 2001b.)

soil-structure stability, the magnitude of the deterioration was not severe.

Soils are a valuable resource that, once degraded, would be extremely difficult and costly to reclaim. Irrigation with TWW should, therefore, be accompanied by close monitoring of different indicators of soil structure in order to maintain the soils in a satisfactory state for continued productive use by future generations.

ISOELECTRIC POINT

The activity of potential determining ion in a solution in equilibrium with a variable charge surface whose net electrical charge is zero. For soils it refers to the pH of the isoelectric point of pH dependent charge materials. It applies only to single components, not mixtures.

ISOTROPY AND ANISOTROPY IN AGRICULTURAL PRODUCTS AND FOODS

Józef Horabik, Marek Molenda

Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland

Definition

The term isotropy means homogeneity of physical properties in all directions.

The term anisotropy is used to describe direction-dependent physical properties of materials as opposed to isotropy. It can be defined as a difference in a value of property when measured along different axes.

Introduction

Numerous solids can be naturally anisotropic. Anisotropy can be also frequently induced during storage, handling, and processing of materials as a result of specific treatment, portion of fine fraction, or mechanical interactions between particles.

For practice of biomaterials storage, handling and processing anisotropy of the mechanical properties (elasticity, plasticity, viscoelasticity, fracture, and mechanical strength), the diffusion properties responsible for filtration in porous materials, and the thermal properties are the most important.

Natural anisotropy

Inherently anisotropic solids are very common in nature. The typical examples in the microscale are crystals and polycrystals in which the grains are not completely

random but have a preferred orientation. Also in the case of plants, the growth of their cells is not completely random. Preferred directions of plant growth result in an anisotropic behavior of the tissue by introducing oriented directions of structure (Erickson, 1976). Preferred directions of cell division and cell wall expansion in a developing organ lead to anisotropic tissue growth (Bittig et al., 2008). The direction of maximal expansion rate is related to the direction of net alignment among cellulose microfibrils (Baskin, 2005). The behavior of plant tissue is not isotropic and related to its structural composition. The apple tissue has marked anisotropy in its fracture properties: flesh of the apple can be split much more easily along the fruit's radius than in a direction parallel to the fruit's tangent (Khan and Vincent, 1993). On the scale of biological tissue, the preferred orientation of fiber bundles creates very strong anisotropy. Their properties vary widely when measured with the growth direction grain or against it. Wood, carrot, onion, and meat are very illustrative examples of naturally anisotropic biological materials. Fiber tissues are much stronger along the fiber than across it. The fibrous structure of meat products leads to anisotropy of the thermal conductivity, which can be enhanced during freezing by the anisotropic growth of ice crystals in the direction of the temperature gradient (van der Sman, 2008).

Introduced anisotropy

Anisotropic structures of solids can be formatted during processing (extrusion, rolling, chopping, and slicing) due to certain texture patterns obtained in processing or due to some inclusions into isotropic matrix. Extrusion cooking can create anisotropy in the mechanical properties of produced foams, which is important to the consumer-perceived textural characteristics (Hutchinson and Simms, 1988). The application of well-defined flow in processing can result in formation of anisotropic structure of complex materials like foods (Manski et al., 2007). Preferred orientation of protein fibers results in anisotropy of fracture properties of Mozzarella cheese (Ak and Gunasekaran, 1997). The dynamics of capillary flow in porous media depends on microstructure: the hydration rate from cut-edges of leaf tea is a hundred fold faster than that from top to bottom surfaces (Weerts et al., 2006). Inclusions of some microfiber or microparticles into isotropic material during food processing results in that the composite either have the structure of reinforcing fibers in a matrix, with fibers oriented in one direction or in multiple directions, which leads to difference in mechanical strength along different directions (food-grade anisotropic materials lumpy micro-rods with microparticle inclusions (Campbell et al., 2009)).

Anisotropy of granular solids

When a bulk of grains is handled, the individual grains tend to be aligned in the Earth's gravitational field. Anisotropy appears in final stage of slow kernels interactions (impacts, rolling, sliding, and shearing) due to

particles tendency to rest in the most stable position with respect to the gravitational field. An example is slow slipping of particles along the line of the cone of natural repose. The particles tend to rest with the longest axes along the cone generatrix. When a granular assembly is composed of spherical particles, anisotropy results from preferred orientation of normal direction in contact points. When a granular assembly is composed of nonspherical particles, the two types of anisotropy are produced: (1) due to the preferred orientation of nonspherical particles and (2) due to concentration of normal direction in contact points (Oda, 1978). As a result, the shear strength of a granular assemble is anisotropic and the resistance to air flow is also anisotropic. The strength anisotropy leads to nonuniform load distribution on structures and nonuniform flow (Horabik et al., 1988). The pressure drop through a bulk of grains can be different in each direction due to difference in associated pores structure (Łukaszuk et al., 2009).

Description of anisotropic behavior

Description of behavior of anisotropic body is much more difficult than isotropic one. For mathematical modeling, the tensor notation is commonly used. Theory of linear elasticity requires two parameters of elasticity for isotropic body while for the anisotropic body the general Hook's law requires 18 independent elastic parameters (Timoshenko and Goodier, 1970). Similarly, plastic behavior of anisotropic body requires much more material parameters than isotropic one. To explain anisotropic response of granular solids the so-called fabric (spatial arrangement of solids and associated voids) derived from micromechanical approach should be introduced into the stress-strain relationship.

Summary

Anisotropic behavior of agricultural products and foods is frequently observed in nature. Proper designing of technological processes requires precise understanding of physical processes. Very important is to recognize whether behavior of solids is isotropic or anisotropic.

L

LAMINAR AND TURBULENT FLOW IN SOILS

Henryk Czachor

Institute of Agrophysics, Polish Academy of Sciences,
Lublin, Poland

Definitions

Laminar flow is streamlined and directly proportional to the pressure difference.

Turbulent flow is a flow without stable streamlines, and it is not directly proportional to the pressure difference.

Laminar flow in a cylindrical channel can be seen as a set of steady state parallel streamlines of different velocities. Radial velocity profile is described by a parabolic function – zero – at the wall and the maximum value in the center equals twice the mean velocity. Streamlines in a turbulent flux are not stable.

Flow character is determined by means of the Reynolds number Re .

$$Re = \rho u D / \mu; \quad (1)$$

where ρ – fluid density (kg m^{-3}), u – velocity (m s^{-1}), μ – dynamic viscosity (N s m^{-2}), D – channel diameter (m).

Type of flow in a cylindrical channel depends on the Reynolds number Re – for $Re < 2,300$, flow is laminar, if $2,300 < Re < 4,000$ – transition zone, $Re > 4,000$ – turbulent flow.

When liquid flows through a porous medium composed of spherical particle of diameter D , the Reynolds number Re can be estimated as (Rhodes, 1989):

$$Re = \rho V D / (\mu(1 - p)), \quad (2)$$

where V – the mean fluid velocity (m s^{-1}), p – porosity.

Laminar flow through a porous medium occurs for $Re < 10$ and fully turbulent for $Re > 2,000$. For example,

the Reynolds number Re of water flow trough, a mono size sand of grain diameter 2 mm, of velocity $V = 2 \text{ mm s}^{-1}$ and porosity $p = 0.4$ equals $6.7 < 10$ what means that it is a laminar one. One can suppose that the water flux in finer soils is a laminar one.

Turbulent flow in soils may occur in macropores ($D > 2-3 \text{ mm}$) made by fauna, for example, earthworms. When laminar, the water flux is proportional to the water potential gradient described by the Richards equation (Iwata et al., 1988).

LAYERED SOILS, WATER AND SOLUTE TRANSPORT

H. M. Selim
School of Plant, Environmental and Soil Sciences (SPESS), Agricultural Center, Louisiana State University, Baton Rouge, LA, USA

Definition

The phenomenon of *layering of the soil profile* is an intrinsic part of soil formation. Soils are naturally made up of several layers or strata having distinct physical and chemical properties. These properties reflect various processes and their soil genesis. Layers are commonly of uniform thicknesses and stratified horizontally. Water and solute movement in soils are naturally occurring processes where the flow must account for the different properties of the various soil layers.

Introduction

Soils are defined as heterogeneous systems that are made up of various constituents having distinct physical and

chemical properties. A major source of soil heterogeneity is soil stratifications or layering. The phenomenon of stratifications or layering of the soil profile is an intrinsic part of soil formation processes and has been documented for several decades by soil survey work.

The transport processes of dissolved chemicals in stratified or layered soils have been studied for several decades by Shamir and Harleman (1967), Selim et al. (1977), Bosma and van der Zee (1992), Wu et al. (1997), among others. Solute transport in layered soils can be investigated through numerical methods as well as approximate analytical solutions. An early analytical method was proposed by Shamir and Harleman (1967) who used a system's analysis approach. They assumed that different layers were independent with regard to solute travel time. Each layer's response served as the boundary condition (BC) for the downstream layer and so on. Later, Selim et al. (1977) discussed the movement of reactive solutes through layered soils using finite difference numerical methods. They considered both equilibrium and kinetic sorption models of the linear and nonlinear types. In the late 1980s, Leij and Dane (1989) developed analytical solutions for the linear sorption type models using Laplace transforms. Their solutions were based on the assumption that each layer was semi-infinite. Bosma and van der Zee (1992) also proposed an approximate analytical solution for reactive solute transport in layered soils using an adaptation of the traveling wave solution. Recently, Wu et al. (1997) developed another analytical model for nonlinear adsorptive transport through layered soils ignoring the effects of dispersion. In addition, Guo et al. (1997) showed that the transfer function approach was a very powerful tool to describe the nonequilibrium transport of reactive solutes through layered soil profiles with depth-dependent adsorption.

When we study transport process of dissolved chemicals in layered soils, it is of interest to investigate whether soil layering affects solute breakthrough. When flow remains one-dimensionally vertical, which is the case when horizontal stratification is dominant, it is of interest whether the layering order affects breakthrough results at the groundwater level (van der Zee, 1994). The early results from Shamir and Harleman (1967) showed that the order of layering did not affect breakthrough significantly. This interesting result was further elaborated upon by Barry and Parker (1987) based on various analytical approaches. Results from various linear and nonlinear numerical simulations for several sorption model types also supported this conclusion (Selim et al., 1977). Furthermore, Selim et al. (1977) concluded that layering order was also unimportant for Freundlich adsorption. Their experimental results also supported this conclusion. However, van der Zee (1994) attributed Selim et al. (1977) results to the small Peclet number assumed for the nonlinear layer, which prevents nonlinearity effects to be clearly manifested. van der Zee (1994) used a hypothetical result to illustrate that layering sequence should have an effect. However, what van der Zee (1994) used to

support his conclusion was the traveling wave, which was the curve of concentration versus depth at different times, i.e., concentration profile. Recently, Zhou and Selim (2001) accounted for several nonlinear and kinetic retention mechanisms for multilayered soils. For individual soil layers, Zhou and Selim (2001) considered solute retention mechanisms of the nonlinear (Freundlich), Langmuir, first- and n th order kinetic, second-order kinetic, and irreversible reactions. For all retention mechanisms used, their simulation results indicated that solute breakthrough curves (BTCs) were similar regardless of the layering sequence in a soil profile. This finding is consistent with earlier finding of Selim et al. (1977) and contrary to that of Bosma and van der Zee (1992) for nonlinear adsorption.

In the subsequent section, we present general equations for solute transport in multilayered systems followed by a discussion of the various choices of boundary conditions at the interface between layers. We further present selected case studies of linear and nonlinear adsorption mechanisms in layered soil systems based on numerical simulations for a range of soil properties and fluxes (or Brenner numbers). Experimental results based on miscible displacements from packed sand-clay soil column for a tracer (tritium) and for reactive solutes (Ca and Mg) BTCs are subsequently presented in support of theoretical findings.

Convection-dispersion equation

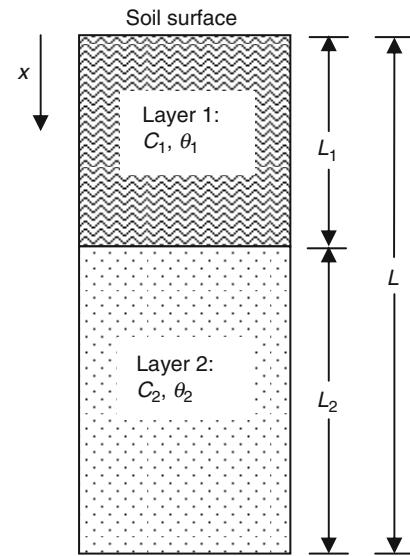

A two-layered soil column of length L is shown in Figure 1. The length of each layer is denoted by L_1 and L_2 , respectively. To show heterogeneity, each soil layer has specific, but not necessarily the same water content, bulk density, and solute retention properties. Only vertical direction steady-state water flow perpendicular to the soil layers (Figure 1) will be considered. The convective-dispersive equation (CDE) governing solute transport in the i th layer (see Figure 1) is given by Equation 1 (Selim et al., 1977):

$$\rho_i \frac{\partial S_i}{\partial t} + \theta_i \frac{\partial C_i}{\partial t} = \frac{\partial}{\partial x} \theta_i D_i \frac{\partial C_i}{\partial x} - q \frac{\partial C_i}{\partial x} - Q_i \quad (1)$$

$$(0 \leq x \leq L_i, i = 1, 2)$$

where (omitting the i) C = resident concentration of solute in soil solution ($\mu\text{g cm}^{-3}$), S = amount of solute adsorbed by the soil matrix ($\mu\text{g g}^{-1}$), ρ = soil bulk density (g cm^{-3}), θ = volumetric soil water content ($\text{cm}^3 \text{cm}^{-3}$), D = solute dispersion coefficient ($\text{cm}^2 \text{day}^{-1}$), q = Darcy soil-water flow velocity (cm day^{-1}), Q = a sink or source for irreversible solute interaction ($\mu\text{g cm}^{-3} \text{day}^{-1}$), x = distance from the soil surface (cm), and t = time (day).

The reversible solute retention from the soil solution is represented by the term $\partial S / \partial t$, on the left side of Equation 1 while the irreversible solute removed from soil solution is expressed by the term Q on the right side of Equation 1.

Layered Soils, Water and Solute Transport,
Figure 1 Schematic diagram of a two-layered soil.

Boundary condition at the interface

An important boundary condition needed in the analysis of multilayered soils is that at the interface between layers. It should be noted that both first-type and third-type boundary conditions are applicable at the interface. Leij et al. (1991) showed that although the principle of solute mass conservation is satisfied, a discontinuity in concentration develops when a third-type interface condition is used. On the other hand, a first-type interface condition will result in a continuous concentration profile across the boundary interface at the expense of solute mass balance. To overcome the limitations of both first- and third-type conditions, a combination of first- and third-type condition was implemented. The first-type condition can be written as

$$C_I|_{x \rightarrow L_1^-} = C_{II}|_{x \rightarrow L_1^+}, \quad t > 0 \quad (2)$$

where $x \rightarrow L_1^-$ and $x \rightarrow L_1^+$ denote that $x = L_1$ is approached from the upper layer and lower layer respectively. Similarly, the third-type condition can be written as

$$\left(qC_I - \theta_I D_I \frac{\partial C_I}{\partial x} \right) \Big|_{x \rightarrow L_1^-} = \left(qC_{II} - \theta_{II} D_{II} \frac{\partial C_{II}}{\partial x} \right) \Big|_{x \rightarrow L_1^+}, \quad t > 0 \quad (3)$$

Incorporation of Equation 6 into Equation 7 yields

$$\theta_I D_I \frac{\partial C_I}{\partial x} \Big|_{x \rightarrow L_1^-} = \theta_{II} D_{II} \frac{\partial C_{II}}{\partial x} \Big|_{x \rightarrow L_1^+}, \quad t > 0 \quad (4)$$

The BC of [Equation 4](#) was first proposed by Zhou and Selim ([2001](#)) and resembles that for a second-type BC as indicated earlier by Leij et al. ([1991](#)).

Equilibrium retention models

The form of solute retention reactions in the soil system must be identified if prediction of the fate of reactive solutes in the soil using the convection-dispersion [Equation 7](#) is sought. The reversible term $(\partial s/\partial t)$ is often used to describe the rate of sorption or exchange reactions with the solid matrix. Sorption or exchange has been described by either instantaneous equilibrium or a kinetic reaction where concentrations in solution and sorbed phases vary with time. Linear, Freundlich, and one- and two-site Langmuir equations are perhaps the most commonly used to describe equilibrium reactions. In the subsequent sections, we discuss Freundlich and Langmuir reactions and their use in describing equilibrium retention. This is followed by kinetic type reactions and their implication for single and multireaction retention and transport models (see [Table 1](#)).

Linear adsorption

[Figure 2](#) shows a comparison of breakthrough curves (BTCs) for a two-layered soil column with reverse layering orders. Here we report results for a layered soil column where one layer is nonreactive ($R = 1$) and the other is linearly adsorptive. For the case of linear adsorption, a dimensionless retardation factor can be obtained from [Equation 1](#) and is given by

$$R = 1 + \frac{\rho K_d}{\theta} \quad (5)$$

Here for the case where $K_d = 0$, the retardation factor R equals 1 and solute is considered nonreactive. The BTC for the case $R1 \rightarrow R2$ where the nonreactive layer was first encountered (top layer) was similar to that when the layering sequence was reversed ($R2 \rightarrow R1$) and the reactive layer ($R2$) was the top layer. Therefore, for the linear adsorption case, one concludes that the order of soil

Layered Soils, Water and Solute Transport, Table 1 Selected equilibrium and kinetic type models for solute retention in soils (Adapted from Selim and Amacher ([1997](#)), with permission)

Model	Formulation ^a
Equilibrium type	
Linear	$S = K_d C$
Freundlich (nonlinear)	$S = K_f C^b$
Langmuir	$S/S_{\max} = \frac{\omega C}{(1+\omega C)}$
Kinetic type	
First order	$dS/dt = k_f (\theta / \rho) C - k_b S$
<i>n</i> th order	$dS/dt = k_f (\theta / \rho) C^n - k_b S$
Irreversible (sink/source)	$dS/dt = k_s (\theta / \rho) (C - C_p)$
Langmuir kinetic	$dS/dt = k_f (\theta / \rho) C (S_{\max} - S) - k_b S$
Second order	$dS/dt = k_f \phi (\theta / \rho) C - k_b S$

^a K_d , K_f , k_b , k_f , k_s , n , S_{\max} , C_p , and ω are adjustable model parameters.

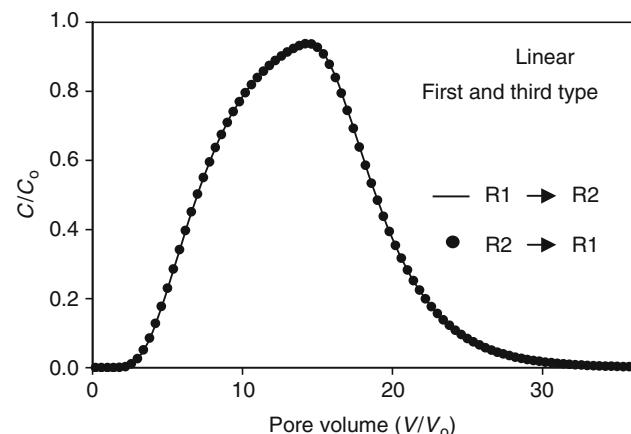

stratification or layering sequence fails to influence solute BTCs and consistent with those reported earlier by Shamir and Harleman ([1967](#)) and Selim et al. ([1977](#)) for systems with two or more layers. Based on these results, a layered soil profile could be regarded as homogeneous with an average retardation factor used to calculate effluent concentration distributions. An average retardation factor \bar{R} for N -layered soil can simply be obtained from

$$\bar{R} = \frac{1}{L} \sum_{i=1}^N R_i L_i \quad (6)$$

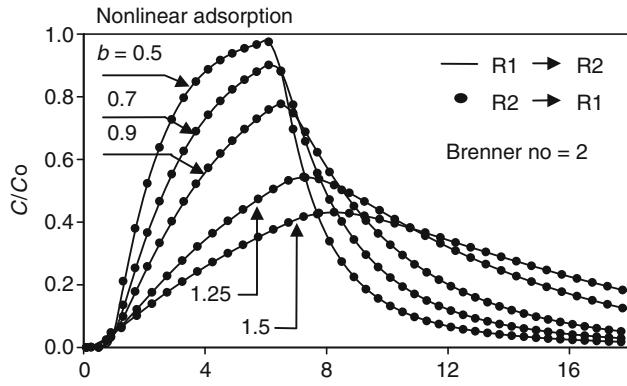

BTCs identical to those in [Figure 2](#) were obtained using the solution to the convection-dispersion [Equation 7](#) presented by van Genuchten and Alves ([1982](#)) and an average retardation factor. This averaging procedure ([Equation 6](#)) can also be used to describe the BTCs from a soil profile composed of three or more layers. However, if solute distribution within the profile is desired, the use of an average retardation factor is no longer valid and the problem must be treated as a multilayered case.

Nonlinear Freundlich adsorption

Simulated BTCs of solutes from a two-layered soil system with one as a nonlinear (Freundlich) adsorptive layer are given in [Figure 3](#). Here, $R1$ represents a nonreactive layer whereas $R2$ stands for a nonlinear (Freundlich) adsorptive layer. Our simulations were carried out for a wide range of the Peclet or Brenner number ($B = qL/\theta D$). We also examined the influence of the nonlinear Freundlich parameter b (see [Table 1](#)) on the shape of the BTCs. For most reactive chemicals, including pesticides and trace elements b is always less than unity (Selim and Amacher, [1997](#)). Based on our simulations, BTCs were not influenced by the layering sequences regardless of the Brenner number B .

Layered Soils, Water and Solute Transport, [Figure 2](#) Simulated breakthrough results for a two-layered soil column under different layering orders ($R1 \rightarrow R2$ and $R2 \rightarrow R1$). Here $R1$ is for a nonreactive layer and $R2$ is for a reactive layer with linear adsorption.

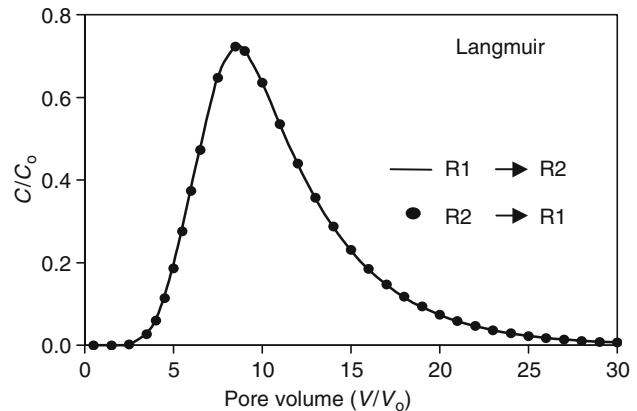

Layered Soils, Water and Solute Transport,

Figure 3 Simulated breakthrough results for a two-layered soil column under different layering orders ($R1 \rightarrow R2$ and $R2 \rightarrow R1$). Here $R1$ is for a nonreactive layer and $R2$ is a reactive layer with nonlinear adsorption with b values (Equation 11) of 0.5, 0.7, 0.9, 1.25, and 1.5. The Brenner numbers B used was 2.

when nonlinear Freundlich adsorption was considered. This result is similar to that of Selim et al. (1977). Dispersion becomes the dominant process in the case where the Brenner number is small whereas convection becomes the dominant process for large B values. The BTCs exhibit increasing retardation or delayed arrival, and excessive tailing of the right-hand side of the BTCs for increasing values of nonlinear adsorption parameter b . In addition, the BTCs become less spread (i.e., a sharp front) with increasing Brenner numbers. All such cases provide similar observations, i.e., the effects of nonlinearity of adsorption are clearly manifested. Nevertheless, for all combinations of b and the Brenner number B used in our simulations, the BTCs under reverse layering orders showed no significant differences. In other words, layering order is not important for solute breakthrough in layered soils with nonlinear adsorptive as the dominant mechanism in one of the layers. Zhou and Selim (2001) arrived at similar conclusions for layered soil profiles when several retention mechanisms of the kinetic reversible and irreversible type were considered.

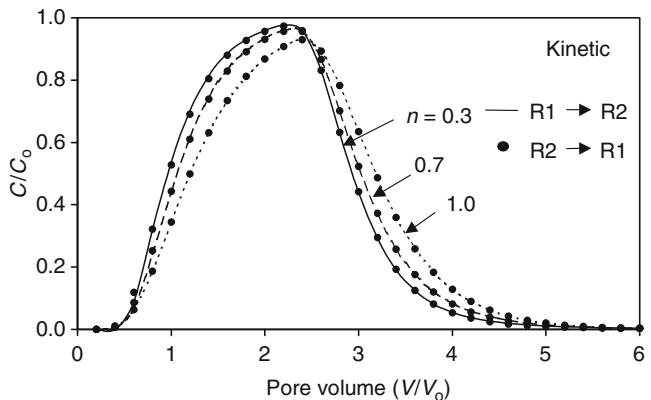

Langmuir

In order to illustrate the universal validity of the above finding, other solute adsorption processes of the nonlinear type were investigated. Langmuir adsorption model is perhaps one of the most commonly used equilibrium formulation for describing various reactive solutes in porous media. We only considered simulated columns consisting of one nonreactive layer and one reactive layer with Langmuir-type adsorption mechanism. The simulation results are shown in Figure 4. The combined first- and third-type BC was used at the interface between the layers. Consistent with the above finding, we found that for all parameters used in this study, the layering sequence has no effect on the BTCs when Langmuir-type adsorption was the dominant mechanism.

Layered Soils, Water and Solute Transport,

Figure 4 Simulated breakthrough results for a two-layered soil column under different layering orders ($R1 \rightarrow R2$ and $R2 \rightarrow R1$). Here $R1$ is for a nonreactive layer and $R2$ is for a reactive layer with Langmuir adsorption.

Layered Soils, Water and Solute Transport,

Figure 5 Simulated breakthrough results for a two-layered soil column under different layering orders ($R1 \rightarrow R2$ and $R2 \rightarrow R1$). Here $R1$ is for a nonreactive layer and $R2$ is for a reactive layer with kinetic adsorption with $n = 0.3, 0.7$, and 1.0, respectively. A second-type boundary condition (BC) was used at the interface.

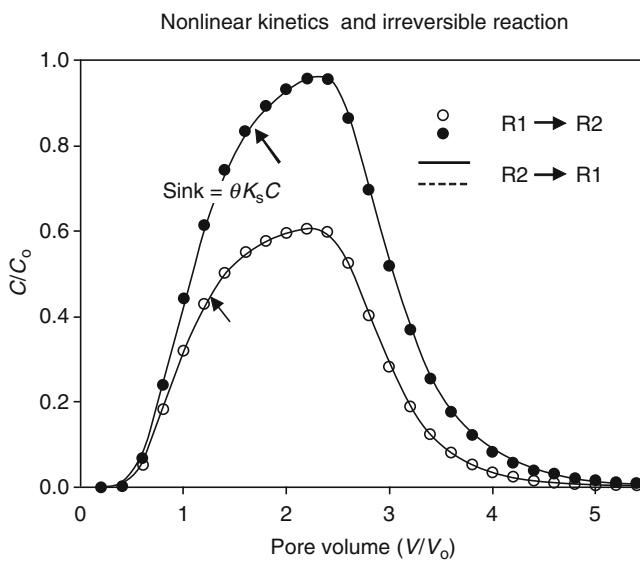

Kinetic retention

In this section, first and n th order reversible kinetics (see Table 1) was considered as the dominant retention mechanism. Values of the reaction order n used were 0.3, 0.7, and 1.0. The BTCs under reverse layering orders showed a very good match regardless of the value of the nonlinear parameter n . For all cases, a good match was also realized (see Figure 5). We also carried out simulations where both layers were assumed reactive. Other retention mechanisms considered included irreversible reaction as well as second-order mechanism. Regardless of the retention mechanism, simulations results indicated that layered soils with reverse layering orders showed BTCs no

significant differences. For example, in the presence of a sink term, the order of soil layers did not influence the shape or the position of the BTCs as illustrated in Figure 6. This finding is consistent with that of Selim et al. (1977) where a similar sink term was implemented.

Water-unsaturated soils

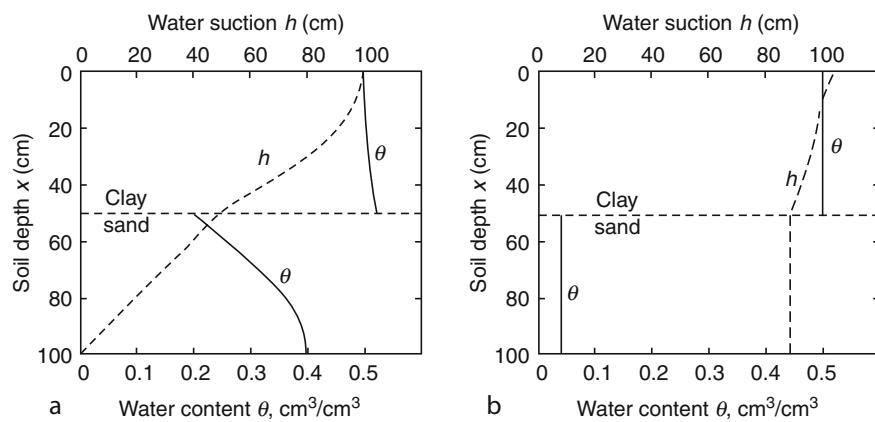

Selim et al. (1977) simulated solute transport through water unsaturated multilayered soil profiles, where a

Layered Soils, Water and Solute Transport, Figure 6 Simulated breakthrough results for a two-layered soil column under different layering orders ($R1 \rightarrow R2$ and $R2 \rightarrow R1$). Here $R1$ is for a nonreactive layer adsorption and $R2$ is a reactive layer with n th order kinetic adsorption and irreversible sink.

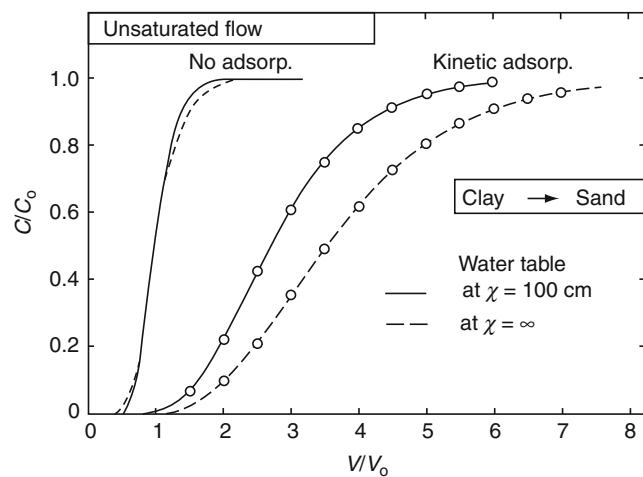

steady vertically downward water flow ($q = \text{constant}$) was considered. A soil profile was assumed to consist of two distinct layers, sand and clay, each having equal lengths and was underlain by a water table at a depth $L = 100 \text{ cm}$. The case where the water table was at great depth ($z \rightarrow \infty$) was also considered. When a constant flux was assumed, the steady-state θ and water suction (h) distributions for a sand–clay and a clay–sand soil profile were calculated (see Figure 7 for the sand–clay case). Solute concentration versus pore volume of effluent (collected at 100-cm depth) for a nonreactive and reactive solute having linear (equilibrium) retention is shown in Figure 7. As expected, similar BTC results for the nonreactive solute for sand–clay or clay–sand soil profiles were obtained. In contrast, BTCs for the reactive solute show a distinct separation, with lower retardation factors for the soil profiles having a water table at $z = 100 \text{ cm}$ than at $z \rightarrow \infty$. This observation is consistent for the sand–clay as well as clay–sand profiles. Due to the higher water contents in the soil profiles where the water table was at $x = 100$, the retardation factor R is less in comparison to the case where the water table was at great depth ($z \rightarrow \infty$).

If the water content distributions were considered uniform, with an average water content within each individual layer (see Figure 8), the problem of solute transport and retention through unsaturated multilayered soil profiles can be significantly simplified as discussed in the previous section. The open circles in Figure 8 are calculated results of concentration distributions for the reactive and nonreactive solutes when an average water content within each layer was used. These results show that, for all unsaturated profiles considered, the use of average water contents (open circles) provided identical concentration distributions to those obtained where the actual water content distributions were used (dashed and solid lines). Thus, when a steady water flux is maintained through the profile, BTCs of reactive and nonreactive solutes at a given

Layered Soils, Water and Solute Transport, Figure 7 Simulated soil–water content θ and water suction h versus depth in a clay–sand profile having a water table (a) at 100-cm depth and (b) great depth.

location in the soil profile can be predicted with average water contents within unsaturated soil layers. Based on the above results, we can conclude that average micro-hydrologic characteristics for a soil layer can be used to describe the movement of solutes leaving a multilayered soil profile. This conclusion supports the assumption made earlier that uniform soil water content can be used to represent each soil layer in order to simplify the solute transport problem. However, such a simplifying approach was not applicable for the general case of transient water-flow conditions of unsaturated multilayered soils. As illustrated by Selim (1978), the transport of reactive, as well as nonreactive, solutes through multilayered soils,

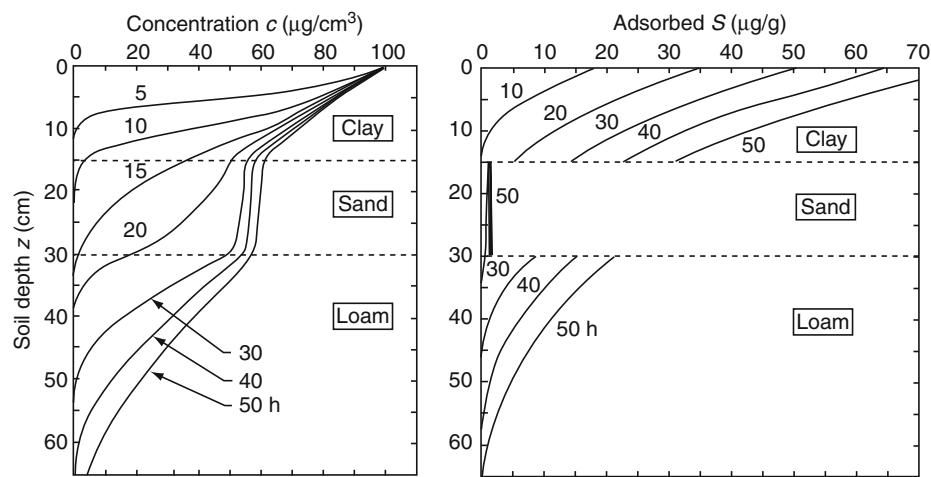

Layered Soils, Water and Solute Transport,
Figure 8 Simulated effluent concentration distribution for reactive and nonreactive solutes in an unsaturated clay–sand profile. Open circles are based on average water content θ for each soil layer.

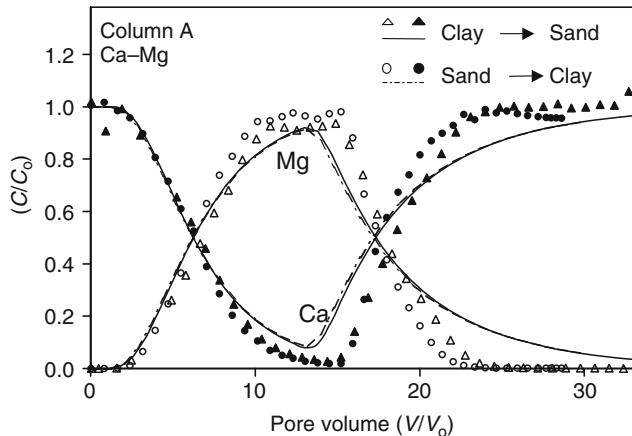

for transient water flow, was significantly influenced by the order in which the soil layers were stratified.

Solute transport in a three-layered soil profile (clay over sand over loam) is shown in Figure 9. In this example, we illustrate solute transport during water infiltration in an unsaturated soil (see Selim, 1978). Here application of a solute solution at the soil surface was assumed for an extended period of time; i.e., continuous application. The reactivity of individual soil layers to the applied solute was assumed to follow first-order kinetics. Because of slow kinetic adsorption, the amount of solute adsorbed S continued to increase with time in the clay layer in comparison to the other two layers. Such a slow adsorption resulted in a decrease of solute concentration with soil depth in the clay layer. In contrast, a somewhat uniform distribution was observed for the sand layer accompanied by an increase in the loam layer. Solute transport during infiltration and water redistribution was investigated for several other combinations of soil layer stratifications and the results indicated that solute transport through multilayered soil was significantly influenced by the order in which the soil layers are stratified.

Examples of experimental and predicted BTC results based on miscible displacements from packed soil columns having two layers are shown in Figures 10 and 11. Predictions and experimental BTC results for tritium are shown in Figure 11 (solid and dashed lines) for a sand–clay and clay–sand sequence and they indicate a good match of the experimental data. All input parameters were directly based on our experimental measurements and support our earlier findings. Zhou and Selim (2001) simulated the breakthroughs of Ca and Mg using a two-layered model for reactive solutes. The simulation results are shown in Figure 10 (solid and dashed lines for different layering arrangements) where the reaction mechanism for the Ca–Mg system was assumed to be governed by simple ion exchange for a binary system:

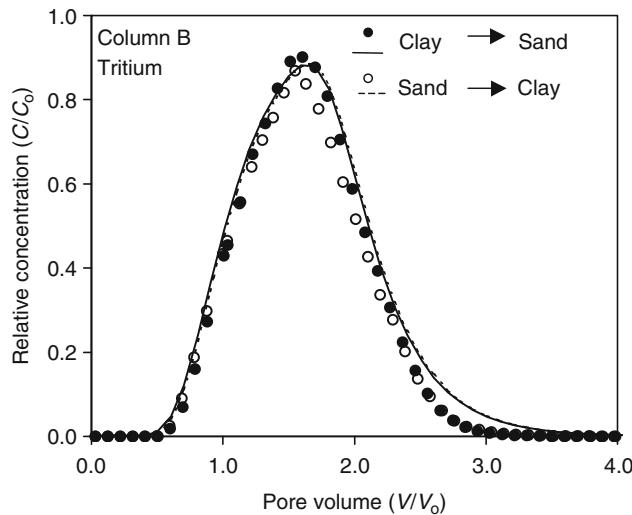

Layered Soils, Water and Solute Transport, Figure 9 Solute concentration and amount of solute absorbed versus soil depth in a three-layered soil profile with first-order kinetic retention reactions.

Layered Soils, Water and Solute Transport,

Figure 10 Experimental (symbols) and simulated (dashed and solid lines) breakthrough results for Ca and Mg in a two-layered soil column (Sharkey clay → sand, column A) under different layering sequences.

Layered Soils, Water and Solute Transport,

Figure 11 Experimental (symbols) and simulated (dashed and solid lines) breakthrough results for tritium in a two-layered soil column (Sharkey clay → sand, column B) under different layering orders.

$$S = \frac{K_{12}cS_T}{1 + (K_{12} - 1)c} \quad (7)$$

where c is relative concentration (C/C_0), K_{12} is the selectivity coefficient (dimensionless), and S_T is the cation exchange capacity (CEC). The simulation curves agree with the experimental data, especially for the adsorption front and also exhibit tailing of the release curve for both Ca and Mg. Such tailing was not observed based on the experimental data, however. Results for nonreactive

tracer solute are shown in Figure 11. Here experimental (symbols) and simulated (dashed and solid lines) breakthrough results for tritium in a two-layered soil column (Sharkey clay → sand, column B) under different layering orders are presented and clearly illustrate that the order of layering does not influence solute transport under steady flow conditions.

Summary and a look ahead

Water and solutes in soils is dependent on the layering of the soil profile. Specifically, physical and chemical properties of individual soil layers as well as the sequence of layering dictate the behavior of water and reactive chemicals in the soil profile. Based on mathematical analyses and laboratory experiments, solute transport is independent of the order of soil layers. This finding is applicable for reversible and irreversible solute reactions of the equilibrium and kinetic types. These reactions include Freundlich, Langmuir, and reversible and irreversible first- and n th order kinetics. Furthermore, simplified approaches can be used to quantify the transport of reactive chemicals in soil profile, if equilibrium type reactions of the linear type are dominant for individual soil layers. Future research should include soil profiles where the layers are not horizontally stratified. Inclined soil layers are common and observed in hilly regions and sloping soils. Areas within delta regions, the soil surface as expected should be nearly flat, however. Preferential flow or flow in fractured media with multiple porosities (macro- and meso-pores) is another area for future research of water and solute transport in layered soils.

LEACHING OF CHEMICALS IN RELATION TO SOIL STRUCTURE

Tom M. Addiscott

 Harpenden, Herts, UK

Synonyms

Channelling; Effect of soil structure on leaching; Mobile/immobile transport; Leaching; Lixivation; Ped structure; Short-circuiting; Soil structure; Pore structure; Transport

Definition

Leaching – washing out soluble chemicals or other materials from the soil by water percolating through the soil. This can be strongly influenced by the structure of the soil. The term “leaching” is sometimes used to describe the washing out chemicals sorbed on soil particulate matter from the soil, but the more general term “transport” may be more appropriate.

History of the topic

The *Oxford English Dictionary* suggests that the word “leach” was first used in about 1800 but that it initially referred to the leaching of solutes from ash. The application of the term must have passed readily from ash to soil. The idea that the soil structure had an influence on leaching can be traced back to the studies of Lawes et al. (1882). They deduced the existence of mobile and immobile categories of water in the soil from their measurements of nitrate and water passing through the soil of the Broadbalk Experiment at Rothamsted to the drains.

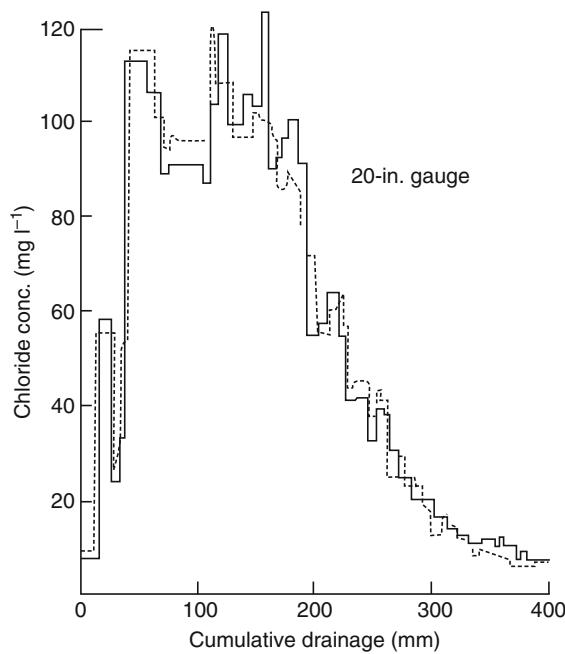

This discovery seems to have remained forgotten for many years, and a number of leaching experiments were made, mainly in the USA in the 1960s, in which the soil

was sieved to a uniform size and leached in a fairly small column (e.g., Nielsen and Biggar, 1961), thereby eliminating the effects of its structure. However, McMahon and Thomas (1974) published an important paper in the USA, showing that the movement of chloride and tritiated water in a column of sieved soil differed very considerably from the movement in a column of the same soil undisturbed, indicating a clear structural influence on leaching. They found the effect in three contrasting soils.

Not long after the McMahon and Thomas paper was published, another of the Rothamsted experiments set up by Lawes and Gilbert provided strong evidence of mobile and immobile water in the soil. The three drain gauges at Rothamsted, constructed in 1870, were designed to measure the quantity of drainage through 20, 40, or 60 in. of soil (0.5, 1, or 1.5 m), their surface area being 1/1,000 acre (4.047 m²). The gauges would be described as lysimeters today. It says much for the scientific foresight of Lawes and Gilbert that they realized that disturbing the structure of the soil would alter the passage of water through the soil, and they constructed the gauges in a way that minimized soil disturbance. Natural blocks of soil were isolated by brick walls and undermined and supported such that collectors for the drainage could be installed. What Lawes and Gilbert do not seem to have realized is that the air–water interface at the base of the soil would have some effect on the pattern of drainage.

Lawes and Gilbert had in effect constructed an almost ideal facility for an experiment on leaching in structured soil, but that experiment was not to be made for more than 100 years. In 1974, D.A. Rose and J. Bolton applied chloride to the 20- and 60-in. gauges and analyzed the drainage for chloride. Plotting the chloride concentration against cumulative drainage for the 20-in. gauge gave the relation shown in Figure 1 (Addiscott et al., 1978), which bore no resemblance at all to the smooth bell-shaped curves obtained in leaching experiments with sieved soil.

The shape of the relation was interpreted by these authors as depending on the changing distribution of chloride within the soil profile and the retention of either chloride or water containing little chloride in the immobile phase. (The term phase is used for convenience and not with the specific meaning given to it by Willard Gibbs.) When most of the chloride was still in the upper part of the profile, large rainfall events tended to cause large concentrations of chloride to “shoot through” into the drainage via the mobile phase. Re-equilibration in the lower part of the profile brings the concentration in the mobile phase back toward the previous concentration in the immobile phase, so that a subsequent small rainfall causes drainage with a small chloride concentration. The situation is reversed when the bulk of the chloride has moved to the lower part of the profile, so that small amounts of rain after large ones give small peaks during the overall decline. In the left-hand side of the diagram, the bulk of the chloride is in the upper part of the profile, whereas in the right-hand side it is in the lower part. Figure 1 thus

Leaching of Chemicals in Relation to Soil Structure,
Figure 1 Relationship between chloride concentration and cumulative drainage in the 20-in. drain gauge. *Solid line:* Measured. *Broken line:* Simulated. Note: By the time drainage had ceased, only 79.5% of the applied chloride had emerged, so the simulation assumes that only 79.5% was applied. (Adapted from Addiscott et al., 1978, Figure 2. Reproduced with the permission of the Ann Arbor Press.)

shows very clearly the kind of effect soil structure can have on leaching.

The Broken line in Figure 1 shows a simulation of the data with Addiscott's (1977) SL3 model. This was a simple layer model in which each layer had a mobile and an immobile phase and it included a routine that enabled incoming rainfall to displace the mobile water down through more than one layer according to the amount of rain. Thus, a 20-mm rainfall event could possibly move mobile water down five or more layers, which would have been about half the depth of the gauge. The fairly good fit of the simulation to the data suggests that the interpretation of the data in the previous paragraph is broadly correct. There can be no doubt that the soil in the drain gauge contains both mobile and immobile water. In fact most soils do.

The relation for the 60-in. drain gauge (not shown here) is even further removed from the bell-shaped leaching curve, with more extreme peaks and troughs. This is because the soil between 20 and 60 in. largely comprises what Lawes and Gilbert called "a rather stiff clay." Water and solute movement through heavy clay soils occurs mainly through cracks and other macro-pores, with little or none passing through the clay matrix. The problem is exacerbated in some clays by the clay-absorbing water and swelling in consequence, thereby diminishing the

water pathways. One consequence of this kind of flow is that the mobile water interacts with only a small proportion of the clay matrix.

Modeling the effects of soil structure on leaching

The SL3 model outlined above can be described as a functional model (Addiscott and Wagenet, 1985). This implies that it incorporates a simplified treatment of the leaching process and makes no claim to fundamentality. In particular, it does not incorporate the convection-dispersion equation (e.g., Wagenet, 1983) in any form. Another simple approach to nonuniform solute displacement is that of Thomas et al. (1978), which uses chromatography theory.

Models based on the convection-dispersion equation are usually described as mechanistic. The first mechanistic approach to leaching in aggregated media was probably that of Passioura (1971), but the best-known mechanistic mobile/immobile leaching model is that of van Genuchten and Wierenga (1976). Indeed, this is probably the most widely known leaching model of all.

Beven and Germann (1981, 1982) were among the first to take up the challenge of modeling solute leaching in heavy clay soils with cracks or macro-pores. Jarvis and Leeds-Harrison (1987) modeled water flow in such soils and their model was adapted to include solutes (Jarvis, 1989; Matthews et al., 1997).

Movement of solutes between the mobile and immobile phases

Most solute movement between the mobile and immobile phases occurs by diffusion. But when water is imbibed by a dry ped in the immobile phase, solutes may be drawn in too. Similarly, solute could be lost from the immobile phase if an oversaturated ped released water and solute into the mobile phase. Nondiffusional movement of this kind between the phases is not discussed further here.

Diffusion

Diffusion of a solute can be measured or modeled most easily when it occurs to or from a sphere or other regular shape immersed in a fixed volume of solution that is not subject to any inputs or removals of the solute. The mathematics of the process is well established (Crank, 1956), but the necessary boundary conditions can only be realized in laboratory experiments. Rao et al. (1980a) made some interesting experiments with porous spheres and successfully simulated the results. They also incorporated their approach into a transport model (Rao et al., 1980b). But one aspect of their diffusion work points to a more general problem. They had to take very small samples of the solution bathing the porous spheres to avoid altering its volume and thence the boundary conditions. The general problem thus highlighted is that the boundary conditions necessary for the application of diffusion theory are virtually never found in the soil. The soil aggregates are neither regular in shape nor uniform in size, and whenever there is an appreciable amount of rain the

water bathing them undergoes a change in concentration, thereby disrupting the diffusion gradient.

Addiscott (1982) avoided some of these problems by developing a simple model for cubic aggregates that could accommodate aggregates of differing sizes in the batch studied as well as changes in the volume or concentration of the bathing solution, but this approach was not mathematically exact. This diffusion model was incorporated in the PEDAL leaching model (Addiscott, 1984).

Diffusion influences leaching by delaying the movement of solute to the surface of the aggregate, where it is vulnerable to leaching and this characteristic is sometimes described as "holdback." Holdback can also be seen as protecting solute-free water against invading solute.

Properties of the aggregates or peds that affect leaching by affecting holdback from diffusion

The property that most determines holdback is the size of the aggregates. According to diffusion theory, the holdback will be proportional to the square of the aggregate radius and, in practice, small aggregates give little holdback. Addiscott et al. (1983) measured diffusion of nitrate from aggregates ranging in size from 0.5–1 mm to 4–5 mm diameter and found in the largest of these categories that it took only 1,600 s, less than half an hour for 93% of the maximum possible diffusion to occur. A theoretical study on cubic aggregates using the PEDAL model (Addiscott, 1984) suggested that aggregates or peds needed to have a side length of at least 15 mm to give any appreciable amount of holdback against leaching. The pattern of rainfall had some influence on this result.

Where there is a distribution of aggregate sizes, the smallest aggregates will release the solute they contain fastest, thereby changing the diffusion gradient for larger aggregates. This implies that the nature of the distribution should be a consideration. As soil aggregates are often produced by a shattering process, their size distribution is likely to be log normal (Epstein, 1948). The PEDAL model suggested that there were appreciable differences in the pattern of leaching from uniform and normally and log-normally distributed aggregates. These patterns were themselves influenced by the pattern of rainfall.

Diffusion in perspective

There can be no doubt that diffusion plays a part in the movement of solutes between the mobile and immobile phases. However, it seems likely that the soil aggregates need to be about 15 mm in size for diffusion to provide appreciable holdback. It is worth noting that neither Addiscott's (1977) SL3 model, which produced the simulation shown in Figure 1 nor the widely used model of van Genuchten and Wierenga (1976) included an explicit treatment of diffusion between the phases. The importance of one factor, however, is emphasized by both the shape of Figure 1 and the simulations with the PEDAL model, and that factor is the pattern of rainfall.

Summary

All soils contain, to a greater or lesser extent, mobile and immobile categories of water. Clay soils show this distinction most because they tend to have the most clearly defined structure. Crumbs, peds, or other aggregates hold back solute against leaching because of the time solute takes to diffuse from the aggregates into the mobile water surrounding them. The involvement of diffusion suggests that the size distribution of the aggregates is an issue, but measurements and modeling studies suggest that aggregate size only matters when it is greater than 15 mm. The pattern of rainfall is more important. At least two computer models for leaching in soils use a "hold-back factor" rather than modeling diffusion explicitly.

LIGHT INTERCEPTION BY PLANT CANOPIES

Pierre Dutilleul
 Department of Plant Science, McGill University,
 Macdonald Campus, Ste-Anne-de-Bellevue, QC, Canada

Synonyms

Light attenuation within the leaf canopy

Definition

Beyond the simple fact that photons hit leaves, several processes must be distinguished in the interception of light

by plant canopies. Some of these processes are established before the interception itself. One is related to the spatial distribution of leaves in the air: (1) whether they are positioned horizontally or vertically, depending on the time of day and the day of the year, (2) whether they are located in the upper layer of the canopy or a lower one, and (3) whether they are small or large in size. Another is of genetic or evolutionary nature and explains why subordinate species are adapted to irradiances lower than the dominant species. A second set of processes become involved after light interception by the leaf canopy has started. Light and carbon dioxide (CO_2) are the major inputs of photosynthesis, which is basically performed at the single leaf level in higher plants. While growing, plants thus contribute to recycling of atmospheric CO_2 .

Light interception by plant canopies can be described at two levels (single leaf, canopy) and from various perspectives (physical, mathematical, statistical).

Single leaf level: Ordinarily (in C_3 plants, where CO_2 is fixed by the enzyme RuBisCo), photosynthesis is performed in the mesophyll cells, which are directly exposed to air spaces inside the leaf, and gas exchange takes place through the stomata, which are pores found in the leaf and stem epidermis.

Canopy level: Treating the canopy as two populations of leaves, sunlit and shaded, and calculating the mean irradiance of these two populations and the corresponding leaf areas provides a canopy model equation in the form of a weighted sum (Norman, 1980). The proportion of sunlit and shaded leaves is determined by the canopy extinction coefficient and the solar zenith angle.

Physical: Average penetration of light through a plant canopy is expected to decrease exponentially with decreasing height following the Beer–Lambert law, which assumes that the plant canopy is a uniform absorber of light in any horizontal layer (Monsi and Saeki, 1953). Hirose (2005) reviews extensions in which the notions of direct versus diffuse light are defined; this has links with Norman's sunlit and shaded leaves.

Mathematical: Fractals possess a non-integer dimension and are characterized by structural similarity at all scales. Fractal geometry elements were applied to study branching pattern structure. In particular, the application of the Beer–Lambert law for light interception by a plant canopy is improved by inclusion of the fractal dimension estimated from the photograph of a leafless plant (Foroutan-pour et al., 2001).

Statistical: With imaging technologies such as computed tomography (CT) scanning, it is possible to collect three-dimensional (3-D) spatial data on developing plant canopies and rebuild them, with leaves distinct from branches, on a computer (Dutilleul et al., 2005). The strong correlation between light interception and the fractal dimension of skeletonized 3-D images of branching patterns constructed from CT scanning data shows that such data contain fundamental information about canopy architecture geometry (Dutilleul et al., 2008).

LIMING, EFFECTS ON SOIL PROPERTIES

Tadeusz Filipek

Department of Agricultural and Environmental Chemistry, University of Life Sciences, Lublin, Poland

Definition

Liming is the application of mineral calcium and magnesium compounds, mainly carbonates, oxides, hydroxides, or a mixture of them and, more rarely, silicates into acidic soils to decrease the concentration of protons (McLean, 1971; Miller et al., 1995). To be effective, a liming material must displace hydrogen, aluminum, and manganese ions from exchange sites of soil colloids and then neutralize H^+ and precipitate Al^{3+} and Mn^{2+} in soil solution (Smallidge et al., 1993; Filipek, 1994; Barak et al., 1997).

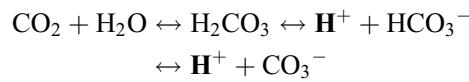

Soil acidification

Acidification of soil is a natural process, one that has a major influence on soil properties and plant growth. During soil acidification, cations of calcium, magnesium, potassium, and sodium are leached out with rainwater and

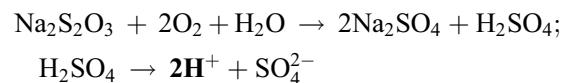

replaced by hydrogen and aluminum. Increasing soil acidity makes some nutrients less readily available, and aluminum and manganese more mobile and toxic. Soils are acidic not only due to natural causes but also due to man-made causes of acidification (Robson, 1989; Dechnik and Kaczor, 1994; Pakpe and Papen, 1998; Filipek et al., 2003; Skowrońska and Filipek, 2007).

Natural causes of acidification

- Leaching of bases (Ca^{2+} , Mg^{2+} , K^+ , Na^+) out of root zone (in humid climate), which intensifies with increasing precipitation and concentration of nitrates as well as chlorides in soil solution; sites of displaced bases are taken up by hydrogen and aluminum ions.
- Organic and inorganic acids formed during decomposition of soil organic matter, plant residues, and soil biota:

- Plant removal of bases from soil and excretion of H^+ to maintain cation ↔ anion balance within the plant
- Microbial and chemical oxidation processes of C, S, N compounds

- Hydrolysis of aluminum salts as follows:

Man-made causes of acidification

- Acid precipitation as the effect of gaseous emissions (mainly SO_2 , NO_x) originating from fossil fuel combustion in power plants, industry, and motor vehicles, which return to the Earth's surface as sulfuric and nitric acids as follows:

- Application of ammonium-based fertilizers contributed to acidity since living organisms release H^+ balancing NH_4^+ cation that is taken up and a two-step (*Nitrosomonas*, *Nitrobacter*) nitrification process generates protons as follows:

Problems of very acidic soils concern aluminum toxicity to plant roots, manganese toxicity to plants, calcium and magnesium deficiency, immobilization of phosphorus and molybdenum by mobile Fe and Al, low soil microbial activity, and reduced nitrogen transformation and fixation (Persson, 1988; Robson, 1989; Filipek, 1994; Barak et al., 1997).

Limes

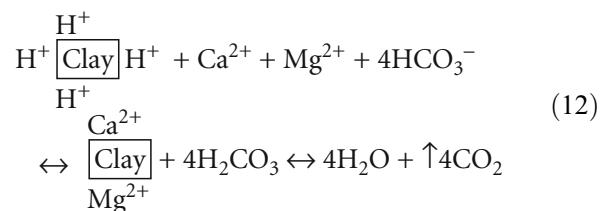

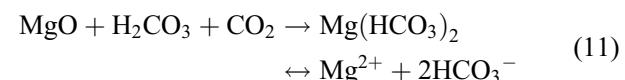

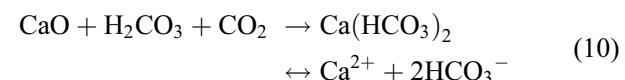

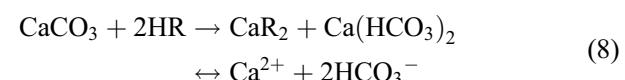

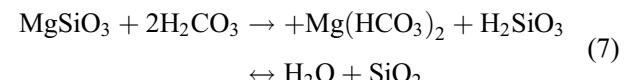

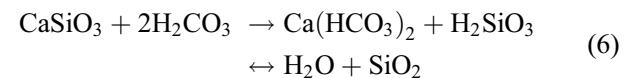

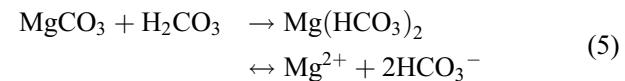

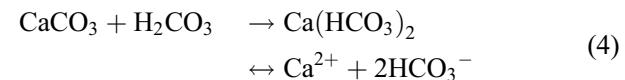

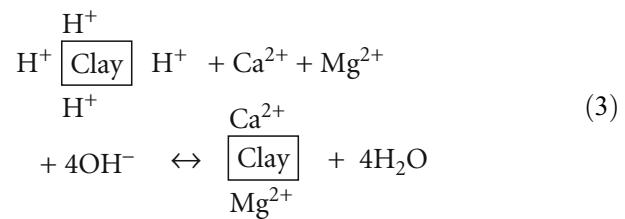

Commonly used materials to raise soil pH are calcitic lime – $CaCO_3$, dolomitic lime – $CaCO_3 \cdot MgCO_3$, manufacturing process products – CaO , MgO , $Ca(OH)_2$, $Mg(OH)_2$, and by-products containing oxides, hydroxides, carbonates, and silicates of Ca, Mg, K, and Na (Erland and Söderström, 1991; Belkacem and Nys, 1995). The quality of liming material is determined by two characteristics: the neutralizing value and fineness (Table 1). The first determines the total power of neutralizing in comparison to pure $CaCO_3$ taken as 1.00 and the second influences the rate of dissolution and neutralization. The fineness of lime determines the efficiency of soil \leftrightarrow lime reactions and, to a large extent, the rate of short-time neutralization.

Liming, Effects on Soil Properties, Table 1 Basic characteristics of limes

Liming material	Neutralizing power expressed as CaO (%)	Relative neutralizing value rate (NV)
Pure $CaCO_3$	56	1.00
Pure CaO	100	1.78
Pure $Ca(OH)_2$	76	1.35
Pure MgO	140	2.50
Pure $MgCO_3$	67	1.20
Pure $CaSiO_3$	48	0.86
Calcareous lime $CaCO_3$	40–56	0.71–1.00
Dolomitic lime $CaCO_3 \cdot MgCO_3$	50–62	0.89–1.11
Burned lime CaO	75–100	1.34–1.78
Hydrated lime, $Ca(OH)_2$	66–80	1.18–1.43
Marls $CaCO_3$ + clay + impurities	28–45	0.50–0.80
Basic slag (oxides, carbonates, silicates)	28–40	0.50–0.71
Wood ash (oxides, carbonates, silicates)	22–40	0.39–0.71
By-products (oxides, carbonates, silicates)	Variable	

Neutralization processes

Calcium or magnesium oxides, carbonates, and silicates applied into the soil reduce soil acidity (increase pH) by changing some of the hydrogen ions into water and carbon dioxide (CO_2) volatilizing into the atmosphere. A Ca^{2+} ion from the lime replaces two H^+ ions from the soil cation exchange sites. The carbon dioxide (CO_2) can react with water to form carbonate acid (H_2CO_3). Protons are neutralized by OH^- and H_2O is formed as follows:

Effect of liming on soil

Liming increases soil pH and removes toxicities of aluminum and manganese associated with acidity, and amends soil physical, physicochemical, chemical, and biological properties (Brown et al., 1959; McLean, 1971; Edmeades et al., 1981; Costa et al., 2004). Calcium cations coagulate soil organic and mineral colloids and can improve soil structure by binding together sand, silt, and clay particles into units called aggregates. Stable aggregates enhance infiltration during heavy rain. On the other hand, liming increases the resistance of the soil to pulverizing when cultivated. Aggregate structure affects other soil physical, physicochemical, and biochemical processes.

Liming affects cation exchange capacity (CEC), which depends on the amount and kind of colloids and base saturation. In general, the more the amount of clay, organic matter, and base cations present, the higher the CEC. Another lime and CEC-related property is soil buffer capacity, that is, the resistance of soil to changes in pH. A high percentage of base saturation of soil (%BS) makes soil more resistant to pH decrease.

Liming promotes the decomposition (mineralization) of soil organic matter (SOM), and consequently, it increases the mobilization of plant nutrients from the organic matter and also decreases the content of organic carbon. The increase in soil pH affects the solubility of most plant nutrients, making most of them more available (N, P, S, Mo, K, Mg, Ca) to the plant and some, less available (B, Mn, Cu, Zn).

In addition, liming a soil can affect its microbial properties. In general, increasing calcium content and pH of the soil stimulate microbial growth and influence nutrient availability and nitrogen fixation. Conversely, the increased microbial growth may result in more rapid loss of soil organic matter, which is usually viewed negatively.

The most important problems of overliming, especially tropical soils, is more physical than chemical because of soil permeability. The structure in many tropical soils is stabilized by iron and aluminum oxides binding particles together with the structure, reaching a high level of stability, accounting for the high infiltration rates, and consequent rapid leaching of bases from these soils. Adding too much lime and a high increase in soil pH can elevate molybdenum content to toxic levels. In addition, plants can become deficient in nutrients, such as P, Mg, Zn, Cu, B. This is both a result of these nutrients being less soluble at higher pH levels and decreased acid weathering of the few nutrient-containing minerals still in the soil.

Conclusions

Because of natural and man-made causes of acidification, a great percentage of natural and agriecosystem soils are acidic. Liming of acidic soils is one of the most effective methods of nutrient, soil, and environment management. The application of mineral calcium and magnesium compounds into acidic soils decreases the concentration of protons. It also removes toxicities of aluminum and

manganese, coagulates soil colloids, and improves soil structure. Liming increases cation exchange capacity (CEC) and base saturation of soil (%BS). The application of Ca and Mg compounds into soil affects mobilization/immobilization of elements and improves nutrient management in ecosystems. It makes soil more resistant to degradation and pH decrease.

LYSIMETERS: A TOOL FOR MEASUREMENTS OF SOIL FLUXES

Johann Fank
 Department of Water Resources Management
 RESOURCES - Institute of Water, Energy, and
 Sustainability, Joanneum Research, Graz, Styria, Austria

Definition

The term *lysimeter* is a combination of the Greek words “*lusis*” meaning solution and “*metron*” meaning measure. A lysimeter is a device that isolates a volume of soil or earth between the soil surface and a given depth and includes a percolating water sampling system at its base. In general, a lysimeter consists of a container filled with soil and a mechanism to collect and quantify the amount of water that accumulates at the bottom (DVWK, 1980). The DIN 4049–3 (1994) (German Industrial Standard) defines a lysimeter as a device to collect seepage water for mass and solute balances in relation to soil, parent rock, vegetation, local climate, and other site conditions.

Lysimeters have a long history of development, and different designs have been adopted. Therefore, an exact definition of a lysimeter cannot be provided.

Introduction

According to the DVWK (Deutscher Verband für Wasserwirtschaft und Kulturbau) in 1980, the explanation and the use of lysimeters may be extended as follows:

- Soil is hydrologically isolated from the surrounding soil.
- Lysimeters are containers filled with disturbed (= artificially filled) or undisturbed (= monolithic) bare soil or soil covered with natural or cultivated vegetation.
- Seepage water is measured directly; vertical water movement is also to be determined.
- Percolating water is collected either gravimetrically (= gravitation lysimeter) or through suction cups/a suction plate with a negative soil water pressure head, identical to that in the field next to the lysimeter (= suction lysimeter).
- An artificial groundwater level can be simulated.
- Lysimeters are either weighable or non-weighable; weighable lysimeters provide information about the change of water storage for any time period; non-weighable lysimeters collect only the water percolating from the soil column.

Accurate crop evapotranspiration (ET) data are required to improve agricultural water resources management. Lysimeters are still considered to be the standard method to directly measure ET. Non-weighable lysimeters are used to determine ET as a residual by measuring all other components of the soil water balance, including water inputs (rain and irrigation), outputs (drainage and runoff), and change in soil water storage (Garcia et al., 2004). If the lysimeters are weighable, the current evapotranspiration can be deduced from their weight change (Young et al., 1996). The ET calculated from the mass changes, however, needs to be adjusted to account for mass changes caused by factors other than ET, such as drainage or water input (Malone et al., 2000). Meissner et al. (2007) have shown that, beside standard Lysimeter data evaluation, precise measurement of dew, fog, and rime is possible using a high-precision gravitation lysimeter. Due to these characteristics, lysimeters are an excellent tool to derive or calibrate water and solute transport models (Wriedt, 2004) for unsaturated zone simulation.

Lysimeters have been designed in different sizes, which vary significantly, and shapes including square, circular, and rectangular. The shape and the size are chosen according to the intended use and the required or desired resolution. According to method in which the soil inside the lysimeter is collected, lysimeters can be monolithic, repacked (or reconstructed), or a combination of both (Payero and Irmak, 2008).

Accurate information about the soil water balance is needed to quantify solute transfer within the unsaturated

zone. A large weighable lysimeter is the best method for obtaining reliable data about seepage-water quantity and quality. However, this method involves significant investment and additional expenses for maintenance (Meissner et al., 2007). The evaluation of lysimeter data allows a much more reliable calculation of the solute load carried toward the groundwater than any other method (Klocke et al., 1993). However, some shortcomings are assigned to lysimeter measurements, such as the well-known oasis effects, preferential flow paths at the walls of the lysimeter cylinders due to an insufficient fit of soil monoliths inside the lysimeters or the influence of the lower boundary conditions on the outflow rates.

The history of the lysimeter

There have been two distinct but interweaving strands in the use of lysimeters. The history of the lysimeter stems back over almost four centuries to the time of the natural philosophers: the development of our understanding of plant physiology and soil constraints to crop development and the understanding of field and regional hydrology (Goss and Ehlers, 2009). Philipe de la Hire (1640–1718) who was interested in discovering the origin of springs is generally recognized as the instigator of the use of lysimeters for hydrological studies. John Dalton (1766–1844) and Thomas Hoyle built their lysimeter to investigate the evaporative return from land to the atmosphere. In the year 1850, Way reported his fundamental studies on the chemical changes of solutions percolating through soil. He was the first experimenter to carry out extensive lysimeter investigations to clarify the problem of soil fertility. The first lysimeters were constructed in Rothamsted, England (1870), and were designed to retain the natural structure and profile of the soil. John Lawes (1814–1900) applied their monolithic construction to determine the quantity and chemical quality of the deep drainage component of the water balance. Improvements in technology allowed a more exact assessment of changes in the water content of the lysimeter soil by weight. The first weighing lysimeter was put together in Germany (von Seehorst, 1902). Early lysimeter studies did not attempt to differentiate between evaporation from the soil and the water moving from the soil to the atmosphere via the plant transpiration stream. The first systematic investigation of the water requirements of maize took place at the Agricultural Experimental Station of Nebraska. Water use by different crops was studied by Briggs and Shantz at Akron, Colorado, USA, between 1911 and 1913 (Goss and Ehlers, 2009).

In 1940, Kohnke and Dreibelbis conducted a critical review of the literature on lysimeters. They cited 489 findings for the period 1688–1939 and stated that lysimeters had distinct limitations. “But without doubt many questions concerning pedology, soil fertility, and hydrology can be answered by the correct use of lysimeters. Filled-in lysimeters may fulfill useful tasks in fertility investigations if a sound water balance is maintained in the soil; but for pedologic and hydrologic studies carefully designed

monolith lysimeters seem to be indispensable” (Kohnke and Dreibelbis, 1940, p. 30).

The lysimeter facilities at the North Appalachian Experimental Watershed, Coshocton, Ohio were built in 1937 and incorporated many of the essential features for studying the components of the soil water balance. Results for the water balance from the Coshocton lysimeters were compared with those of an adjacent small watershed, and were found to be highly similar (Harrold and Dreibelbis, 1967).

The use of lysimeters of smaller surface area allowed the collection of soil monoliths that could be transported to a central facility, where the weather variables were the same, thereby permitting a greater insight into how the water balance changes over time in different soils (Letcombe Laboratory, Oxfordshire, UK 1973; Brandis, Germany, 1980; German Research Center for Environmental Health, Munich 1996 and others). All the lysimeter installations described above are limited in the fact that agronomic activities associated with soil management (tillage), for example, sowing, crop protection, harvesting, residue management as well as manure management are limited to hand operation. In 1978, a large-scale field lysimeter installation was established in deep clay soil at a field site of Letcombe Laboratory near Faringdon, Oxfordshire, the UK (Cannell et al., 1984).

Lysimeters have been used extensively to determine the crop coefficients of water use, particularly the evapotranspiration relative to a reference crop, or to a standard device for measuring evaporation. In all cases, a key issue is how well the growth and water dynamics associated with the crop in the lysimeter installation accord with those of a crop in the field (Allen et al., 1991).

A survey conducted in 2004 (Lanthaler and Fank, 2005) on lysimeters used in Europe (updated in 2006) found 151 locations in Europe where lysimeter facilities were in operation. The majority of the lysimeter vessels (86.2%) are non-weighable. This strengthens the “disadvantage” of ponderable lysimeters as the weighing equipment is more expensive and in fields, weighable lysimeters are more difficult to use. Approximately 70% of the non-weighable lysimeters are backfilled, whereas 44.4% of all ponderable vessels are filled monolithically. Lysimeters in Europe are predominantly used for agricultural research (approximately 63% of all lysimeters are installed in arable land/field).

Essential concepts and applications

The need for water quality and nutrient management as well as the need for a better understanding of water drainage and chemical leaching through the vadose zone is continuing to grow. Therefore, monitoring and measuring techniques that can determine drainage flux from undisturbed soil profiles is critical for the determination of nutrient budgets and the evaluation of land-use practices on water quality (Masarik et al., 2004). Equilibrium tension lysimeters were developed by Brye et al. (1999) to address the problems associated with zero-tension

lysimeters and fixed-tension lysimeters, and can be installed below a soil profile that is intact. By adjusting lysimeter suction to match soil-water matric potential, equilibrium tension lysimeters maintain an equilibrium between lysimeters and the bulk soil.

The undisturbed extraction of a soil monolith during the filling of a lysimeter vessel is of great importance for all subsequent investigations, especially for establishing flow and transport conditions that mimic natural field conditions. An evaluation of different methods to obtain large undisturbed soil cores is provided by Derby et al. (2002). Substantial progress concerning the collection of cylindrical lysimeter monoliths is achieved by the development of an extraction technology, which cuts the outline of the soil monolith employing a rotary cutting system (Meissner et al., 2007). The new procedure avoids structural damages and substantially reduces the necessary technical expenditure during monolith extraction. The extraction site is only minimally affected, since the force needed to cut the soil monolith is small, due to reduced coat friction.

In connection with the additional recording of the amount of percolating water ($SW [l m^{-2}]$) and precipitation ($P [l m^{-2}]$) a weighing lysimeter permits the quantification of the water balance of the soil column. The change in the amount of water stored in the lysimeter ($\Delta S [l m^{-2}]$) is detected based on measuring the mass change of the soil column. Evapotranspiration ($ET [l m^{-2}]$) can be calculated at any point in time using the water balance equation (Equation 1).

$$ET = P - SW \pm \Delta S \quad (1)$$

If the water balance is calculated correctly, the solute balance can be determined for a defined time interval with sufficient accuracy using Equation 2, where $L (mg m^{-2})$ is equal to the solute load, and C_s represents solute concentration in seepage water ($mg l^{-1}$).

$$L = C_s SW \quad (2)$$

The quantification of soil water balance parameters is hardly possible when using traditional soil hydrological measurement procedures, especially in the event of flooding. Therefore, a weighable outdoor groundwater lysimeter was developed (Bethge-Steffens et al., 2004). This weighable groundwater lysimeter provides the basis for recording the water balance quantities such as precipitation, evapotranspiration, groundwater recharge, capillary rise, and interaction with the watercourse (reflected in the groundwater level). It enables an accurate quantification of the vertical water flow at floodplain sites. The modified water balance equation for groundwater-influenced and temporarily waterlogged sites is

$$P + P_{ond} = ET(R_{out} - R_{in}) \pm \Delta S \quad (3)$$

where $P_{ond} (l m^{-2})$ = surface floodwater, $R_{out} (l m^{-2})$ = groundwater outflow, and $R_{in} (l m^{-2})$ = groundwater inflow (Meissner et al., 2008).

Lysimeters are often located at a special lysimeter station with an access point for functional inspection as well as for the accommodation of measuring, checking, and weighing devices. To reduce costs and secure mobility Meissner et al. (2008) presented a polyethylene lysimeter station as a container, where four lysimeter vessels are located in a clover type arrangement around a central access point.

However there are some arguments against the use of lysimeters for monitoring water balance parameters and measuring solute transport parameters in the soil and unsaturated zone. These include the discussion of some sources of error existing potentially in lysimeter measurements, such as the well-known oasis effects, preferential flow paths at the walls of the lysimeter cylinders due to an insufficient fit of soil monoliths inside the lysimeters or the influence of the lower boundary conditions on the outflow rates. In 2004, monolithic equilibrium tension lysimeters were implemented in the Wagna agricultural test field in southern Austria (Fank and von Unold, 2007). Due to the implementation of the lysimeter directly in the agricultural field, no oasis effect is cognizable. The two scientific field lysimeters (von Unold and Fank, 2008) have a depth of 2 m and a surface area of 1 m². The precision load cells on the concrete fundament measure the lysimeters mass with a resolution of 35 g (0.035 mm water equivalent). The bottom of the lysimeter – the lower boundary condition – is realized as a suction cup rake. The soil water tension measured at 1.8 m below the surface of the undisturbed field is transferred to the suction cups that guarantee the same flow rates in the lysimeter as in the undisturbed soil using an automatically controlled vacuum pump. For tillage purposes, the load cells are lowered to the fundament and the upper ring of the lysimeter is removed. The field and the lysimeter may be cultivated in the same manner as the field. Afterward, the ring is remounted and the lysimeter is lifted onto the load cells. In April 2005, a tracer experiment was performed. Data analysis shows conservative behavior of the bromide. Mass uptake by plants was proportional to the water uptake, and the total mass recovery of bromide was >95%. Based on the evaluation of the tracing experiments, no fringe effects have been found; this finding indicates that the excavation technique done by hand causes no significant disturbance. The comparison of measured soil water parameters between a hydrologic measuring profile close to the lysimeter and the lysimeters monolith have shown that the differences are very small and reflect natural heterogeneity.

Conclusions

Based on the developments of lysimeter techniques – not of too expensive high precision weighable monolithic lysimeters – we get accurately measured water balance and solute transport parameters. Due to these characteristics, lysimeters are an excellent tool to validate the transferability of water and solute transport models, which are

mostly derived on the basis of laboratory experiments for their application on the field scale. Monolithic field lysimeters cover one scale of scientific or applied research working level, which is suited between laboratory scale and field scale. They combine the advantages of true field conditions and laboratory possibilities of varying parameters, handling, and maintenance.

From their inception, lysimeters have allowed the role of the plant in the local hydrological balance to be investigated and established. At the same time, the lysimeter has been a powerful tool in developing a greater understanding of the components of the soil water balance and allowing a detailed quantitative assessment. The ability to integrate information obtained at different levels of investigation, both in terms of scale and intensity, has resulted in a more holistic understanding of soil water dynamics. Lysimeters have allowed the quality of water draining from agricultural land to be determined, and, as exemplified by information from plant nutrient studies, the role of management practices to be evaluated (Goss and Ehlers, 2009).

MACHINE VISION IN AGRICULTURE

John Billingsley
University of Southern Queensland, Toowoomba, QLD, Australia

Definition

Machine vision: Visual data that can be processed by a computer, including monochrome, color and infra red imaging, line or spot perception of brightness and color, time-varying optical signals.

Agriculture: Horticulture, arboriculture and other cropping methods, harvesting, post production inspection and processing, livestock breeding, preparation and slaughter.

Introduction

The combination of low-cost computing power and applications that target its use for entertainment has led to a readily available platform for analyzing vision signals in a variety of ways. Applications are many and various, but some of the most potentially significant ones are found in agriculture.

Sorting by color

For some decades, a simplified form of machine vision has been used for sorting produce (Tao et al., 1995). Tomatoes may be picked green for ripening in the shed. When their color is changing, they ride a conveyor that has pockets for individual fruit. These holders can be tripped by a computer signal, to eject the tomato at one of many packing stations corresponding to the degree of ripeness, as defined by color.

A very similar system is used for grading apples, as seen in [Figures 1 and 2](#).

Fragments of nut shell can be detected when pecan nuts are shelled, once again by detection of the color. Kernels fall through the inspection area at a speed of around one meter per second. In an early system, light that was reflected from the kernel was split between two photocells that detected the intensity of different wavelengths. The ratio enabled color to discriminate between nut and shell. More recent versions incorporate laser scanning. As the nut falls further, a jet of air is switched to deflect any detected shell into a separate bin.

Detection of weeds

Color discrimination can also be used in the field to discriminate between plants and weeds for the application of selective spraying (Åstrand and Baerveldt, 2002; Zhang et al., 2008). It is possible for the color channels of the camera to include infra-red wavelengths, something that can be achieved by removing the infra-red blocking filter from a simple webcam. [Figure 3](#) is a low-resolution frame-grab showing one stage in the detection of a grass-like weed, “panic,” during trials in sugar cane. The computer has marked pixels determined to be “weed” in yellow.

Quality assessment

True machine vision concerns shape information. One example is the assessment of fodder quality. From a web-cam image of a sample handful of hay, the stem-widths can be measured and a histogram displayed. Color can also be determined by comparison of the video signal against that from the image of a calibration card. This makes an objective standard possible, to achieve agreement between vendor and purchaser (Dunn and Billingsley, 2007).

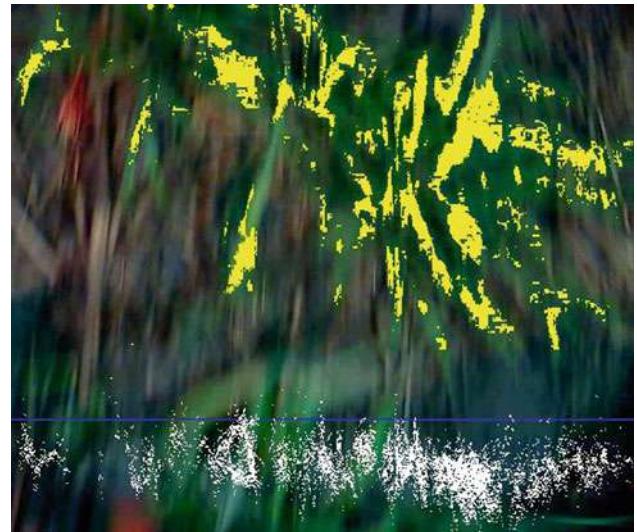

Shape information can also be used to monitor the growth of a crop, measuring stem length between nodes automatically (McCarthy et al., 2008).

Machine Vision in Agriculture, Figure 1 Apples moving towards washing and grading.

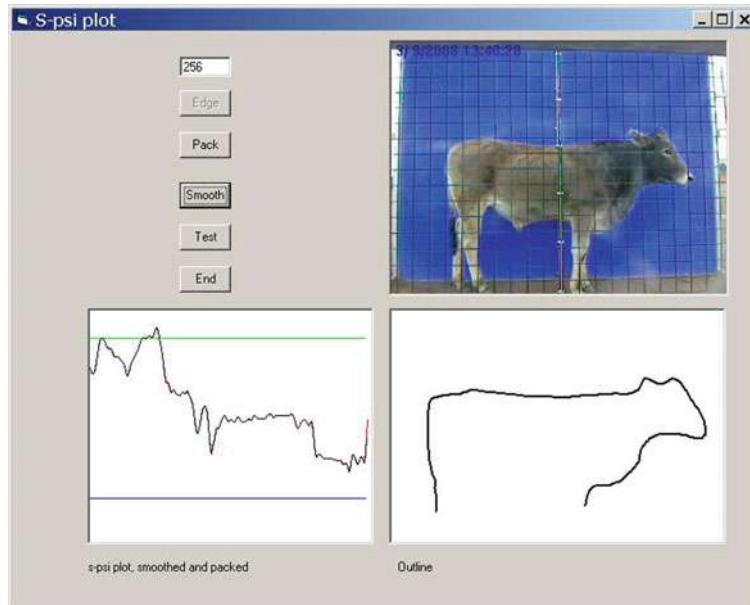

Machine Vision in Agriculture, Figure 2 A conveyor automatically ejects each apple at the correct station.

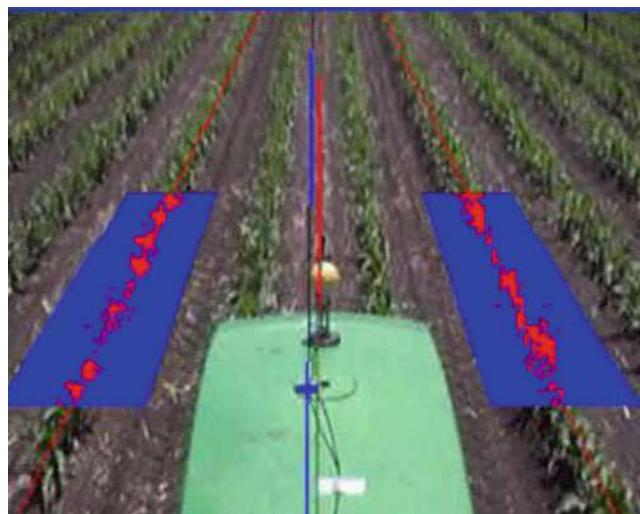

Machine Vision in Agriculture, Figure 3 A frame-grab from the computer-processing of image data to locate weeds.

Livestock identification

A more detailed version of shape information, in the form of an s-psi profile, has been used to discriminate between animals of different species passing a checkpoint while they approach a watering place. Now the image represents the profile of the animal as seen against a background. A blue background simplifies discrimination for producing a silhouette. From this a boundary can be found by edge-tracing, which yields a sequence of incremental

Machine Vision in Agriculture, Figure 4 S-psi plot of the outline of a steer.

Machine Vision in Agriculture, Figure 5 Frame-grab from the video image that is steering a tractor at speed.

vectors that form a “Freeman chain.” These in turn deliver a sequence of tangent angles, to be plotted against the distance travelled around the circumference of the silhouette, as seen in [Figure 4](#).

From the original megabyte image, some 256 bytes of data now define the shape of the animal in view, for correlating against a set of templates to separate sheep from goats or camels from cattle. A gate is then driven to exclude or to draft the animals. This work is being refined to assess the condition of cattle as they pass a point where

their RFID tag can be read, to monitor their progress towards “harvesting.”

Picking

Many attempts have been made over the years to use machine vision to detect and locate fruit for automatic picking. Although positive research results have been reported, operational speeds are generally low and there has been very limited commercial success. It has been suggested that the growing availability of broadband communication can make it possible for “armchair pickers” to tele-operate picking machinery, with the aid of real-time imaging.

Machine guidance

Vision guidance has been applied with great technical success to tractors (Billingsley and Schoenfisch, [1996](#)). Within each received image, the software locates the rows of crop and assesses the control action needed to bring the vehicle back on course. The algorithms were developed in the early 1990s, when computing power was much less plentiful. The result is a robust strategy that can time-share with GPS analysis and other signal processing.

Within the field of view, “keyholes” are defined that will each contain the image of a single row. Within each keyhole, plant images in the form of green pixels are regarded as data points through which to construct a regression line. For the next image, the keyholes are moved to be centered on these regression lines. The set of two or three keyholes move at once to indicate the vanishing point, from which the heading error and the lateral displacement can be deduced. These signals then give a steering command to bring the tractor back on track, to

an accuracy of a centimeter or two. A frame-grab from the steering software is shown in [Figure 5](#).

The method is greatly superior to the use of GPS, satellite navigation, since an operation such as cultivating will cut the ground at a point relative to the actual location of the plants, not relative to where the plants are supposed to have been planted.

It is unfortunate that marketing of the system started when enthusiasm for GPS was reaching fever pitch and success has passed it by. Nevertheless research on vision guidance is widespread (Gottschalk et al., [2008](#)).

Conclusions

As sensors and computing power become ever cheaper, the opportunity for farm robotics increases. It would be unwise to make a large machine autonomous, not least for insurance against the damage it might cause. Small robot machines, however, can already be equipped with vision, navigation, detection and communication systems at a very modest price. We may very soon see teams of “Autonomous Robot Farmhands” at work in the field.

MAGNETIC PROPERTIES OF SOILS

Andrey Alekseev

Laboratory Geochemistry and Soil Mineralogy, Institute of Physicochemical and Biological Problems of Soil Science, Russian Academy of Sciences, Pushchino, Moscow Region, Russia

Synonyms

Environmental magnetism; Soil magnetism

Definition

Magnetic properties of soils are dominantly controlled by the presence, volumetric abundance, and oxidation state of iron in soils. Different types of Fe oxides, Fe–Ti oxides, and Fe sulfides are the predominant causes of magnetic soil characteristics. The concentration of magnetic Fe oxides in soils is affected by the parent material and soil-forming factors and processes.

Introduction

Magnetism is a fundamental property of all natural materials. The most important kinds of magnetic properties are those called diamagnetism, paramagnetism, ferromagnetism, ferrimagnetism, and superparamagnetism. The magnetic properties of soils are a subject of investigation started first more than 50 years ago (Le Borgne, [1955](#)). Magnetism of soils have traditionally been investigated in the environmental science and geophysics communities to indicate soil development, paleosols and climate change, pollution, and as tools for archaeological mapping and prospecting (Thompson and Oldfield, [1986](#); Maher and Thompson, [1999](#); Evans and Heller, [2003](#); Maher, [2008](#)).

Soil magnetics

The magnetic characteristics of soil and sediments reflect the amount and quality of ferruginous minerals they contain and are connected with their content, mineralogy, and the grain size. The presence of Fe oxides in different forms and quantities is the predominant cause of the magnetic properties of soils. Iron oxide minerals can be both pedogenic (product of soil formation) and lithogenic (unweathered minerals from the parent material) in origin. Iron is the most common element in the crust of the earth. Iron is not only essential to plant development, but it also participates in the formation of complexes of clay and organic matter, which in turn influence soil structure and fertility. Iron-containing minerals can be found in igneous, metamorphic, and sedimentary rocks. As a rule, clay minerals possess paramagnetic properties. The most widespread minerals of sedimentary rocks and soils quartz, carbonates, feldspars are diamagnetic or weak paramagnetic and also do not bring the appreciable contribution to the magnetic behavior of soils. Hydrated Fe oxides like goethite, which is the most abundant Fe oxide in soils around the world, ferrihydrite, and lepidocrocite play

a minor role in determining the magnetic character of soils. The concentration of (magnetic) Fe oxides in soils is affected by the parent material, soil age, soil-forming processes, biological activity, and soil temperature (Singer et al., 1996). In soils, primary ferromagnetic minerals of detrital origin derive from the disintegration of the bedrock and they reflect its mineralogy. Secondary minerals are formed through complex chemical and biological processes, which also depend on climate and the soil pH, humidity, and organic matter content. These processes operate not only on primary ferromagnetic minerals, but also on the elementary iron contained in many silicates. Depending on the parent material, the physicochemical conditions and the pedogenetic processes, goethite, hematite, maghemite, or magnetite can be formed. Mineralogically, by soil magnetism point of view, the most important ingredients are magnetite (Fe_3O_4), maghemite ($\gamma\text{-Fe}_2\text{O}_3$), and hematite ($\alpha\text{-Fe}_2\text{O}_3$). The main properties and pathway of formation of these minerals are discussed in many books and review papers (Thompson and Oldfield, 1986; Cornell and Schwertmann, 2003; Mullins, 1977; Schwertmann, 1988). The nature, content, and grain size of each magnetic phase reflect the physicochemical conditions of the soil. For example, magnetic susceptibility enhancement in topsoil is found in most temperate soils (Le Borgne, 1955; Babanin, 1973; Maher, 1986; Alekseev et al., 1988), except in acidic, podzolic, and waterlogged conditions (Maher, 1998); it can be related to soil conditions at the surface. Magnetic minerals, which occur in very small concentration in most soils, are as fingerprints of pedological processes. At present, several theories are put forward to explain the concentration and distributions of the ferrimagnetic minerals in soils: burning, biotic transformation of hydrous ferric oxides; abiotic transformation of hydrous ferric oxides; residual primary minerals; magnetotactic bacteria; anaerobic dissimilatory bacteria; and atmospheric contamination and pollution. Environmental magnetic studies have revealed that a range of ferrimagnetic minerals can be formed at Earth surface temperatures and pressures within soils and sediments, rather than merely "inherited" from disintegration and weathering of magnetic mineral-bearing igneous rocks. Notably, trace concentrations of nanoscale magnetite can be precipitated *in situ* in the soil matrix of well-drained, generally oxidizing, near-neutral soils (Maher, 2008). The generally accepted view is that most soils produce secondary nanoscale iron oxides magnetite/maghemite in surface horizons (Maher 1998; Alekseev et al., 2003; Maher et al., 2003; Blundell et al., 2009). The magnetic research techniques are express which allow producing the mass analysis in comparison with other methods. Magnetic methods have many advantages over other techniques: nearly all rocks and soils contain magnetic iron oxides/sulfides, sample preparation and measurement is quick, easy and generally nondestructive, and the methods are sensitive to both concentration and grain-size – particularly for ultrafine grains, which can be difficult to detect by other means.

Magnetic parameter and instrumentation

To describe magnetic properties of soil, different types of magnetization are commonly used.

Magnetic susceptibility – when a low-intensity magnetic field is applied to a material, the net magnetic moment (magnetization, M) is proportional to the applied field strength (H). Therefore, the low-field magnetic susceptibility, which is defined as M/H and expressed per unit volume (κ) or per unit mass (χ), is a material-specific property. Magnetic susceptibility (χ) reflects the total concentration of ferrimagnetic or total concentration of paramagnetic minerals and antiferromagnetic with low content of ferromagnetics. A magnetic susceptibility (χ) is one of most simply obtained magnetization characteristics and rather large set of the data on the application of this parameter for the problems of soil science exists.

Remanent magnetization occurs within ferromagnetic and ferrimagnetic minerals and exists in the absence of an applied field.

Viscous remanent magnetization refers to the delay of the secondary magnetic field relative to the primary magnetic field and has been linked to the presence of superparamagnetic grains of iron oxides.

Four laboratory instruments make up the basic requirements for magnetic characterization of environmental samples and soils: a susceptibility bridge (preferably dual frequency); a magnetometer; magnetizing coils; and a demagnetizer. These magnetic techniques are nondestructive and sensitive to trace amounts of magnetic minerals (Thompson and Oldfield, 1986; Maher and Thompson, 1999; Maher, 2008).

The magnetic properties of soils typically have been studied using the following equipment as example: – magnetic susceptibility (χ) – MS 2 Bartington or Kappameter KT-5-9 (field measurements), Kappabridges (2–4) (laboratory measurements); frequency – dependent magnetic susceptibility (χ_{fd}) – MS 2 Bartington; curves of saturation magnetizations (IRM) in magnetic fields with strength up to 1–4 T – Molspin magnetometer and Molspin pulse magnetizer; anhysteretic remanent magnetization (ARM) – complex of the equipment included Molspin demagnetizer and Molspin magnetometer; complete magnetization curves (hysteresis curve) – vibrating sample magnetometer-VSM Molspin (Table 1).

Soil magnetism applications

Present instruments and methods enable very sensitive determination of low concentrations of strong ferrimagnetic minerals in soils. Possible mechanisms of magnetic enhancement of soils due to increased concentrations of secondary ferrimagnetic minerals are discussed above. Herewith, we will outline some examples of application of magnetic study of the soils. Magnetic properties measurements of soils are mostly used for three purposes: to read the climatic signal recorded by palaeosols, to identify pollution in soils, and as tools for archaeological mapping and prospecting.

Magnetic Properties of Soils, Table 1 Magnetic parameters and their interpretation (Thompson and Oldfield, 1986; Maher and Thompson, 1999; Evans and Heller, 2003; Maher, 2008)

χ ($10^{-8} \text{ m}^3 \text{ kg}^{-1}$)	Magnetic susceptibility (χ or χ_{lf}) – total concentration of ferrimagnetic or total concentration of paramagnetic minerals and antiferromagnetic by low content of ferrimagnetic
χ_{fd} %	Frequency-dependent magnetic susceptibility. Is calculated on a difference of measurements at different frequencies (for MS2 460 Hz and 4,600 Hz χ_{hf} accordingly): $(\chi_{fd})\% = (\chi_{lf} - \chi_{hf})/\chi_{lf} \times 100$
χ_{ARM} ($10^{-8} \text{ m}^3 \text{ kg}^{-1}$)	Reflects the presence of ultrafine ferrimagnetic grains. Is especially sensitive to the size of particles in an interval 0.015–0.025 μm
$\chi_{ARM/SIRM}$ (m A^{-1})	Susceptibility of anhysteretic remanent magnetization (ARM). Maximum intensity of the alternating field used in the instrument Molspin demagnetizer for magnetization –100 mT, with step of decrease of a magnetic field for each cycle 0.016 mT, strength of the constant biasing field –0.08 mT. It is high sensitive to ferrimagnetic with the size of particles in an interval 0.02–0.4 μm . Reflects the presence of fine-grained magnetite (stable single domain grains)
$\text{IRM}_{100\text{mT}}/\text{SIRM}$	The ratio is sensitive to grain-size changes of ferrimagnetics. For superparamagnetic particles the significances in an interval –0.5 to 1.5 are characteristic, for stable single domain particles 1.8–2.0
$\text{SIRM-IRM}_{300\text{mT}}$	Allows evaluating the contents of ferrimagnets (magnetite, maghemite). As the majority of ferrimagnetic is fully saturated in fields of 100 mT
	Can be used for approximating the total concentration of high coercivity minerals (hematite + goethite)
	Remanence acquired in a field of 1 T is referred as SIRM (SIRM = $\text{IRM}_{1,000\text{mT}}$). It is necessary to note that the full saturation for antiferromagnetic phases can be reached at fields strength above 4 T

As example, recently, a quantitative, soil magnetism-based climofunction has been established for the area of the Russian steppe (Maher et al., 2002; Maher et al., 2003). A similar correlation between rainfall and magnetic susceptibility was previously obtained for the Chinese Loess Plateau and explained as a result of pedogenic formation of magnetite and maghemite via oxidation/reduction processes through soil wetness events (Maher and Thompson, 1999).

The pedogenic magnetic response of these well-drained, near-neutral, Russian steppe soils appears strongly correlated with that of the similarly well-drained and buffered modern soils across the Chinese Loess Plateau (and across the wider Northern Hemisphere temperate zone). Such correlation suggests that the rainfall component of the climate system is a key influence on soil magnetic properties in both these regions. This direct coupling of the soil magnetism of modern soils with present-day climate substantiates the use of magnetic climofunctions to make quantitative estimates of past rainfall variations from the magnetic properties of buried palaeosols for both the Russian steppe and the Chinese Loess Plateau.

Applying a soil magnetism climofunction, calculated from a modern-day soil training set, to each set of buried soils enables quantitative estimation of precipitation at each time step when soil burial occurred as for Holocene paleosols or loess-paleosols sequences of Pleistocene (Alekseeva et al., 2007).

Atmospherically deposited ferrimagnetic particles of anthropogenic origin also contribute a great deal to the concentration-dependent magnetic properties of top soils, such as low-field magnetic susceptibility. The highest concentration of anthropogenic ferrimagnetic particles is usually found in humic layers (e.g., Strzyszcz et al., 1996). Practically all industrial fly ashes contain a significant fraction of ferromagnetic particles, the most important sources being fly ashes produced during combustion of fossil fuel (Hanesch and Scholger, 2002; Kapička et al., 2003). Other sources, such as iron and steel works, cement

works; public boilers and road traffic also contribute to contamination by anthropogenic ferrimagnetics (Heller et al., 1998; Scholger, 1998; Hoffmann et al., 1999). In contrast to particles of pedogenic origin, anthropogenic ferrimagnetics are characterized by specific morphology and distinct magnetic properties. They are often observed in the form of spherules, with the magnetic phase frequently sintered on aluminum silicates or amorphous silica. Prevailing ferrimagnetic phases are Fe oxides, namely magnetite and maghemite, with Fe ions very often substituted by other cations (Strzyszcz et al., 1996). Application of the comparatively simple technique of measuring magnetic susceptibility enables delineation of areas with concentrations of deposited anthropogenic ferrimagnetics significantly above background values. Magnetic mapping thus represents a rapid, sensitive, and cheap tool for targeting the areas of interest. These studies showed that in polluted areas, the magnetic susceptibility of surface soil layers is considerably higher. Recently, rock-magnetic methods have been applied to modern soils in several environmental studies (for an overview see, e.g., Petrovský and Ellwood, 1999). Measurements of low-field magnetic susceptibility of surface soils have been applied recently around local pollution sources and at a larger, regional scale, areas in Poland and Great Britain and Austria have been investigated (Strzyszcz et al., 1996; Heller et al., 1998; Hanesch and Scholger, 2002; Magiera et al., 2006).

Summary

In a course of soil formation, the change of magnetic properties of soils in comparison with parent material takes place. The amplitude of these changes depends on the factors of soil formation. Generally, the conditions of transformation of iron-containing minerals result in enhancement of the contents of ferric oxides in soils. The analysis of magnetic properties of zonal soils shows that the behavior of soil magnetics in profile reflects genetic properties of soils at the soil type level and

connected with distribution and state of iron minerals in soils and landscapes. Atmospherically deposited ferrimagnetic particles of anthropogenic origin also contribute a great deal to the concentration-dependent magnetic properties of top soils. Magnetic properties measurements of soils are mostly used for three purposes: to read the climatic signal recorded by palaeosols, to identify pollution in soils, and as tools for archaeological mapping and prospecting. The definition of soil magnetism as a genetic parameter, which is able together with other soil properties to be used for diagnostics of soil looks to be useful and important. Magnetic methods have many advantages over other techniques: sample preparation and measurement is quick, easy and generally nondestructive, and the methods are sensitive to both concentration and grain-size – particularly for ultrafine grains, which can be difficult to detect by other means. Hence, magnetic analyses of soils provide an additional, sensitive window on soil iron.

MAGNETIC RESONANCE IMAGING IN SOIL SCIENCE

Andreas Pohlmeier
ICG-4, Research Centre, Jülich, Germany

Definition

Magnetic resonance imaging (MRI) or magnetic resonance tomography (MRT) is a noninvasive, three-dimensional

(3D) imaging technique for monitoring water content, water fluxes, and tracer transport in porous media. It uses the effect of nuclear magnetic resonance (NMR) of certain atomic nuclei, mostly ^1H in H_2O , which is modulated by the chemical and physical environment inside the porous medium. The methods yield finally 2D (slices) or 3D (volume graphics) images of the medium under investigation.

Basics

Magnetic resonance imaging is based upon the physical effect of nuclear magnetic resonance (NMR) of spin bearing atomic nuclei (Callaghan, 1991; Blümich, 2000). The most important NMR active nuclei in soil science applications are ^1H , ^{13}C , ^{19}F , ^{31}P , and ^{23}Na , of which mostly ^1H with a spin quantum number of $I = \frac{1}{2}$ (e.g., in H_2O) is used for imaging purposes leading to a nuclear magnetic moment μ . If placed in an external magnetic field \mathbf{B}_0 pointing into z -direction of a Cartesian coordinate system, (The direction of the external magnetic field \mathbf{B}_0 is mostly determined by convention as “ z ”) the nuclear magnetic moment precesses around the axis of \mathbf{B}_0 with the *Larmor frequency* v_0 :

$$v_0 = \omega_0/2\pi = -\gamma|B_0|/2\pi \quad (1)$$

The parameter γ , a proportionality constant termed as gyromagnetic ratio, is a basic property of the respective nucleus. For protons its value is $\gamma_{\text{H}} = 2.68 \times 10^8 \text{ T}^{-1} \text{ s}^{-1}$, leading to typical values of $v_0 = 300 \text{ MHz}$ at $|B_0| = 7 \text{ T}$ in stationary superconducting magnets, and $v_0 = 4.3 \text{ MHz}$ at $|B_0| = 0.1 \text{ T}$ in mobile low-field relaxometers and scanners. Due to the quantum mechanical nature of the nuclear spin for proton magnetic moments, only two states are allowed in an external magnetic field: parallel (\uparrow) and antiparallel orientation (\downarrow). The energy gap between these two states is $\Delta E = h\nu_0$, where h is Planck's constant and the two states are populated according to Boltzmann's law: $n\uparrow/n\downarrow = \exp(-\Delta E/kT)$. In practice, it is more convenient not to regard single spins but ensembles of spins, which may be treated semi-classically. If an ensemble is sufficiently large, the x - and y -components of the nuclear magnetic moments precessing around the z -axis cancel mutually, so only the z -component persists. Since the lower energy state is slightly higher populated than the higher state, a macroscopic magnetic moment \mathbf{M}_0 pointing into z -direction is observable. Now, by absorption of electromagnetic radiation matching exactly the *Larmor frequency*, spins may swap from parallel to antiparallel orientation. Regarding the ensemble, this irradiation by a sufficiently long pulse, termed as 90° pulse, leads to a rotation of \mathbf{M}_0 into the xy -plane, where it precesses again with the Larmor frequency v_0 around the z -axis. Subsequently, the excess energy of the ensemble is lost by two relaxation mechanisms:

Firstly, the coherence of the magnetic moments in the xy -plane decays with the *transverse relaxation time* T_2 , see Equation 2 and radiation is emitted, which is detectable by an external receiver coil. This is the free induction decay (FID).

$$M_{xy} = M_0 \exp(-t/T_2), \quad (2)$$

It is composed of two contributions: coherence loss (dephasing) in static inhomogeneities, which is reversible, and irreversible loss due to stochastic motions. The reversible contribution of dephasing can be restored by the creation of a *spin echo* by means of the application of a 180° pulse after a period of $t_E/2$ (cf. Equation 5) after the 90° pulse. What remains is the irreversible part. For details, see textbooks (Callaghan, 1991; Blümich, 2000).

Secondly, the thermal equilibrium is restored, that is, magnetization in the z -direction is reformed again. This is called *longitudinal relaxation* characterized by the relaxation time T_1 :

$$M_z = M_0(1 - \exp(-t/T_1)) \quad (3)$$

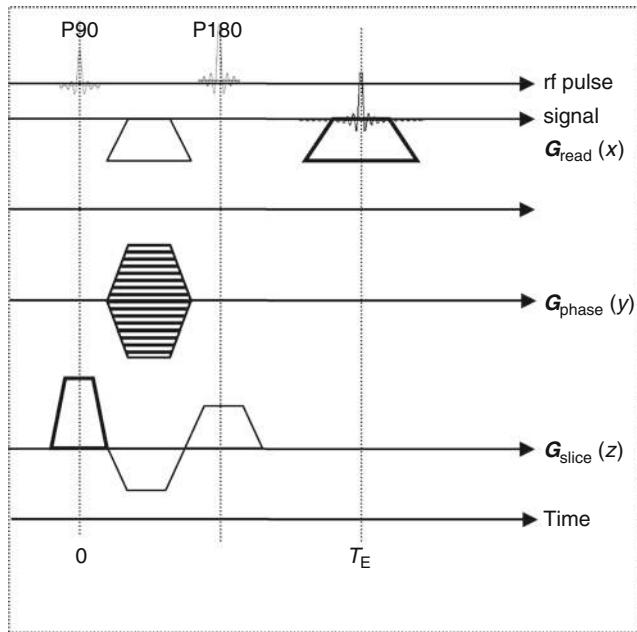

Pure water possesses relaxation times of about 3 s in high field, but the environment, in which the interesting water molecules are located, reduces T_1 and T_2 considerably. Decisive factors are (1) pore size, (2) pore filling factor, (3) pore geometry, (4) chemical nature of pore walls, (5) dissolved paramagnetic substances and, in case of T_2 , (6) diffusive motion in internal magnetic field gradients. By the latter effect T_2 can get much faster than one millisecond, which has implications on imaging capabilities, see below. The investigation of relaxation times is the basis of relaxometric exploration of pore space in geological materials (Dunn et al., 2002), see also the article Proton NMR Relaxometry in Soil Science, Nr of G. Schaumann in the encyclopedia.

Imaging

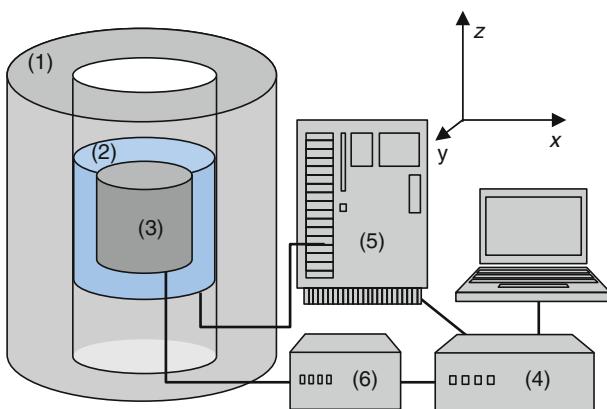

Magnetic resonance imaging (MRI) is the extension of NMR by adding spatial resolution to the observed NMR signal. In the following a basic spin echo imaging method is presented exemplarily (see Figure 1). According to Equation 1, the precession frequency is proportional to the magnetic field \mathbf{B}_0 . If an additional spatially variable magnetic field (a *gradient* $\mathbf{G}_{\text{slice}}$) is added to \mathbf{B}_0 during excitation only one slice is excited according to Equation 4:

$$v_0 = -\gamma|B_0 + \mathbf{G}_{\text{slice}} \cdot \mathbf{z}|/2\pi. \quad (4)$$

All subsequent detectable signals originate only from this slice leading to the family of the so-called multi-slice imaging sequences, see Figure 1. The next dimension (here: x) is addressed by application of a further gradient \mathbf{G}_{read} (orthogonal to $\mathbf{G}_{\text{slice}}$) during the detection of the signal that encodes the frequency of the received signal with respect to the x -direction. The third dimension is finally encoded by the phase-selective $\mathbf{G}_{\text{phase}}$, orthogonal to the other two gradients. After its application, the phase of the signal is turned with respect to a reference, and the phase shift is proportional to the position on the y -axis. The real-space image is finally obtained by two-dimensional Fourier transformation. The signal intensity is given by

Magnetic Resonance Imaging in Soil Science, Figure 1 Basic spin echo imaging pulse sequence. P90 and P180 mean 90° and 180° pulses of electromagnetic irradiation for excitation of the spin ensemble system and creation of the echo, respectively. The gradients in this example are applied in x -, y -, and z -directions, but can also be applied in other orders.

Magnetic Resonance Imaging in Soil Science, Figure 2 Schematic magnetic resonance imaging (MRI) scanner. For details, see text.

$$S(xyz) \propto \rho_0(xyz)(1 - \exp(-t_R/T_1(xyz))) \times \exp(-t_E/T_2(xyz)), \quad (5)$$

where ρ_0 is the spin density, t_R is the repetition time between successive excitation pulses, and t_E is the echo time, that is, twice the period between 90° and 180° pulse, T_1 and T_2 are the longitudinal and transverse relaxation times, respectively. Note that ρ_0 as well as T_1 and T_2 depend on space. The sequence in Figure 1 is only an

example of a basic, but still widespread MRI pulse sequence (Spin echo multi slice sequence, also termed as spin warp sequence). Besides this, many partly very specialized sequences exist, for example, rapid imaging, relaxometric imaging, and motion sensitive imaging (Callaghan, 1991; Blümich, 2000).

Hardware

Schematically, the necessary hardware consists of following components (Figure 2): (1) a cylindrical magnet with a bore, in which the gradient system (2) and the transmitter–receiver coil (3) is placed. Stationary magnets are mostly superconductors, where permanent current flows in a liquid helium cooled coil, which creates a main magnetic field B_0 pointing along the axis of the cylinder (z -direction). The gradient system consists of three additional coils that create orthogonal magnetic field gradients in the x -, y -, and z -directions. These gradients are operated by the spectrometer (4), which creates and controls the pulse sequences via gradient amplifiers (5). The excitation of the spin system and the monitoring of the transmitted signals are performed by the rf-coil (3), which transmits and receives rf-pulses. This is also controlled by the spectrometer (4) and the rf amplifier (6). In order to be able to turn the magnetization M_0 into the xy -plane the direction of the magnetic field B_1 of the rf-pulses must be orthogonal to B_0 . This is performed in conventional superconducting scanners by a so-called birdcage-rf coil. For novel low-field scanners, which are composed of Halbach-rings of permanent magnets (Raich and Blümller, 2004), B_0 points orthogonal to the main axis, and the rf coil can be a simple solenoid coil.

Applications

The application of MRI for soil systems started in the 1980s. A very early example was the unilateral imaging of water content in a natural soil on the field scale, where an electromagnet was positioned on a sledge and pulled across a field by a tractor (Paetzold et al., 1985). The signal created by a radiofrequency irradiation pulse was detected and water content was derived from the signal intensity. Most recently, the imaging of water on the field scale draws again attraction by the further development of magnetic resonance sounding (NMRS) or surface NMR (Roy and Lubczynski, 2005; Mohnke and Yaramanci, 2008; Yaramanci et al., 2008). Originally, this method has been developed for detection of aquifers in geological formations like karsts. But with the advancing technology, especially with respect to noise compensation, the method might get available for the investigation of soils with much less water content and much faster relaxation times (Hertrich et al., 2007).

In the lab, MRI has also been applied for the investigation of water content and dynamics in repacked natural porous media and natural soil cores (Nestle et al., 2002). The general problem for its application in soils is the inherently rapid T_2 relaxation times (Hall et al., 1997;

Votrubova et al., 2000), down to the sub-millisecond range. Also, one must take into consideration that T_2 for a given porous medium is not a constant but depends also on t_E due to diffusional motion in internal gradients (Barrie, 2000; Dunn et al., 2002). The limiting value of t_E is about 1.5 ms at present, so in the past many imaging studies in natural soils failed. However, the group of M. Cislerova was able to apply the method on infiltration processes in natural soil cores (Cislerova et al., 1997; Votrubova et al., 2003), where the infiltrating water followed preferential flow paths in a network of macropores, which are characterized by comparably long T_2 relaxation times. Figure 3 shows an image of a central vertical slice through a soil core after infiltration from top, which was obtained by a spin-echo sequence using $t_E = 5$ ms. Clearly visible are the preferential flow paths.

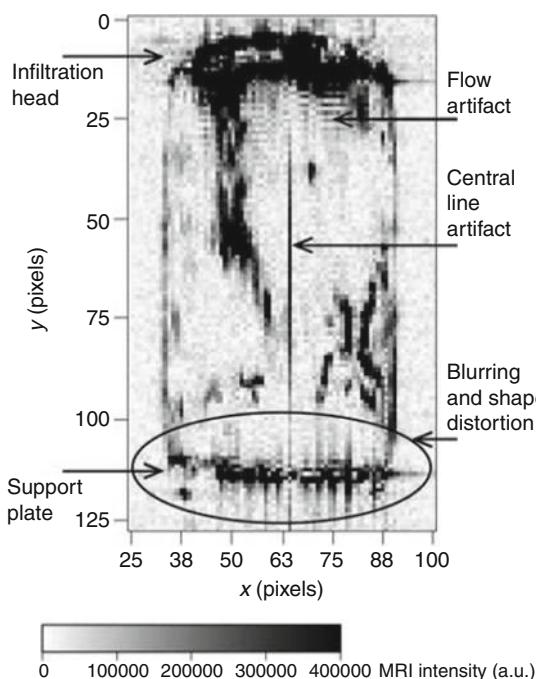

Besides $^1\text{H}_2\text{O}$ imaging, also other nuclei can be used for monitoring soil processes. This method is quite rare, but promising for the quantification of dual phase fluxes. Simpson et al. monitored water and fluorinated compounds (fluorinated benzene, NaF, trifluralin) in four natural soil cores. Since free water possesses longer relaxation times, and it is still visible when imaged at long t_E , the authors varied t_E in the range between 2.5 and 40 ms in order to differentiate between bound water and free water. Then the displacement of water by hexafluorobenzene during infiltration from top was imaged by ^{19}F MRI. This

fluorinated liquid has been chosen as model nonaqueous phase liquid (NAPL), because ^{19}F possesses the same spin like water and a similar gyromagnetic ratio of $\gamma_F = 2.52 \times 10^8 \text{ T}^{-1} \text{ s}^{-1}$.

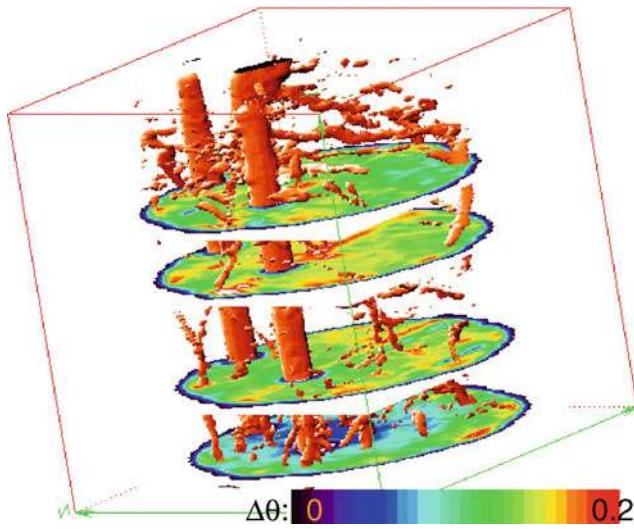

A permanently challenging topic in soil science is the imaging of flow processes. MRI is principally very suitable for such purposes, since it can monitor the motion of water and therefore flow velocities and diffusion coefficients directly (Callaghan et al., 1988; Baumann et al., 2000; Scheenen et al., 2001). This is performed by the introduction of additional motion encoding gradients before the detection of echoes, which prolongates interval between excitation pulse and detection. Therefore, these methods are restricted to the investigation of sediments and model porous media with sufficiently slow transverse relaxation times (Baumann et al., 2000; Herrmann et al., 2002b). For applications in soils, the first difficulty is the short transverse relaxation time, which lets signals vanish after some milliseconds. Secondly, flow processes in soils are mostly slower than the few tenths of mm/s, which is the present limit for flow imaging (Bendel, 2009). So, fluxes should be better visualized indirectly by motion of tracers. Popular tracers are paramagnetic ions like Cu^{2+} , Ni^{2+} , or Mn^{2+} (Greiner et al., 1997; Herrmann et al., 2002a; Oswald et al., 2007), and complexes like GdDTPA^{2-} that are widely used in medicine (Hermann et al., 2008; Haber-Pohlmeier et al., 2009, 2010). The mode of action is predominantly the reduction of the longitudinal relaxation time T_1 . If one sets the experimental parameter T_R in Equation 5 to a sufficiently small value, the signal intensity in regions without tracer is low, whereas signal intensities originating from regions with high tracer concentrations remain high. This technique has been successfully applied for quantifying flux processes in natural porous media and very recently for the first time in a natural soil (Haber-Pohlmeier et al., 2009, 2010).

As already mentioned, soils possess short relaxation times, which can reduce the intensities of echoes considerably or prevent the detection of echoes completely. A family of MRI techniques based on *single point imaging* can overcome this restriction by avoiding the creation of echoes and probe directly the free induction decay, which appears after any exciting pulse (Balcom et al., 1996). Their general drawbacks are long measuring times combined with low resolution. However, such methods are used for the investigation of water in porous rocks (Gingras et al., 2002; Chen et al., 2006) and root–soil systems (Pohlmeier et al., 2008).

The final topic to be addressed here is the investigation of root–water–soil relations by MRI. MRI is especially suitable for this, since such interactions are sensitive for classical invasive methods but possess huge importance for the understanding of plant growth and stress tolerance. The earliest investigations range back to the 1980s (Bottomley et al., 1986; Bacic and Ratkovic, 1987; Brown et al., 1990; Chudek et al., 1997). For imaging of root systems, the short transverse relaxation times of soil material helps, since roots possess relative long relaxation times, so

Magnetic Resonance Imaging in Soil Science,

Magnetic Resonance Imaging in Soil Science, Figure 4 *Ricinus* root-soil system. Water content difference maps $\Delta\theta$ between day-6 and day-1, overlaid by the root system. The long cylinders in the left part are reference tubes. (From Pohlmeier et al., 2010.)

by the choice of long echo times (t_E in Equation 5) the signal from the soil is completely faded out, and only the root system appears in the images (MacFall and van As, 1996; Menzel et al., 2007; Pohlmeier et al., 2008). In contrast, if one intends to measure water content in the vicinity of roots one should use very short echo times or even employ single point imaging techniques (Pohlmeier et al., 2007). Figure 4 shows an example of water content changes during a desiccation experiment over 6 days in a ricinus root system grown in fine sand, where the water content was determined by a multi-slice multi-echo pulse sequence with quite short echo time. The resulting echo-trains are fitted by exponential functions and the water content was obtained from the amplitude of these functions and calibration on reference tubes with known water content. The root system architecture was imaged by a fast spin echo method with longer echo time. The stronger depletion in the top layers of the soil is visible, whereas the bottom regions remain wetter.

Using MRI, several authors stated water depletion zones around roots (MacFall et al., 1990; Segal et al., 2008) while under very dry conditions also hints on opposite trend, that is, increased water contents around roots are found (Carminati et al., 2010). This is still a topic of discussion. Further necessary for the interpretation of such effects is the combination of noninvasive 3D images with model calculations based on soil physical principles (Javaux et al., 2008), see also the article Plant Soil Interactions, Modelling of M. Javaux in this encyclopedia.

Summary and outlook

Summarizing, one can state that MRI is very suitable for monitoring processes in model and natural soils like water content changes, root system architecture, flow processes,

and tracer motion. One should always take into account that transverse relaxation times decrease with decreasing pore size and water content and increasing content of paramagnetic ions like Fe^{3+} and Mn^{2+} . Thus, MRI is generally more sensitive for water in macropores. Therefore, quantitative water content imaging should employ fast echo times in combination with multi-echo sequences and extrapolation to zero time, or even ultrafast pulse sequences like SPRITE (Single Point Imaging with T_1 Enhancement [Balcom et al., 1996; Pohlmeier et al., 2007]). Such sequences abandon the creation of an echo and sample the FID directly on the expense of enhanced overall measuring time. Flux processes can be visualized directly in macropores or indirectly by the usage of contrast agents (tracers).

MAGNETIC TREATMENT OF IRRIGATION WATER, EFFECTS ON CROPS

Basant Maheshwari, Harsharn Grewal
School of Natural Sciences, Hawkesbury Campus,
Building H3, University of Western Sydney, Penrith South
DC, NSW, Australia

Definition

Water productivity: Crop yield per unit volume of water used. Definitions of water productivity differ based on the context. For example, from the point of view of growing

crops, obtaining more kilograms per unit of transpiration is the main aspect productivity of water. In the case of regional or catchment scale, the focus of water productivity is the value derived from the use of water for purposes such as crops, forests, fisheries, ecosystems, and other uses.

Electromagnetic field: A field of force associated with a moving electric charge equivalent to an electric field and a magnetic field at right angles to each other and to the direction of propagation.

Magnetic treatment: Exposure of material such as water to a magnetic field for a short duration (a few seconds) or longer to possibly change some of its properties for beneficial effects.

Introduction

The total volume of fresh water available is limited but the demand for water is growing at a rapid pace. In this context there has been a growing interest to use water more efficiently and effectively, increase reuse of effluent, develop ways to use lower quality water and improve the overall productivity of water used for irrigation. This means we need to develop ways that will increase the productivity and sustainability of water used for irrigation. One of the ways by which we can reduce the total water used for irrigation is to employ practices that improve crop yield per unit volume of water used (i.e., water productivity). There have been claims made that the magnetic treatment of irrigation water can improve water productivity. If those claims are valid there is scope for magnetic treatment of water to save water and assist in coping with the future water scarcity.

Effects of magnetic field

There is very little study reported, with valid scientific experiments, on the effects of magnetic treatment of water on crop yield and water productivity. However, there have been some closely related studies that report on the effects of magnetic field on seed germination, plant physiology, and overall plant growth and, as such, those studies may indirectly help to understand the role of magnetic treatment of irrigation water and plant growth. For example, Lin and Yotvat (1990) reported an increase in water productivity in both livestock and crop farming with magnetically treated water. Some studies have shown that there is an increase in the number of flowers, earliness and total fruit yield of strawberry and tomatoes by using magnetic fields (Esitken and Turan, 2004; Danilov et al., 1994). An increase in nutrient uptake by magnetic treatment was also observed in tomatoes by Duarte Diaz et al. (1997).

External electric and magnetic fields influence both the activation of ions and polarization of dipoles in living cells (Johnson and Guy, 1972; Moon and Chung, 2000). Electromagnetic fields (EMFs) can alter the plasma membrane structure and function (Paradisi et al., 1993; Blank, 1995). Goodman et al. (1983) reported an alteration of the level of some mRNA after exposure to EMFs. Amaya et al. (1996) and Podešný et al. (2004) have shown that an optimal

external electromagnetic field accelerates the plant growth, especially seed germination percentage and speed of emergence.

Some studies focused on how static magnetic field affect chlorophyll and phytohormone levels in some plants. Turker et al. (2007) observed that chlorophyll and phytohormone levels decreased when static magnetic field, parallel either to gravity force (field-down) or anti-parallel (field-up) was applied to maize plants. However, chlorophyll concentration increased in sunflowers by applying magnetic field in either direction.

Magnetic fields can also influence the root growth of some plant species (Belyavskaya, 2001, 2004; Muraji et al., 1992, 1998; Turker et al., 2007). In the case of maize (*Zea mays*) the exposure of maize seedlings to 5 mT magnetic fields at alternating frequencies of 40–160 Hz improved root growth (Muraji et al., 1992). However, there was a reduction in primary root growth of maize plants grown in a magnetic field alternating at 240–320 Hz. The highest growth rate of maize roots was achieved in a magnetic field of 5 mT at 10 Hz. Turker et al. (2007) reported an inhibitory effect of static magnetic field on root dry weight of maize plants but there was a beneficial effect of magnetic fields on root dry weight of sunflower plants.

Belyavskaya (2004) and Turker et al. (2007) reported that a weak magnetic field has an inhibitory effect on the growth of primary roots during early growth. The proliferative activity and cell reproduction in meristem in plant roots are reduced in weak magnetic fields (Belyavskaya, 2004). The cell reproductive cycle slows down due to the expansion of the G1 phase in many plant species and the G2 phase in flax and lentil roots. There was a decrease in the functional activity of genomes at early pre-replicate period in plant cells exposed to weak magnetic fields. In general, these studies conclude that weak magnetic fields cause intensification of protein synthesis and disintegration in plant roots.

Impact of heat stress at 40°C, 42°C, and 45°C for 40 min in cress seedlings (*Lepidium sativum*) was reduced by exposing plants to extremely low-frequency (ELF) magnetic field (50 Hz, 100 µT) (Ruzic and Jerman, 2002). Magnetic fields act on the same cellular metabolic pathways as temperature stress and as such the study suggests that magnetic fields act as a protective factor against heat stress.

Magnetic treatment and seed germination

Magnetic treatment of seed or water used for germination can influence germination and seedling emergence. Reina et al. (2001) reported an increase in germination percentages of lettuce seeds by treating these with 10 mT stationary magnetic fields. They reported that magnetic fields resulted in an increase in water absorption rate of lettuce seeds and may have contributed to increased germination percentages. Some studies reported that the magnetic exposure of seeds, viz., cereals and beans, prior to sowing can improve germination rate and early growth (Pittman 1963a, b;

Pittman and Anstey, 1967). Similarly, the application of stationary magnetic fields before sowing had a significant increase in germination rates and seedling vigor in groundnut, onion, and rice seeds (Vakharia et al., 1991; Alexander and Doijode, 1995). The exposure of broad bean seeds by Podlešny et al. (2004) to variable magnetic strengths before sowing showed some beneficial effects on seed germination and emergence. In particular, they found that seedling emergence was more regular after the use of the magnetic treatment and occurred 2–3 days earlier in comparison to seedlings in the control treatment. In tomatoes, De Souza et al. (2006) observed that the magnetically treated tomato seeds improved the leaf area, leaf dry weight, and yield of tomato crop under field conditions.

The beneficial effects of magnetically treated irrigation water have also been reported on germination percentages of seeds. For example, an increase in germination of *Pinus tropicalis* seeds from 43% in the control to 81% with magnetically treated water was observed by Morejon et al. (2007). For tomatoes, pepper, cucumber and wheat seeds Hilal and Hilal (2000) reported that germination and seedling emergence was improved when magnetically treated water and seeds were used. In particular, germination of pepper seeds was higher with magnetically treated seeds when compared with magnetically treated irrigation water and cucumber seeds had the highest germination percentage when both irrigation water and seeds were magnetically treated.

How do magnetic fields influence?

The mechanisms that influence plant growth and seed germination through magnetic treatment are not well understood. Some beneficial effects of the treatment could be related to the “gas bubble-water interface” (Vallée et al., 2005). Furthermore, these effects may be related to mechanisms such as intramolecular and intra-ionic interactions, effects of Lorentz forces, dissolution of contaminants and interfacial effects (Baker and Simon, 1996). The changes in hydrogen bonding and increased mobility of Na^+ and Cl^- ions with exposure of irrigation water to magnetic fields may also play some role in the plant growth and seed germination (Chang and Weng, 2008). It is also suggested that the magnetic treatment of water may result in changes in physical and chemical properties of water such as hydrogen bonding, polarity, surface tension, conductivity, pH, refractive index and solubility of salts (Smikhina, 1981; Srebrenik et al., 1993; Amiri and Dadkhah, 2006; Otsuka and Ozeki, 2006; Chang and Weng, 2008).

Magnetic treatment and water productivity

Maheshwari and Grewal (2009) investigated the effects of magnetically treated potable water, recycled water and saline water on crop yields and water productivity under controlled environmental conditions in a glasshouse. The main aim of the study was to examine the impact of magnetic treatment of different water sources on water productivity and yield of snow peas, celery, and peas.

The study has provided some preliminary results on how the magnetic treatment influences the key parameters of (1) water – pH and EC; (2) crop – yield, water productivity, total crop water use and crop nutrient composition; and (3) soil – pH, EC, and available N, P, and K. Statistical analysis of the data indicated that the effects of the magnetic treatment varied with crop type and the source of water. There was no statistically significant effect of magnetic treatment on the total water used by the crop during the growing season in any of the three crops. However, the magnetic treatment of water tends to increase (statistically significant) crop yield (fresh weight) and water productivity (kg of fresh or dry produce per kL of water used) of celery and snow peas. On the other hand, the magnetic treatment had no significant effect on both crop yield and water productivity for peas.

In general, the results obtained during this preliminary study on the use of magnetically treated water on celery and snow peas are interesting but the effect of the magnetic treatment on crop yield and water productivity was variable and occurred under some set of conditions and not in others. Therefore, from the glasshouse experimental data, it is difficult to make any recommendation with certainty as to the effectiveness of the magnetic treatment under field conditions.

Summary

The past studies reveal that the magnetic field or treatment can affect plant growth and other related parameters. Similarly, the past studies have indicated that there are some beneficial effects of magnetic treatment on seed germination and seedling emergence. Nevertheless, we have no clear understanding yet as to the mechanisms behind these effects on plant growth, water productivity, and the changes magnetic treatment brings about in nutritional aspects of seed germination and seedling growth.

To assess the potential of the magnetic treatment for practical applications, we need further testing under field conditions to clearly understand and demonstrate the beneficial effects of the magnetically treated irrigation water for crop production under real-world situations. Further research is also warranted to understand how the magnetic treatment affects crop and soil parameters and therefore soil, crop and water quality conditions under which the treatment will be effective to provide water productivity gains.

MANAGEMENT EFFECTS ON SOIL PROPERTIES AND FUNCTIONS

Rainer Horn

Institute for Plant Nutrition and Soil Science,
Christian-Albrechts-University zu Kiel, Kiel,
Germany

Definition

The introduction and application of agricultural and forestry machinery often result in severe soil compaction and soil deformation with intense decrease in total pore volume, alterations in the pore-size distribution, and especially in their functions concerning gas, water and heat transfer as well as altered accessibility of chemical adsorption sites of clay minerals, organic substances, and further variable exchange places.

Introduction

Soils as three-phase systems fulfill not only the archive function (historical memory of former properties, climates, management practices, land use, etc.), they are essentially needed for plant growth and yield, as reservoir for microbes and they are also responsible for filtering and buffering of soil water in order to get clean drinking- and groundwater, they contribute to the transformation under *in situ* conditions and serve as the resource for raw material. In the following, the process of soil deformation will be shortly summarized in order to derive the interactions between soil structure and chemical as well as physical and biological properties, which are affected by soil deformation. Finally, some conclusions for a sustainable land use and soil management will be given.

Soils: their functions in view of the existing soil protection laws or recommendations

Soils as nonrenewable goods have to be protected and should be only used according to their properties. The European Soil Charta 1972 of the European Assembly was the first, which did underline and support this idea and which in 1998 became the nucleus for the German Soil Protection Law. This law was the first and until now the only one in Europe while, e.g., the European Soil Framework Directive (2006) is still under a very controversial debate. However, there is an urgent need to specify more in detail the requests and limitations but also to quantify the limits of an unprevented or unhindered land use. It has to be pointed out that for a sustainable soil land use their physical, chemical, and biological soil functions must be related to the intensity and function values and have to include the dependent recommendations in order to prevent any irreversible soil degradation.

If we consider the properties for arable horticulture, landscape planning, and in forestry soils, they all require primarily a sufficiently rigid pore system, which guarantees the water, gas and heat exchange, nutrient transport and adsorption as well as an optimal rootability, which also includes a sufficient microbial activity and composition in order to also decompose the plant debris. All these requests must be included in a quantitative way in the Protection law but there is still an urgent need to specify these “optimal” properties. However, it is very difficult for the land user to forecast and to relate their own farming management practices to coming weather conditions, e.g., the storage capacity for water and nutrients in the topsoil sufficient to grow a good crop yield during the following season under dry conditions or are the soils permeable enough to drain off the access rain water and to reaerate the root zone quick enough in order to avoid declining redox potential values and the accumulation of anoxic gases in the pores. Thus, the major challenges are interlinked between soil and weather conditions, which request a more intense analysis of the effect of soil structure on the nutrient, gas, and water fluxes in anthropogenically managed soils under various land uses.

Processes of aggregate formation and persistence

Soils containing more than 12% clay (particle size < 2 µm) or even pure sandy soils with some salts tend to form aggregates. Usually the process occurs when soils dry and swell, and it is further enhanced by biological activity. Aggregates may show great variation in size from crumbs (diameter < 2 mm) to polyhedres or subangular blocks of 0.005–0.02 m, or even to prisms or columns of more than 0.1 m. During the first period of shrinkage, mineral particles are pulled together by capillary forces, which increase the number of points of contact and result in a higher bulk density. The initial aggregates always have rectangular-shaped edges because, under these conditions, stress release would occur perpendicular to the initial crack and stress would remain parallel to the crack (strain-induced fracturing). However, due to the increased mechanical strength the particle mobility declines and results in the formation of nonrectangular shear plains as the following crack generation. They are created after repeated swelling and shrinking processes and result in fractures in which the value of the angle of internal friction determines the deviation from 90° (Or and Ghezzehei, 2002). In newly formed aggregates, the number of contact points depends on the range of water potential and on the distribution of particle sizes as well as on their mobility (i.e., state of dispersion, flocculation, and cementation). Soil shrinkage, including crack formation, increases bulk density of aggregates. The increase in bulk density with the initial wetting and drying of the soil permits the aggregates to withstand structural collapse. The increase of the strength of single aggregates is further enhanced by a particle rearrangement, if the soil is nearly saturated with water increasing the mobility of clay particles due to dispersion and greater menisci forces of water (Horn and Dexter, 1989). Subsequent drying causes enhanced adhesion by capillary forces, which lead to greater cohesion as mineral particles are brought into contact following the evaporatory losses of the capillary water. Thus, the strength of the bigger, i.e., initial aggregates is increased due to a particle mobilization and results both in smaller and stronger aggregates with even a smaller aggregate bulk density. The strongest aggregate type under this aspect is the spherical shape, which has reached the stage of the smallest free entropy. Therefore, aggregate strength depends on (1) capillary forces, (2) intensity of shrinkage (normal/residual), (3) number of swelling and shrinkage cycles, i.e., the shrinkage/swelling history, (4) mineral particle mobility (i.e., rearrangement of particles to achieve arrangements of lowest free energy), and (5) bonding energy between particles in/or between aggregates or in the bulk soil. Generally, aggregates persist as long as the soil strength (defined by the failure line of Mohr–Coulomb) is higher than the given load or shrinkage forces soils remain rigid. If however, additional kinetic energy (which even is more efficient in combination with accessible water) is applied, aggregate deterioration and homogenization occur. Thus, a complete

homogenization of the soil structure due to shearing and/or puddling takes place if kneading (expressed as octahedral shear stresses and mean normal stresses) exceeds the aggregate and structure strength. After a mostly complete homogenization normal shrinkage, processes restart again (Horn et al., 1994). Consequently, a weaker soil structure and finally a pasty structure can be defined by very small cohesion and angle of internal friction values (Horn, 1976; Janssen et al., 2006). Thus, the determination of soil and/or aggregate strength has always to be subdivided into (1) mechanically, hydraulically, or chemically prestressed and (2) virgin conditions, which also ultimately affect the predictability of physical properties. These general ideas have been described in greater detail by Horn and Baumgartl (2002), Groenevelt and Grant (2002), Grant et al. (2002), and Peng and Horn (2005).

In conclusion, it has to be stated, that aggregate formations as well as changes in aggregate strength are directly related also to tillage systems. Conventional tillage especially of the A-horizon annually includes plowing, chiseling, and the seedbed preparation apart from multiple wheeling events depending on the crop management requirements, which ends in mostly homogenized structure conditions annually. Thus, a more complete aggregate formation will not take place. Conservational tillage systems on the other hand causes less disturbance and allow a more complete rearrangement of particles and strengthening of the structure system if preserved throughout several years.

Soil structure and soil use: how to sustain the required and natural soil and site-specific functions

During the last 4 decades, not only the mass of the agricultural and forestry machines but also the frequency of wheeling has increased intensely and resulted in a compression and soil deformation status, which can be suboptimal concerning plant growth and crop yield as well as the uncertainty of getting a predictable yield. At present, the maximum mass of machines exceeds by far 60 Mg and therefore also enhance the probability of subsoil compaction and long-term soil degradation. Not only in agriculture but also in forestry, such enlarged machines are used for tree harvesting and clear cutting and results in an intense subsoil degradation due to shear and vibration induced soil deformation especially if the soil water content in the subsoil is high and the internal soil strength very low (Horn et al., 2007).

Soil processes like the formation of a platy structure, deterioration of a continuous pore system are therefore signs of an intense soil degradation, which also coincides with an increased anisotropy of pore functions and may cause an increased lateral soil movement (= soil water erosion). For more details, see Soane and van Ouwerkerk (1994), Pagliai and Jones (2002), Ehlers et al. (2003), Lipiec and Hatano (2003), and Horn et al. (2005, 2006).

Consequences of soil deformation on changes in soil functions

Cation adsorption capacity, intensity, and accessibility

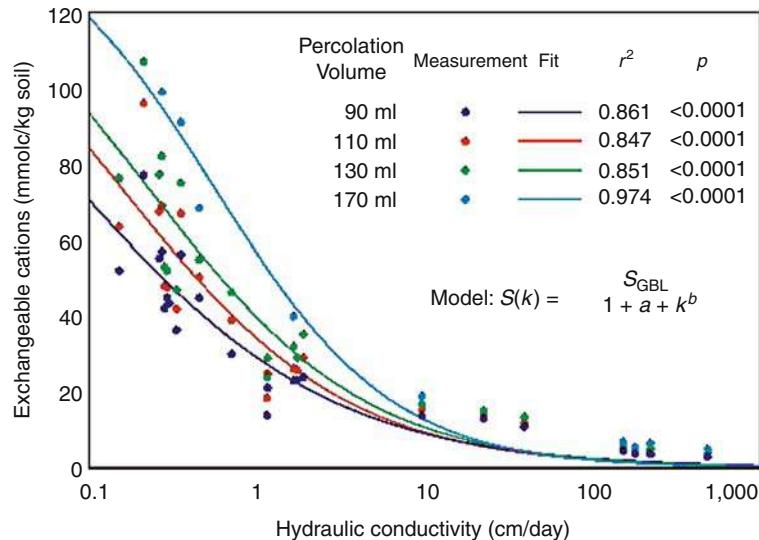

Soil aggregates can be classified by a certain accessibility of the exchange places for cations, which in comparison with that one of the homogenized material may be intensely reduced. We have to differentiate between the capacity and intensity properties. In homogenized soils, capacity (= potential) and intensity (= actual) parameters are identical, which holds true especially for the seedbed where fertilized ions are mostly adsorbed at the exchange places of the soil particles. For soil horizons with a prismatic structure, we can assume a reduction of up to 15% from the potential properties, while soil horizons with blocky or subangular blocky structure will even have a reduction of up to 50–80%.

In this context also soil texture and bulk density of the bulk soil and of the single aggregates further affect these actual conditions. Soils with a crumbly structure have again an improved accessibility due to a macroscopic homogenization of the aggregates themselves by the microbial activity as can be also derived from their particle and organic substance arrangement in the bulk soil. Thus, we can assume a nearly 90% accessibility of the cation exchange capacity values under these conditions. If, however, soils have a platy structure, the intensity (= actual) properties are as small as 30% of the capacity values due to the compressed pores in between singles particles within the plats and because of correspondingly retarded ion mass flow and diffusion within the plats. Thus, plats provide the greatest differences between the capacity and intensity properties and therefore also the most reduced accessibility of the exchange places. These differences can also be derived from the relationship between the exchangeable cations and the actual hydraulic conductivity, which is a measure of the effect of preferential flow processes. Compared to the theoretical CEC of 140 mmol kg⁻¹ soil, the actual values were the smaller the higher was the hydraulic conductivity (Figure 1). The drier the soil the smaller the water fluxes and the more retarded are the exchange processes the higher is the actual value but it will not reach the maximum values under the dominating hydraulic site properties (Figure 2).

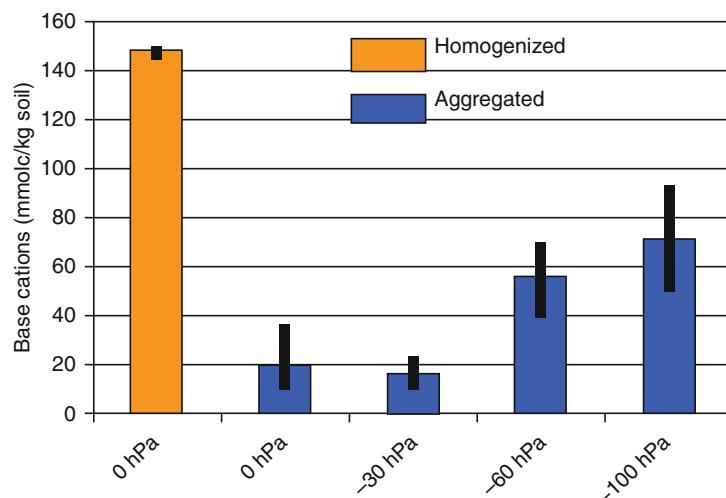

Thus, neither the fertilized nutrients nor the natural ions within the soil can be fully accounted for a good yield, if the aeration, the accessibility, and nutrient availability are not provided.

Soil water and gas

An increased soil volume coincides with a reduced pore volume with the dominance of finer pores and less coarser ones. Thus, the air capacity is reduced with increasing soil deformation but the changes in the pores, which contain the water available for plants depends on the applied stresses as well as the texture and the bulk density.

Management Effects on Soil Properties and Functions, Figure 1 Effect of soil structure on chemical exchange processes (taken from Hartmann et al., 1998).

Management Effects on Soil Properties and Functions, Figure 2 Effect of predrying and of aggregation on the base cation adsorption in comparison to the homogenized conditions (Bt-horizon of a Luvisol derived from loess, blocky structure).

The hydraulic conductivity as a water available for plants depends tensorial function in principle decreases with applied stresses by many orders of magnitude while the unsaturated hydraulic conductivity is even increased at a given matric potential value (Figure 3).

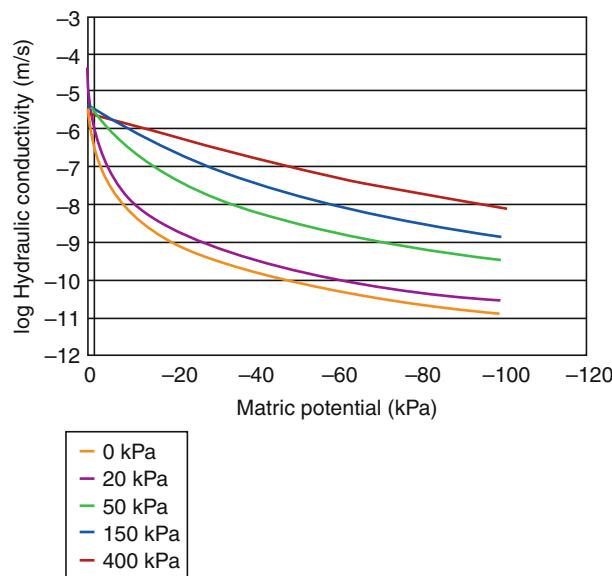

Even more important is the increased relevance of the anisotropy of hydraulic functions. Mualem (1984), Tigges (2000), Doerner (2005), and Doerner and Horn (2009) documented the increasing effect of stress-and shear-affected horizontal anisotropy of the hydraulic and gas permeability, which coincides not only with a retarded gas exchange and an increased proportion of, e.g., CO₂

in the pores but which will also result in an enhanced lateral water flow and soil erosion. Figure 4 documents the stress-and strain-induced changes in hydraulic properties and functions.

Effect of soil management on gas composition

Each reduction in conducting coarse pores also result not only in a prevented CO₂ exchange to the atmosphere and a prevented O₂ flux in the soil but will also lead to anoxic conditions in the soil, which will also affect the quality and quantity of the emitted gas (Glinski and Stepniewski, 1985).

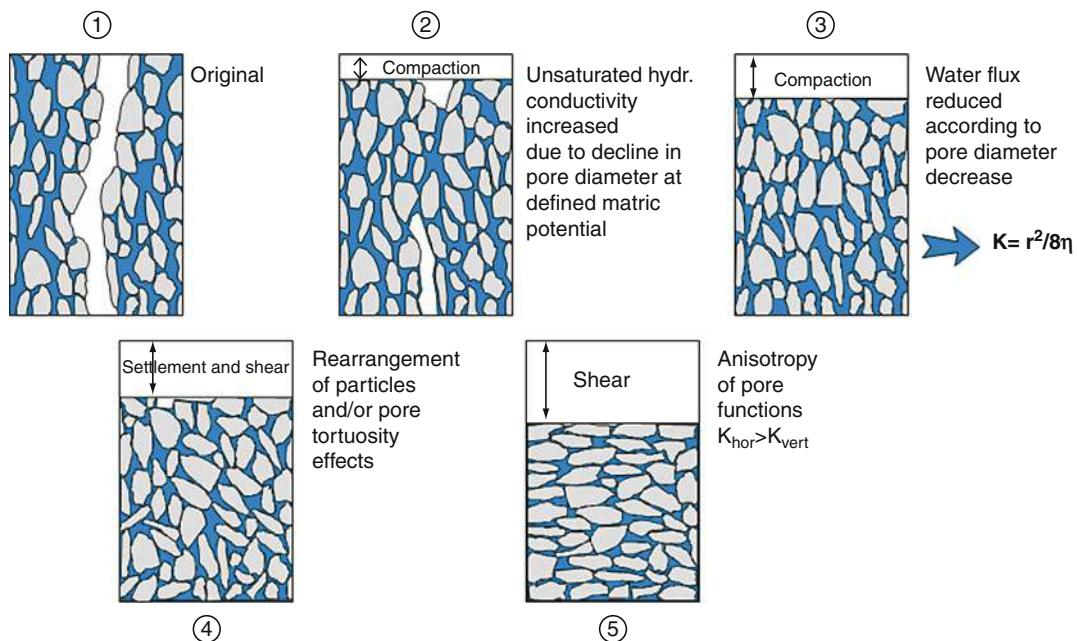

Aeration and gas exchange in soils always depend on the microbial composition and activity, which depending on the pH value and water saturation can lead to an enormous alteration of the gas composition, microbial activity and composition, and redox potential values. As an example of possible stress effects on redox potential changes in dependence of the internal soil strength (expressed as

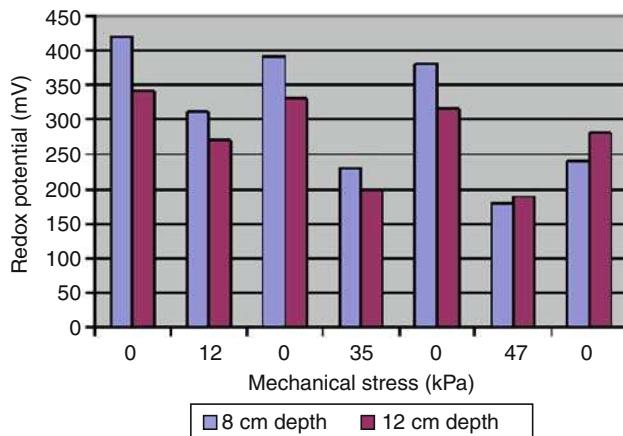

Management Effects on Soil Properties and Functions,
Figure 3 Stress-dependent change of hydraulic properties: hydraulic conductivity as a function of matric potential.

precompression stress) Figure 5 informs stress-dependent Eh value changes in an Ah horizon of a Cambisol. It can be seen that stressing with up to 35 kPa followed by a stress release (0 kPa) at both depths always resulted in a complete recovery. If exceeding the internal soil strength of approximately 42 kPa by a further increase to 47 kPa a significant and irreversible decline was detected with no recovery after stress release. Thus, all chemical elements, which undergo a valence change, depending on the actual Eh value at the given pH may be also mobilized and translocated to the more aerated soil volumes. Amongst the Eh-sensitive elements are under more un-aerated soil conditions, e.g., from the completely aerated condition: NO_3^- (to N_2O or at last NH_4^+) or CO_2 (to CH_4 in case of complete anoxic conditions) as well as Fe^{3+} to 2^+ or Mn^{4+} to 2^+ . Thus, also the chemical compositions of the gas composition in the soil or that of the seepage water are affected.

Ball et al. (2000), e.g., described the effect of N_2O emission due to wheeling throughout the year and also included N-fertilization. In compacted soils, N_2O emission was significantly increased after fertilization and especially if in addition rainfall had re-saturated the soil. Under zero compaction, no intense changes were to be seen, which can be explained by a higher water infiltration rate and a quicker reaeration of the coarse and gas and water-conducting pores. If we further consider the compaction dependent reduction of CH_4 consumption in soils, which is approximately 50%, we can also calculate the CO_2 equivalents from CH_4 consumption are texture dependent (Teepe et al., 2004): 47 kg ha^{-1} a (silty clay loam), 157 (silt), and 249 (sandy loam). Assuming that

Management Effects on Soil Properties and Functions, Figure 4 Stress and strain effects on hydraulic properties.

Management Effects on Soil Properties and Functions,
Figure 5 Redox potential values as a function of applied cyclic mechanical stress. Cambisol Ah horizon, pH: 5.2, -60 hPa (data taken from Horn, 1985).

only 6% of the area was compacted, the reduction of the CH_4 consumption in terms of CO_2 equivalents resulted in 4, 11, and 13 $\text{kg CO}_2 \text{ha}^{-1} \text{a}^{-1}$. In forest soils, the spatial pattern of the depth dependent CO_2 concentration reveals a significant increase directly below the wheel track, which fades off to the side and to the depth (Figure 6).

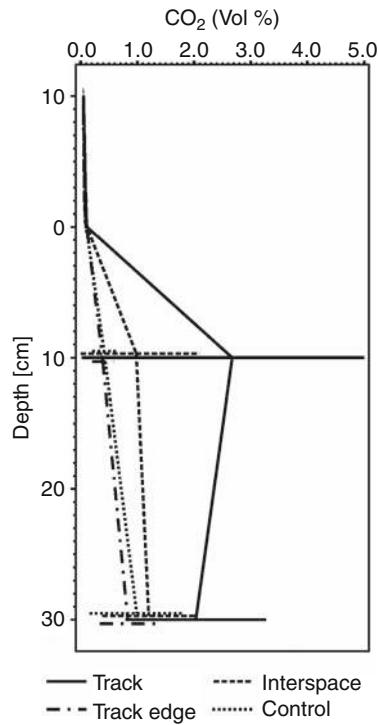

Based on the dataset of Stepniewska et al. (1997), a soil texture-dependent resistivity values for a given redox potential value of 300 mV could be used to quantify the resistance against Eh changes. If 300 mV irrespective of the stress applied at a given texture is still available after 5 days, we could classify the soil as rigid. If, on the other hand, within less than 3 days the critical value is further declined a more severe stress effect has to be considered.

Soil deformation and thermal properties

Denser, less aerated, and more water saturated soils are not only less aerated but they are mostly cold due to the higher specific heat capacity and thermal conductivity.

Additionally, radiation effects are reduced during cold nights but as a negative effect also the often expected freezing effect for structure reamelioration is furthermore reduced.

Under European climatic conditions, such soil amelioration is mostly restricted to the plowed A horizon but does not deeper down. Even if the subsoil gets frozen, the ice lense formation gain would primarily create a horizontal platy structure due to water volume expansion during freezing. Furthermore, we have to evaluate the orientation of newly formed pores, which as soon as they are mostly horizontally oriented would collapse during the following restressing of the topsoil during trafficking.

Management Effects on Soil Properties and Functions,
Figure 6 CO_2 -concentration in the soil air at different depths and distance from the wheel track due to the application of a chain harvester (45 Mg) in the Black Forest. The wheeling was carried out in 2000 (taken with courtesy from J. Schäffer, 2005).

Soil deformation and microbial activity

Soil compaction causes a reduced accessibility for soil microbes, which may be partly not negative because the damages caused by ingestion through collemboles and mollusk are reduced. The activity of earthworms (penetration and formation of new burrows) depends on the internal soil strength. They can apply up to 200 kPa lateral pressure in order to translocate soil particles to the side and even 100 kPa in radial direction. The less intense the tillage treatments the higher are the number of earthworms. Under conservation tillage, more than 100 individuals were counted per meter square, while less than ten were available at the same time under conventional tillage in a luvisol derived from loess. However, even if we consider these 100 individuals/m² their activity results only in the realevation of 30 Mg/ha *a (for year), which is an enormous amount but less than 1% of the strain-affected soil compaction. McKenzie et al. (2009) documented that earthworms like *Lumbricus* and *Allolobophora* species can withstand high external stresses, which is not the fact for mesofauna: acari and collembolae, which will be squeezed under the wheels even within the top 30-cm apart from the fact that soil compaction and deformation result in a retarded aeration and accumulation of CO_2 or even CH_4 in soil pores and hinders the normal population growth.

Consequences of soil deformation on further environmental processes

The effects of soil compaction on plant growth are widespread. They depend not only on the intensity of soil compaction but also on the plant properties themselves.

The closer to the soil surface and the thicker the compacted layer is, the more pronounced negative effect on plant growth and yield. It is essential to analyze whether or not the compacted soil layer is completely impermeable or there are still a few coarse pores, which can help to reach the deeper and less dense soil layers and to overcome such limitations in the topsoil. Oxygen deficiency results in a reduced root growth, increased CO₂ and ethylene concentration and the formation of short-chained fatty acids in the soil. Because the stress propagation with depth is always three-dimensional, we also have to analyze the effects in deeper depth because compacted areas at depth will be mostly surrounded by roots but not penetrated and cause a reduced availability of nutrients and also of oxygen at these depths.

Consequences of soil deformation on soil erosion

It is obvious that stress application always results in the formation of a platy structure and horizontally oriented coarse pores, which increase the horizontal hydraulic conductivity and result in an increased water and solute transport. Among others Fleige (2000) proofed that the soil loss due to water erosion in the slightly sloppy glacial till region of Schleswig Holstein increased ten times compared to non compacted sites and also resulted in a downhill mass transport of more than 35 Mg ha⁻¹ a⁻¹ and the formation of a colluvisol in the flatter region (onsite damage compared to the even worse offsite effects).

Some remarks on crop yield

From the agricultural point of view, crop yield and the net benefit are the main criterion. Thus, yield decline of up to 35% in the first year after soil compaction are to be considered as more than critical. But even if these reductions are only rarely to be seen the uncertainty of getting sufficient yield continuously increased over the years. At present, more than 32 Mio ha of arable soils are irreversibly degraded even only in Europe due to soil compaction the effect is even continuously increasing in recent years. The yield decline due to soil compaction for sugar beets can be derived from the smaller beet weight per ha also because the destruction of the beets during harvest is increased.

Van den Akker et al. (1999) mentioned that a single wheeling with a 38 Mg sugar beet harvester results in an annual yield loss of 0.5%, which sums up to approximately 100 Mio € a⁻¹ loss calculated on the basis of 500,000 ha in Europe.

If the machine mass of the sugar beet harvesters increases with 5 Mg/10 years (as it was the fact in the past), we have to even expect higher yield losses in the future. Concerning the yield losses of corn in the USA

we have to consider approximately 6%/year due to soil compaction while corresponding losses of grain in the former USSR results in 7–8% of the total yield; sugar beets showed a decline by 3% while corn yield was lowered by 4% due to soil compaction effects. Finally, in Germany the often predicted wheat yield increase due to the beneficial climate, soil and genetic properties of the seeds under the improved CO₂ concentration in the atmosphere and the higher temperature only resulted in 0.1 Mg ha⁻¹ a⁻¹ in Schleswig Holstein while in Bavaria the yield remained only constant irrespective of all these improvements because the proportion of the headland increased because of the larger machines, which require more space for turning round in comparison to the total field area.

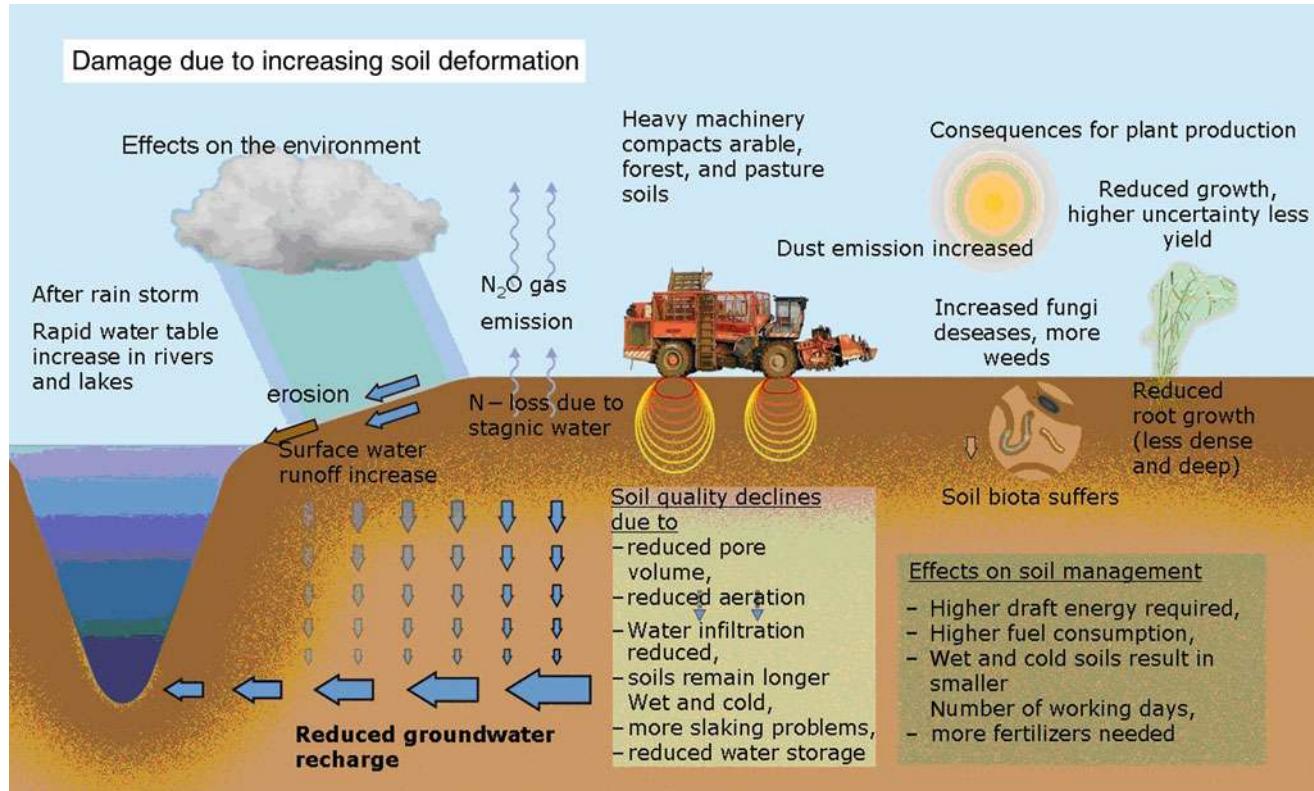

Effect of soil structure degradation on the landscape hydrology

Deep drainage of rainwater requires permeable soils with a continuous and large pore system. As soon as the arable landscapes remain compacted with a reduced water infiltrability (can be reduced up to three orders of magnitude) and storage capacity. Very pronounced are these effects during and after heavy rainstorm events and can result in an increased surface water runoff also in combination with a pronounced nutrient and heavy metal leaching. If during a rain storm most of the pores become water saturated but only the coarse pores (which due to soil compaction are reduced in diameter and total amount) are still aerated but additional rainwater will completely saturate the soil volume, then the storage capacity is quickly filled and all the additional rainwater will result in surface water runoff.

If we further assume that the natural saturated hydraulic conductivity of uncompacted soils in the loess area with approximately 40% pore volume reaches 2.7 cm day⁻¹ on average we can assume a corresponding water infiltration of 2.7 cm day⁻¹ at a hydraulic gradient of 1. If due to soil compaction the hydraulic conductivity is reduced to 1 cm day⁻¹ but the rainfall is the same as before, 1.7 cm day⁻¹ of water contribute to the surface water volume. If we now multiply this amount with the total landscape area, the small value of 17 l m⁻² result in 17,000 m³ km⁻². Thus, the high floods in riverbeds like the Rhine or Elbe in Germany can be easily also related to the negative effects of subsoil compaction. Soil slaking due to the kinetic energy input of the water droplets, which is the more pronounced, the higher is the initial water saturation in combination with the increased shear forces of the water suspensions result in an even higher soil deterioration and soil loss (for more detailed information see Van der Ploeg and Schweigert, 2001 and Gieska et al., 2003).

Protection measures

The worldwide identical tendency of increased machine masses at an identical contact area pressure, which is far beyond the acceptable values for a sustainable land management prevent a natural reamelioration of the

Management Effects on Soil Properties and Functions, Figure 7 Summary of the effects of stress application on soil properties and functions (translated and slightly modified from van der Ploeg et al., 2006).

precompressed (= overcompacted) soils by increasing the pore volume and improved pore continuity. In order to gain better and safer growth conditions, these precompressed (= overcompacted) and deformed soils must be improved by more site-adjusted soil management systems (conservation instead of conventional tillage and a more intense shrinkage due to water uptake by roots followed by a corresponding increased soil shrinkage and stabilization. The consequent application of traffic lanes for all field operations would result in normal compacted seedbeds in between (like in horticulture) with highest yields, the consequent application of machines, which are light and have a contact area pressure smaller than the precompression stress over depth throughout the years/decades will certainly result in a newly arranged and stronger pore system, which guarantees a better aeration and quicker water infiltration linked with a better rootability.

In the past, numerous approaches tried to improve the effectiveness of the machines and to reduce the soil deformation risk but all attempts like reduced tire inflation pressure, belts, larger tires were not as successful as expected because the main problem remains the still increasing machine mass and/or the frequency of wheeling throughout the year. The final concluding picture, which underlines the multidisciplinary effects of soil deformation on site properties is shown in Figure 7.

Summary

The rigidity of soils depends primarily on the internal particle arrangement and thus on the rigidity of the soil structure, which guarantee gas, water, heat, and nutrient transport and exchange processes. If, however, the external stresses applied exceed the internal soil strength, not only the pore system collapse and will be diminished in volume and size but also the pore continuity and the accessibility of surfaces (e.g., for cation exchange) are negatively affected. Consequently, not only the plant growth, yield, and the predictability of them become more undefined but also the emission of green house gases increases or flooding events will occur more often.

MAPPING OF SOIL PHYSICAL PROPERTIES

Jan Gliński¹, Janusz Ostrowski²

¹Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland

²Institute of Technology and Life Sciences, Raszkow, Poland

Definition

A map is a visual reflection of an area drawn to different scales. To illustrate special purposes thematic maps are designed.

Introduction

Soil physical properties show great variability as well in vertical as horizontal scale. Their significance for

agricultural and environmental purposes requires maps (Várányay, 1989; Várányay, 1994; Stepniewska et al., 1997; Ostrowski et al., 1998; Wösten, 2000; Walczak et al., 2002a; Duffera et al., 2007; Iqbal et al., 2005; Leenhardt et al., 2006; Santra et al., 2008).

One can distinguish two groups of soil physical properties which are mapped:

- Current such as: water content, soil temperature
- Not significantly dependent on time such as soil mineral composition, texture, specific surface area

Maps can reflect:

- Physical short-lasting properties such as soil moisture, soil temperature.
- Physical long-lasting processes such as soil erosion and soil desertification. These maps are continuously repeated.
- Soil physical properties based on their spatial variability.

A variety of different techniques are used for construction of maps of soil physical properties. They are based on: delineation of soil units, which represent areas of determined classes of soil physical property units, remote sensing, digital format, and spatial interpretation of point-based measurements of soil physical properties. The conversion of point data into continuous raster maps allows the survey data to be incorporated into computer and more easily used for decisionmakers (Taylor and Minasny, 2006). Maps can be prepared on the basis of existing data or on data coming from analyses of field soil samples derived from representative places (areas) appointed in advance. Most maps of soil physical properties concern top soil layers, but for modeling of environmental processes mapping of deeper soil layers is also made (Stepniewska et al., 1997; Stawiński et al., 2000; Walczak et al., 2002a; Walczak et al., 2002b). Within soil taxonomic unit areas of some soil maps, the extent and distribution of physical properties such as texture and hydrology are distinguished (Białousz et al., 2005). Now, the general procedure applied in the preparation soil maps is based on the estimation semivariogram parameters of soil properties using geostatistical tools and further applying them to drawing maps using ordinary kriging (Usowicz et al., 1996; Santra et al., 2008).

Computer maps of physical properties of soils

Wösten (2000) elaborated the map of total available water for plants on a European scale. In his work he based on the database of HYdraulic PROPERTIES of European Soils (HYPRES) which contained information on about 4,500 soil horizons representing 95 different soil types of 12 European countries. Computerized manipulation of this database and its derived pedotransfer functions in combination with the 1:1,000,000 scale Soil Map allowed for the generation of the spatial distribution of soil water availability within Europe.

On the smaller, regional (country) scale application, the construction of maps of field water capacity, water conductivity, specific surface area, redox properties, and also potential denitrification in soils is presented on the example of Poland. These maps were prepared in cooperation between two institutes: the Institute of Agrophysics of the Polish Academy of Sciences in Lublin and the Institute of Grassland Farming and Land Reclamation in Falenty.

Construction of maps

Polish soils (mostly mineral arable soils) are very much differentiated in terms of their origin, connected with different parent rocks (mostly sands, loams and silts of glacial and post-glacial formations), location in the landscape (lowlands, uplands, mountains), and influences of climate which has a transition character between the maritime and continental. On the surface of the land, they form a mosaic of various soil taxonomic units which are cartographically presented on maps of different scales. According to the FAO classification they are Rendzinas, Phaeozems, Cambisols, Luvisols, Podzols, Fluvisols, Gleysols, and Histosols (Białyusz et al., 2005). The preparation of maps of physical properties variability and differentiation of Polish arable soils was based on data derived from the existing Bank of Soil Samples (Gliński et al., 1992) stored in the Institute of Agrophysics in Lublin. The samples represent 29 soil units of similar properties concerning homogeneous areas (Table 1), distinguished on the basis of works of the Institute of Soil Science and Plant Cultivation in Puławy (Witek, 1974).

The area of soil units ranges from 380 to 40,980 km² in terms of their appearance in Poland. Each of the unit is represented by a number of soil profiles in proportions appropriate to its area. Soil samples with disturbed and undisturbed structures were taken from topsoils (0–20 cm), upper subsoils (20–40 cm), with predominance of the mineralization processes of the organic matter contained in it, and lower subsoils (below 40 cm) with natural features of the mineral soil substrate. This way a collection was created of soil samples coming from 1,000 soil profiles localized throughout the country, representative of the variability and differentiation of the soil cover. Soil samples collected in the Bank served for the acquisition of point data from measurements and standardized studies on physical properties of soils which were stored in the Soil-Cartographic Database (Ostrowski et al., 1998) and then computer processed to generate color maps of: field water capacity, water hydraulic conductivity, specific surface area, redox properties, and potential denitrification in soils. The maps were obtained through statistical analysis of a set of soil units and of individual measurements of random soil samples. They were plotted using computer technology by combining the results of measurements with the content of the arable land map on a scale of 1:1,000,000 and digitally recorded in the Soil-Cartographic Database. The base consists of a set of files containing the contents of the soil map and the software necessary for the storing and

Mapping of Soil Physical Properties, Table 1 Soil units, their area in Poland, and number of profiles representing particular units

No. of soil unit	Soil unit	Area (km ²)	No. of soil profiles
1	Rendzic Leptosols – pure	1,900	8
2	Rendzic Leptosols – mixed	450	8
3	Haplic Phaeozems	2,360	10
4	Haplic Luvisols and Dystric Cambisols – loose sands	40,980	169
5	Haplic Luvisols and Dystric Cambisols – light loamy sands	1,630	18
6	Haplic Luvisols and Eutric Cambisols – loamy sands	6,050	10
7	Eutric Cambisols – loamy sands over loams		26
7a	Haplic Podzols – loamy sands	18,580 (7 + 7a)	47
8	Eutric Cambisols – light loams		34
8a	Haplic Podzols – light loams	18,970 (8 + 8a)	43
9	Eutric Cambisols – medium loams		27
9a	Haplic Podzols – medium loams	9,370 (9 + 9a)	13
10	Eutric Cambisols and Haplic Luvisols – heavy loams	1,210	9

22	Eutric Fluvisols – light silty loam	700	7
23	Mollic Gleysols – dev. from loams and silts	6,600	31
24	Mollic Gleysols – dev. from sands	3,940	27
25	Terric Histosols	11,400	11
	Total	162,320	672

creating of various sorts of derivative maps relating to the soil cover (Walczak et al., 2002a). The basic file contains a map of soil units distribution. The main function of the processing system is grouping the soils into appropriate classes and then applying an identical color to the contours of all soils belonging to this class. As a result, a color topical map showing class distribution is created. In the mathematical approach, the solution consists in a topological connection of soil contours into one topical contour according to the assumed function of subordination. When working out the topical maps, a preliminary assumption is that a soil map will be introduced to the computer for the automatic generation of topical data by the input of transformation tables of soil units into topical units (expressed for given physical soil property values). The basis for the generation of a computer map image is a procedure based on an algorithm:

$$< J_{g1} \in - O_n, J_{g2} \in O_n \dots \dots , J_{gm} \in O_n > \in TJ_n,$$

where TJ_n – the nth topical unit, O_n – the nth soil evaluation, J_{g1}, \dots, J_{gm} – soil units belonging to the n evaluation.

Due to the character of the generalization of results, it was established that maps would be generated on the scale of 1:2,500,000, so that they can be sized to an A-3 format, ensuring appropriate clarity and legibility of the spatial structure of soil feature carted. It was assumed that soil

contours with a determined property would be signaled with a coloring into which other forms of land use would be incorporated, i.e., grassland, larger housing areas (towns), forests, and inland water reservoirs. Since the distribution of the above elements, supplementing the content of the map gives sufficient information on the spatial location on the country scale, no topographic content was introduced into the maps of physical soil properties such as roads, river nets, names of towns, so as not to disrupt legibility and clarity of their content or diminish their informative value. The contours shown in the color maps group mean physical properties values within the classes of the property determined preserving also individual deviations resulting from detailed studies.

Maps of hydro-physical properties of soils

The hydro-physical properties of soils play a significant role both in agriculture, through biomass production, and in natural environment through water quality. Their knowledge is necessary for the interpretation and forecasting of nearly all physical, chemical, and biological processes which occur in soil environment. Two main hydro-physical properties of soils were mapped, e.g., those concerning field water capacity (Walczak et al., 2002b) and water conductivity (Walczak et al., 2002a). Using the standard method (pressure chamber), the relation between

soil water potential and water content within the range from 0.1 kJ m⁻³ (pF 0) to 1,500 kJ m⁻³ (pF4.2) was determined in soil samples representing the plough layers, subsoils, and deeper layers. The results obtained were subordinated to ten 5% intervals from <5 to 45–50% water capacity (cm cm⁻³) and used to construct color maps for topsoils, upper subsoils, and lower subsoils. An example of one of such maps is shown in Figure 1.

Water conductivity coefficient k was determined in standard 100-cm³ cylinders filled with undisturbed soil in which holes were drilled at heights of 1, 2.5, and 4 cm from the bottom and TDR humidity measuring probes together with micro-tensiometers measuring soil water potential were installed in the holes. The soil samples were saturated with water till full water capacity was reached and then left under cover for 24 h in order to reach a state of thermodynamic equilibrium. Afterward, the samples were uncovered and their humidity level and soil water potentials (at 0.1, 16, and 100 kJ m⁻³) were monitored during evaporation. The TDR gauges were linked to a PC which made automatic measurements possible, and the values of humidity and water potential taken were recorded on the computer. These measurements were used to calculate the coefficient of water conductivity k . Its values were divided into three intervals:

- For 0.1 kJ m⁻³ – above 0.5 cm day⁻¹
- For 16 kJ m⁻³ – from 0.01 to 0.5 cm day⁻¹
- For 100 kJ m⁻³ – below 0.01 cm day⁻¹

and were then related to generalized soil units on color maps for topsoils, upper subsoils, and lower subsoils.

Maps of soil specific surface area

Knowledge of the specific surface area of soils permits joint interpretation of clay and humus content and composition in soil phenomena and processes affecting productive properties of soils and natural environment. This knowledge and cartography of this feature also makes possible better creation of spatial hydro-physical and fertility prognostic models of soil processes. Four color maps of total and external soil surface area expressed in m² g⁻¹ of soil were elaborated for the topsoils and upper subsoils (Stawiński et al., 2000). Soils for mapping were grouped in categories, e.g., eight categories of total specific surface area for topsoils: <12, 12–16, 16–20, 20–30, 30–50, 50–70, 70–90, and >90 m² g⁻¹.

Maps of soil redox properties

Redox status of soils is a base for understanding many soil properties such as composition of soil solution, soil reaction, availability of water and nutrients for plants, gases emission to the atmosphere, stability of metal-organic compounds, electrokinetic soil properties, biological activity, and others. Redox potential (Eh) is a measure of soil aeration status. When analyzing soil properties under oxygen deficit due to an excessive soil moisture, a new term – *redox resistance*

of soil was found purposeful to introduce (Gliński and Stepniewska, 1986). Its measure is a time (in days) after which, in a fixed conditions of moisture (full saturation with water) and temperature, soil Eh drops below 300 or 400 mV. These values, named t_{300} and t_{400} indicators, correspond with the reduction of iron and manganese in soil at 300 mV and nitrate decomposition at 400 mV. For surface layers of Polish soils, at a temperature of +20°C, values of t_{300} range from 0.2 to 4.4 days and t_{400} from 0 to 1.7 days. For deeper layers they are higher. The color maps, in the amount of 33, were gathered in the Atlas of the Redox Properties of Arable Soils in Poland (Stepniewska et al., 1997).

These maps show:

- Soil redox resistance indicators t_{300} and t_{400} of plough layers, subsoils and deeper layers at the temperatures of 4°C, 10°C, 15°C, and 20°C for t_{300} , and 4°C, 7°C, and 20°C for t_{400}
- Standardized redox potential (Eh at pH 7) at two temperatures 4°C and 20°C

The maps may be used for:

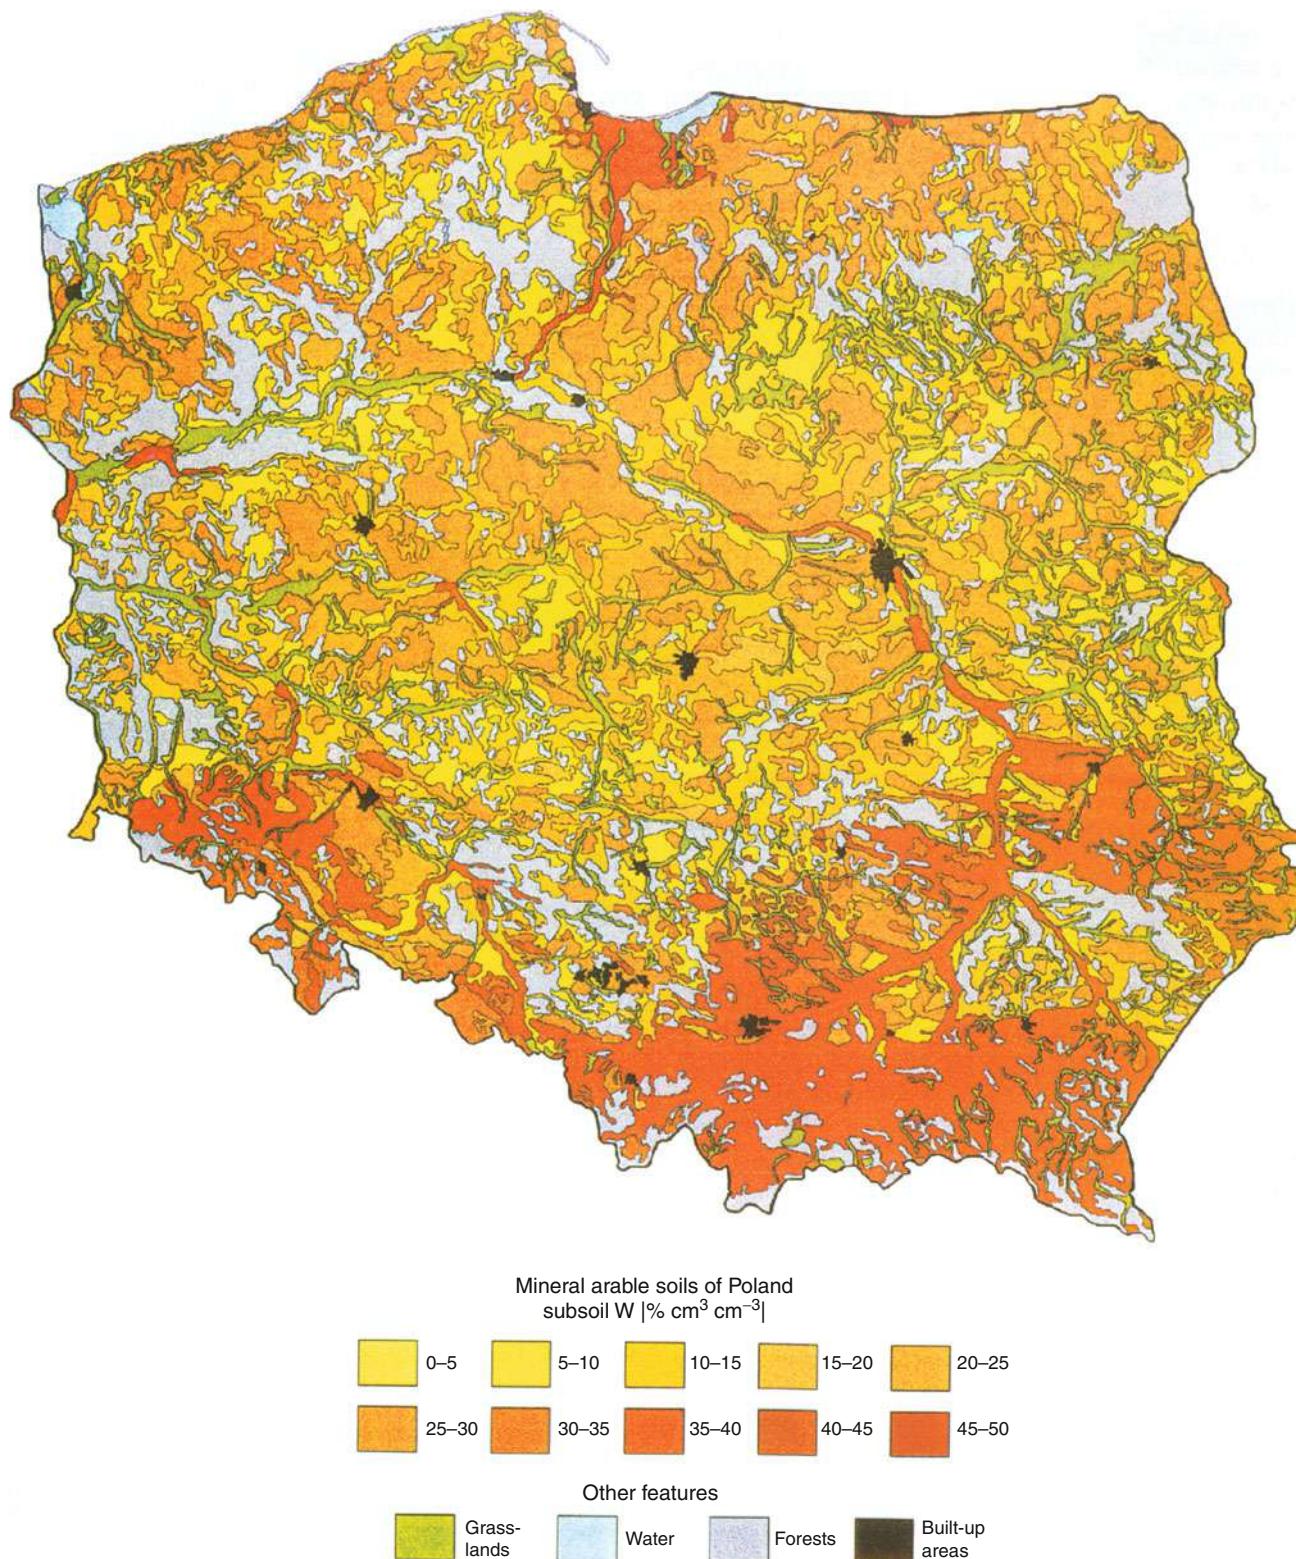

- Evaluation of hazards and agricultural damage (e.g., crop yield losses) connected with temporal water saturation of soil.
- Estimation of ecological damage connected with nitrogen losses due to denitrification and the emission of nitrous oxide (strong greenhouse gas) to the atmosphere.
- Prediction of negative ecological and agricultural effects of climate change.
- Using t_{300} and t_{400} values for land reclamation design and as an environmental parameter for hydrological calculations (admission time of soil waterlogging).

Map of potential denitrification in soils

Denitrification of nitrates (V) is the main mechanism responsible for N₂O production in ecosystems under hypoxic conditions. To show its importance the term *potential denitrification (PD)* was proposed as an important feature in agriculture (efficiency of nitrate fertilization) and natural environment (greenhouse gas emission). The formula used for the calculation of PD (kg ha⁻¹ day⁻¹ N–N₂O) is based on the knowledge of soil redox resistance indicators t_{300} and t_{400} , nitrogen content C_{NO_3-N} (mg (kg soil⁻¹)), soil layer thickness H (m), and soil bulk density d (Mg m⁻³):

$$PD = 10HdC_{NO_3-N}/t_{300} - t_{400}.$$

The analyses carried out on about 700 samples representing topsoils gathered in the Bank of Soil Samples allowed to calculate PD for soil units of the entire territory of Poland. On the basis of homogenous values of potential denitrification six groups of PD were distinguished (<7.5, 7.5–15, 15–30, 30–50, 50–80, and >80) and presented in the form of a map (Gliński et al., 2000).

Mapping of Soil Physical Properties, Figure 1 Map of water retention at field water capacity (pF 2.2) of Polish soils. (From Walczak et al., 2002b.)

Conclusions

Maps constructed on local (plot, field) and regional scale showing distribution of soil physical properties have a definite area of interest, e.g., for irrigation planning, soil water management, land reclamation, precision agriculture (precision farming, precision tillage), drought mitigation, and efficient use of fertilizers. They are also essential for modeling various current and predicted soil physical properties (processes) and are helpful for decisions on application of these management practices to defined soil areas.

MECHANICAL IMPACTS AT HARVEST AND AFTER HARVEST TECHNOLOGIES

Zbigniew Ślipek, Jarosław Frączek
 Department of Mechanical Engineering and Agrophysics,
 University of Agriculture, Kraków, Poland

Definition

Mechanical impact. A complex of physical phenomena that takes place at impact of two or more bodies.

Harvest technology. A sequence of activities and operations occurring one after the other, performed by machine or carried out manually in order to gather the ripened crop from the field.

After harvest technology. Operations regarding the handling of harvested crop, including transportation, sorting, cleaning, drying or cooling, storing, and packaging.

Introduction

Each technological system of harvest and post-harvest handling requires the use of machines whose operating elements bring about plant material load, thus permitting the end product to be satisfactory both in terms of quantity and quality (Figure 1). On the one hand mechanical impact is required in order to permit the machine to function according to its purpose, but on the other hand this often causes undesired effects (loss). The desire to increase

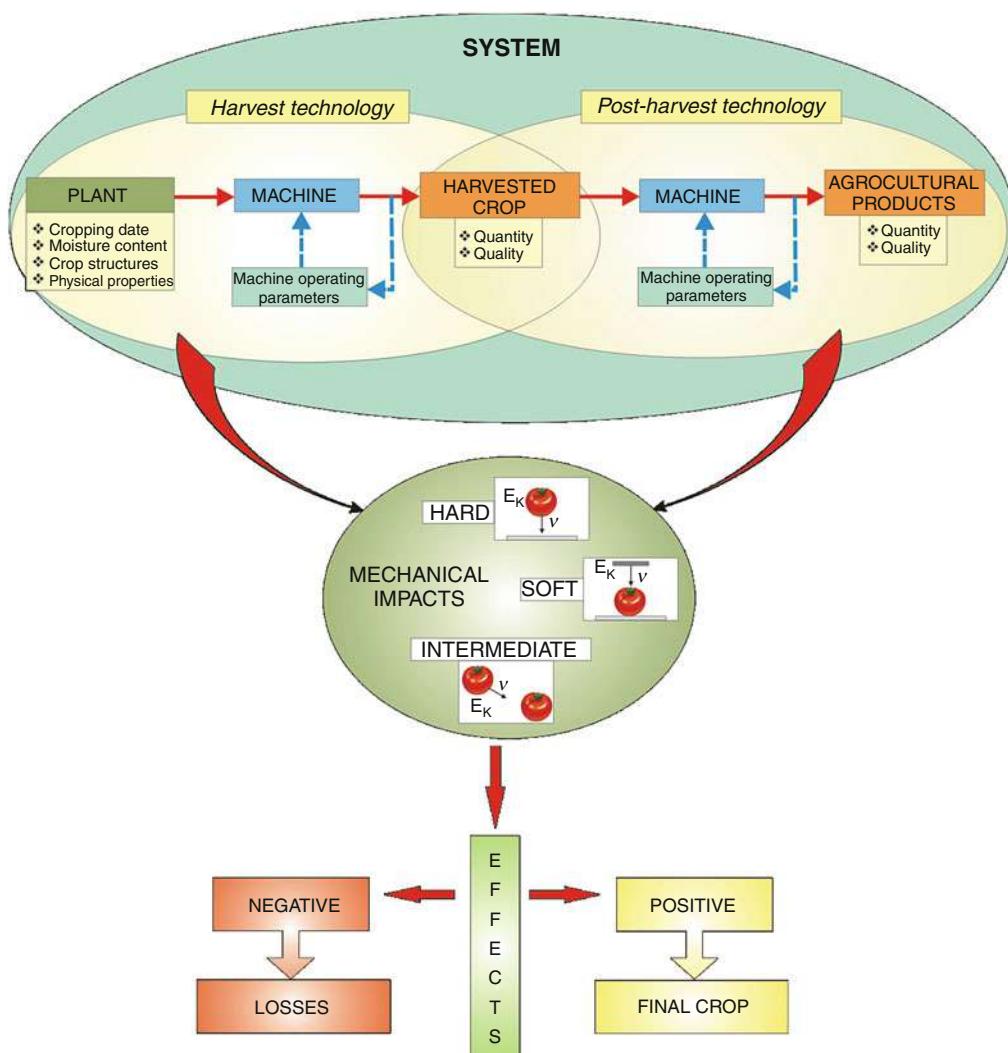

machine output is connected with the ever more aggressive impact of machines on material, which usually leads to greater damage being caused to crops.

There are two ways in which the rational use of machines for harvest and post-harvest handling may take place:

- By appropriate selection and by steering the operating parameters
- By selecting the best time for performing the technological process

Theory

Machine–plant interaction that takes place during the post-harvest collection and handling process is primarily of an impact nature. Concerning the physical description of interaction that occurs in such situations, it is necessary to take into account the mechanics of impact and its implication to plant materials (Mohsenin, 1986).

Mechanical Impacts at Harvest and After Harvest Technologies, Figure 1 Machine–plant material system relations.

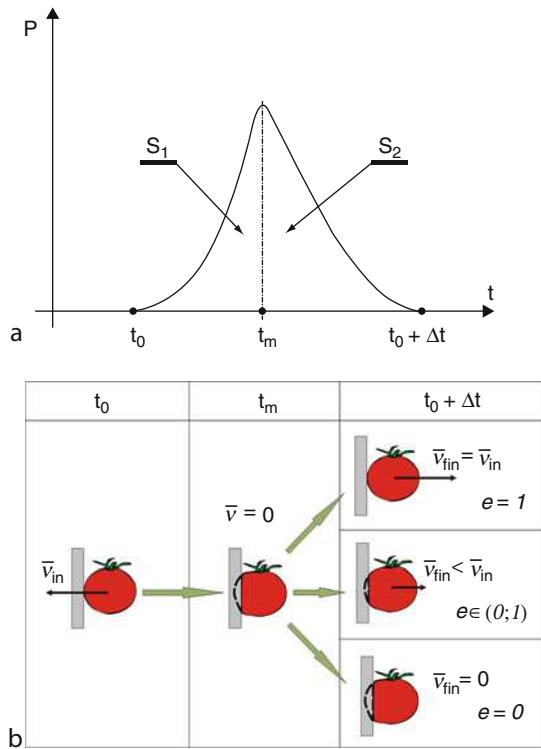

In order to indicate the presence of forces during impact it is necessary to consider the mechanical properties of both the impacting object and the object being impacted. A typical characteristic of impact is the occurrence of so-called instantaneous forces, which act very briefly ($\Delta t \rightarrow 0$) and attain high values in comparison to other forces that occur. The measure for instantaneous forces is the impact pulse:

$$S = \int_{t_0}^{t_0 + \Delta t} P(t) dt \quad (1)$$

where S – impact pulse t_0 – moment of occurrence of the instantaneous force Δt – time of operation of the instantaneous force $P(t)$ – instantaneous force.

The course of impact may be divided into two phases: compression and restitution (Gilardi and Sharf, 2002). The first phase, which involves a sudden increase in force, starts as soon as the bodies encounter each other at t_0 point and end at t_m point when distortion attains maximum value (Figure 2a). The relative velocity of both bodies is then equal to zero. In the second phase instantaneous force decreases. The shape of the $P(t)$ curve depends on:

- The elastic–plastic properties and dimensions of the impacting bodies

Mechanical Impacts at Harvest and After Harvest Technologies, Figure 2 Body impact against a motionless obstacle (a) change of instantaneous force; (b) types of impacts.

- Body surface shape (particularly at the point of contact)
- The direction of the velocity vector
- Impact energy value
- Freedom of distortion

For plant materials this curve is determined empirically. S_1 and S_2 , impact pulse values, respectively in phases one and two of impact, serve the purpose of determining the restitution coefficient:

$$e = \frac{S_1}{S_2} \quad (2)$$

It defines the proportion between elastic and plastic distortion. If $e = 1$ we have to do with ideally elastic impact; however for $e = 0$ impact is ideally plastic. For true plant materials “ e ” belongs to the $(0; 1)$ range and to a very large degree depends on the moisture content of the material (the lower the moisture content the greater the restitution coefficient). It is determined when a body impacts a motionless obstacle (Figure 2b). In such cases normal velocity is defined: initial v_{in} and final v_{fin} , while the restitution coefficient is calculated as the ratio of both velocities.

Total distortion ε that takes place during impact is the sum of elastic distortion ε_s and plastic distortion ε_p . The magnitude of these distortions depends on anatomical and morphological structure and the physical properties of plant material. The anisotropicity of these types of materials hinders any clear definition of mechanical and endurance parameters, which are very strongly correlated with moisture, which has a decisive influence on elastic and plastic properties (and therefore on the type of distortion). Plant materials with large water content are dominated by plastic traits, while dry material contains elastic or brittle characteristics. This is reflected in the effects of impact. Concerning materials with large water content, the energy of elastic distortions constitutes only a small part of overall distortion energy. During harvest and post-harvest handling one may distinguish the following types of load (Figure 2b):

- Hard – these are manifest when the initial value of E_{in} impact kinetic energy is dissipated by the impacting body (e.g., the fall of an apple, tomato, or melon onto the hard surface of a crate leads only to the distortion of the impacting fruit).
- Soft – this is the kind of impact in which distortion of the impacted body is considerably greater than distortion of the impacting body (e.g., the impact of a beater against threshed material leads only to the distortion of the impacted plant mass).
- Intermediate – this is the simultaneous distortion of the impacting body and of the impacted body (e.g., the fall of a single piece of fruit onto a pile of fruit kept in a container leads to all of the impacted bodies being distorted).

In terms of agrophysics the negative effect of impact is plastic distortion, which leads to a permanent deterioration

in the quality of the biological material. The following should be distinguished:

- Local distortion – these cover a relatively small area that focuses immediately on the point of impact and leads to different types of micro-damage (abrasion, skin puncture, etc.). These distortions are the result of instantaneous force and depend on local plant material susceptibility and the shape of the surface at the point of contact.
- Global distortion – these appear in the form of disturbance waves (distortions, stress) covering the entire volume of the impacted body. Under such circumstances permanent distortions appear on a macro scale (grain fragmentation, tomato cracking, apple crushing etc.).

It must be noted that surface and internal stress caused during impact are far greater at the point of contact than beyond that point.

Harvest and after harvest processes – agrophysical aspects

Grain crops

Most frequently the harvesting of these plants takes place in the form of a single phase. The technological process involves the cutting of plants, transport, threshing, separation and cleaning, and the gathering of grain (seed) in a container. In combine-harvesters, the most intensive effect on plant material takes place in the threshing unit which, depending on the construction, threshes by striking, wiping, and vibrating the threshed material. Threshing drum operations considerably distort plant mass (e.g., cereals) by soft impacts, which, depending on instantaneous contact conditions (moisture content in grain, grain orientation in terms of the working element, collision velocity, and friction) could lead to total grain fragmentation or to a variety of damage to the grain. Low intensity threshing which is favorable in terms of mechanical damage (low drum revolutions, large operating slot between the drum and the threshing floor) may, however, cause grain loss through incomplete grain threshing.

Threshing output and effectiveness depends on:

- The properties of the threshed material (type and variety, material threshing capacity, moisture content, the elastic properties of stalks or culms, the ration of grain to straw, and others)
- Technical conditions (the type of threshing unit, regulating parameters, and others)
- Threshing unit feed (the volume of feed, evenness, the arranging of plants in the threshing layer, and others)

The operating parameters of modern combine-harvesters may be steered electronically, on the basis of information on the exit and entry points of harvested material, supplied online. The implementation of information

used for steering purposes is the subject of research. The gauging of the mechanical properties of plant material, including susceptibility to mechanical impact, is carried out at laboratory workstations, which permit the application of precise loads under determined and controlled conditions (Kang et al., 1995).

Transport, cleaning, and drying take place after the harvesting of grain. During these processes the material is subject to a variety of additional mechanical impacts. The danger of damaging the grain during these processes is, admittedly, far smaller; however, mechanical load may overlap and the damage previously caused to grain may become worse (Frączek and Ślipek, 1999). This leads to a reduction in raw material quality during storage (infestation by microorganisms, the settling of pests, increased respiration intensity) and processing. Mechanical damage to grains to be used as seeds (in particular damage to the germ) may reduce their ability to germinate and emerge.

Fruits and vegetables

The market of today requires that fruits and vegetables, in particular those items intended to be eaten directly, be of high quality – this includes the right shape, color and, above all, the absence of any damage. The collection of these products with the use of machines, therefore, requires that extreme care be exerted as a result of load impact. The technological collection of fruit is based on the mechanical effects of vibrating or rotating parts.

Mechanical collection from trees usually takes place by means of vibration (e.g., Mateev and Kostadinov, 2004). The fruit falls on special screens which are spread out beneath the crowns of trees or (when using simplified technologies) directly onto the ground from where it is gathered and loaded onto containers. These types of technologies are primarily used when fruit is collected for processing.

Fruits such as raspberries, currants, gooseberries, and strawberries are collected with the use of harvesters only for processing purposes. Collection for consumption purposes still takes place by hand. That does not mean that with this technology the fruit does not come in direct contact with mechanical elements. During collection various types of devices are used in order to facilitate manual collection and increase output (conveyors, elevators). In recent times, the use of autonomous robots for collecting fruit considerably decreases load impact, which is the reason why fruit gets damaged. Further development of these robots will undoubtedly help reduce the damage caused to fruit, particularly if collected for direct consumption purposes.

During the mechanical collection of fruit it is also important to make sure that machines operate under conditions not permitting any considerable damage to occur to the parent plant because of the need for yielding in the next vegetation season.

The main purpose of post-harvest technologies is to increase the added value of the product. Various technological lines perform the selection, cleaning, washing, sanitation, classification, weighing, and packing of products. While these technologies are in operation, mechanical influence, admittedly, takes place at low mechanical speed, but still the fruits and vegetables are exposed to the danger of damage and bruising (e.g., Ragni and Berardinelli, 2001). When products are subject to gravitational transport or change the direction in which they move they are particularly prone to damage.

The technologies for collecting vegetables usually involve separating the usable part growing above the ground (e.g., cabbage, cucumber, tomato), extracting the root (e.g., carrot, parsley) or tubers (potatoes), separation, gathering the yield, and transporting it. Most frequently machines damage the skin and bruise the harvestable products. During post-harvest handling the products are calibrated, washed, weighed, and packed. Multiple impact events and associated damage result later in greater respiration intensity and loss of storage life.

Conclusion

Originally, research in agrophysics concentrated on assessing various mechanical traits of agricultural plants and was based primarily on destructive methods. In recent years a range of nondestructive methods of assessing the physical condition of plant material has been elaborated (e.g., Ortiz et al., 2001). These methods include image analysis (size, shape, weight, surface morphology, skin color), electrical and optical properties, vibration and acoustic tests and nuclear magnetic resonance techniques. Destructive methods that offer direct information about the mechanical properties of fruits and vegetables (mechanical impact tests) are used less and less frequently when assessing the suitability of plants for collection. These tests, however, are used for verifying the methods of direct assessment, outlining the mechanical characteristics of materials for the purpose of designing machines or for modelling work processes.

Post-harvest collection and handling machines whose designs are based on comprehensive scientific know-how, should meet the requirements on high quality and safety of agricultural products. The implementation of mechatronic systems permits, to an increasingly large degree, the subtle control and steering of technological processes. Comprehensive operations aimed at improving the quality of agricultural products require thorough knowledge of machine and plant systems. It is particularly important to be aware of the physical parameters of plant material, which are quickly and easily gauged in the dynamic technological processes.

MECHANICAL RESILIENCE OF DEGRADED SOILS

Heiner Fleige

Institute for Plant Nutrition and Soil Science, Christian-Albrechts-University zu Kiel, Kiel, Germany

Mechanical resilience of soils can be defined by the value of the precompression stress (P_c), which depends especially on soil texture, soil structure, and water content. P_c is derived from confined compression tests on undisturbed, aggregated, and unsaturated soils. It is assumed that at stresses lower than the P_c , an elastic stress path exists, resulting in no extra soil deformation and thus, no change in the pore system and its function. Stresses beyond the P_c induce changes of pore functions and pore continuity because of plastic soil deformation (= degraded soil). Consequently, not only water infiltration will be reduced but it also causes reduced gas, and water fluxes, as well as water logging, interflow, runoff, and soil erosion. The prediction of the P_c and its effects on physical properties by pedotransfer functions as well as P_c -maps on different scales (e.g., Europe, Germany, farm scale) are demonstrated in Horn et al. (2005) and Horn and Fleige (2009).

MEMBRANES, ROLE IN WATER TRANSPORT IN THE SOIL-ROOT-XYLEM SYSTEM

Marian Kargol

Independent Department of Environment Protection and Modelling, The Jan Kochanowski University of Humanities and Sciences, Kielce, Poland

Introduction

This article discusses agrobiophysical aspects of soil water intake by a plant root and water transport along its radial route. In other words, this article presents certain interpretative ideas explaining the mechanisms of water transport in the soil–root–xylem system. In this context, a certain amount of basic information on membranes (cell membranes in particular) and permeability of various substances across them shall be presented first. Next, major membrane theories on the processes of water intake from the soil and its two-way transport across the root (from the soil to the xylem of the vascular cylinder, and in the opposite direction) shall be discussed. The issue of root pressure generation shall also be investigated (Fiscus, 1975, 1986; Ginsburg, 1971; Kargol, 1994, 1995, 2007; Pitman, 1982; Steudle et al., 1987; Taura et al., 1987).

Membranes and mathematical formalisms of their substance transport

Porous membranes

In general, membranes can be divided into *artificial* and *biological*. The former include, for example, cellophane, nephrophan, or collodion membranes. The latter include cell and cellular organelle membranes, as well as tissue membranes.

In research practice, we mostly deal with porous membranes. This also pertains to cell membranes. Porous membranes can be divided into two groups, that is, *homogeneous* and *heterogeneous*. A membrane is homogeneous if its pores do not differ from one another in cross-section radius dimensions. If a membrane's pores do differ from one another in their cross-section radius dimensions, it is to be treated as heterogeneous. Processes of permeability across a variety of membranes have been investigated mainly with the use of the Kedem & Katchalsky (KK) formalism equations (Katchalsky and Curran, 1965). In recent years, equations of the mechanistic formalism (MF) have been developed (Kargol, 2002, 2006, 2007; Kargol and Kargol, 2003, 2006).

Equations of the KK formalism

Transport equations of the KK formalism have been derived on the grounds of linear thermodynamics of irreversible processes, basing on a model of a membrane treated as a “black box.” A practical version of these equations may be thus written:

$$J_v = L_p \Delta P - L_p \sigma \Delta \Pi, \quad (1)$$

$$j_s = \omega \Delta \Pi + (1 - \sigma) \bar{c}_s J_v, \quad (2)$$

where J_v and j_s are density of the solution volume flow (v) and density of the solute flow (s); $\Delta P = P_2 - P_1$ is the mechanical pressure difference between P_2 and P_1 ; $\Delta \Pi = RT(C_2 - C_1)$ is osmotic pressure difference; L_p , σ and ω are coefficients (of filtration, reflection, and permeability); $\bar{c}_s = 0.5 (C_1 + C_2)$ is the mean concentration of concentrations C_1 and C_2 ; R is the gas constant; T is temperature.

Transport parameters occurring therein are given by the formulas

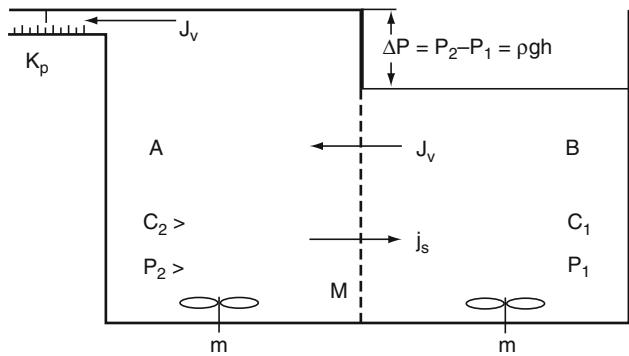

$$L_p = \left(\frac{J_v}{\Delta P} \right)_{\Delta \Pi=0}, \quad (3)$$

$$\sigma = \left(\frac{\Delta P}{\Delta \Pi} \right)_{J_v=0}, \quad (4)$$

$$\omega = \left(\frac{j_s}{\Delta \Pi} \right)_{J_v=0}. \quad (5)$$

The above notation of Equations 1 is adequate to the membrane system as schematically depicted in Figure 1. In this system, the membrane M separates the compartments A and B, filled with solutions, which satisfy the inequality $C_1 < C_2$. They are under mechanical pressures, which satisfy the relation $P_1 < P_2$. Generally speaking, the KK equations are rather difficult in terms of interpretation. This pertains particularly to the parameter ω , which appears in Equation 2. This results from the fact that this parameter, as defined by the Formula 5, is determined at $J_v = 0$, that is, at simultaneous existence on the membrane of two stimuli that satisfy the relation: $|\Delta P| = |-\sigma \Delta \Pi|$.

This means that, in the case of membranes for which σ is found in the interval $0 < \sigma < 1$, the transport of a given solute across the membrane is generated by two stimuli. Hence it follows that ω is not only the coefficient of diffusive solute permeability. The terms $\omega \Delta \Pi$ and $(1 - \sigma) \bar{c}_s J_v$ also pose problems for interpretation. According to this

Membranes, Role in Water Transport in the Soil-Root-Xylem System, Figure 1 Model membrane system with stirrers m,m (description in text).

formalism, membranes can be divided into *semipermeable* (at $\sigma=1$), *selective* (when $0 < \sigma < 1$), and *nonselective* (if $\sigma=0$).

Equations of the mechanistic formalism (MF)

In research work, we mainly deal with porous membranes. This also pertains, as we now know, to cell membranes. Consequently, in recent years, we have developed the so-called mechanistic formalism for membrane substance transport (Kargol, 2002, 2006, 2007; Kargol and Kargol, 2003, 2006). The equations of this formalism take the following forms:

$$J_{vm} = L_p \Delta P - L_p \sigma \Delta \Pi, \quad (6)$$

$$j_{sm} = \omega_d \Delta \Pi + (1 - \sigma) \bar{c}_s L_p \Delta P, \quad (7)$$

where (analogous to the KK equations), J_{vm} is the solution volume flow and j_{sm} is the solute flow. These flows are functions of the pressure difference ΔP and the pressure difference $\Delta \Pi$.

Individual terms of these equations signify filtration, osmosis, diffusion, and convection. The equations have been derived on the basis of a model of the membrane system as shown in Figure 2. In this system, the heterogeneous porous membrane M contains the statistical number of cylindrical pores permeable to water. The membrane separates the compartments A and B, which contain solutions of the concentrations C_1 and C_2 under mechanical pressures P_1 and P_2 .

In a real membrane, pores are arranged randomly. In order to facilitate the present considerations, it has been assumed that pores of that membrane are arranged according to their dimensions in one direction, from the pores with the smallest radii (r_1^{\min}), to the largest ones (r_N^{\max}). With reference to this membrane, it is possible to

find such a solute (s) with such a molecule radius r_s that the following relation will be fulfilled:

$$r_1^{\min} = r_w < r_2 < \dots < r_s < \dots < r_N^{\max},$$

where r_w is the radius of the solvent (water) molecules. Under the circumstances, the membrane M may be divided into Part (a), which contains a certain number n_a of semipermeable pores (with the reflection coefficient $\sigma_a=1$ and filtration coefficient L_{pa}), and Part (b), which contains $n_b=N-n_a$ of permeable pores. This part of the membrane has the filtration coefficient L_{pb} and reflection coefficient $\sigma_b=0$. From the above, it follows that a single pore of the membrane may take values of the reflection coefficient σ_p amounting to either 0 or 1 (Kargol, 2002, 2006; Kargol and Kargol, 2003a, b, 2006).

Having analyzed the membrane system as shown in Figure 2, it is easy to understand that $J_{va}=J_{vwa}$ is the solvent (water, w) volume flow, while J_{vb} is the solution volume flow, which permeates across Part (b) of the membrane. The flow J_{vb} has two components, that is, J_{vwb} (water volume flux) and J_{vsb} (solute volume flux). These flows, in turn, also have two components each, that is, $J_{vwb}^{\Delta P}$ and $J_{vwb}^{\Delta \Pi}$, and J_{vsd} and J_{vsk} (which are solvent (w) and solute (s) volume flows respectively). All these flows are generated by the stimuli ΔP and $\Delta \Pi$ respectively. It must be noted that in the light of this membrane model, the transport situation appears to be absolutely clear in terms of interpretation. On this basis, it also makes sense to say that the mechanistic formalism for membrane transport (MF) offers a more thorough investigation tool than the KK formalism.

On the equivalence of the equations of the KK formalism and the MF formalism

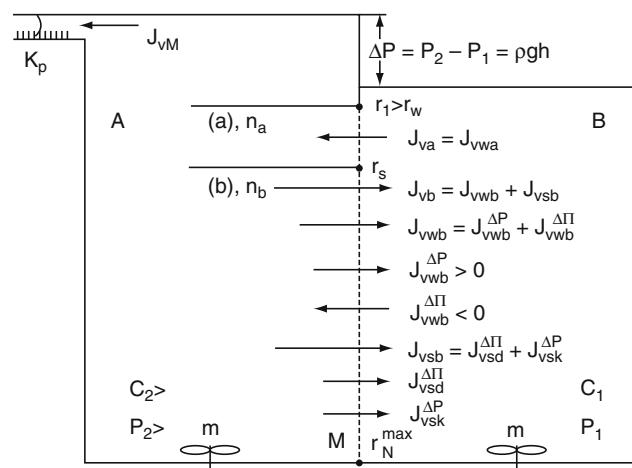

Transport equations of the mechanistic formalism (MF) may in general be treated as alternative to the equations of the KK formalism. This view results mainly from the fact that the equations for the solute flow of these formalisms, that is, Equations 2 and 7, display certain differences. Yet thanks to our introduction of the so-called transport parameter correlations between L_p , σ and ω (KK), and L_p , σ and ω_d (MF), it is easy to observe that these (KK and MF) equations are mutually equivalent (Kargol, 2007; Kargol and Kargol, 2006). The relations are given by the formulas

$$\omega = (1 - \sigma^2) \bar{c}_s L_p, \quad (8)$$

$$\omega_d = (1 - \sigma) \bar{c}_s L_p. \quad (9)$$

On the basis of the above, the following relation is obtained: $\omega = \omega_d (1 + \sigma)$.

Thanks to these relations, it becomes possible to use – for further and more thorough investigations – the enormous experimental potential (related to substance permeation across cell membranes), which has so far been obtained on the basis of the transport equations of the KK formalism.

Membranes, Role in Water Transport in the Soil–Root–Xylem System, Figure 2 Membrane system (M, membrane; A and B, compartments; m, m, stirrers).

Cell membranes as porous structures

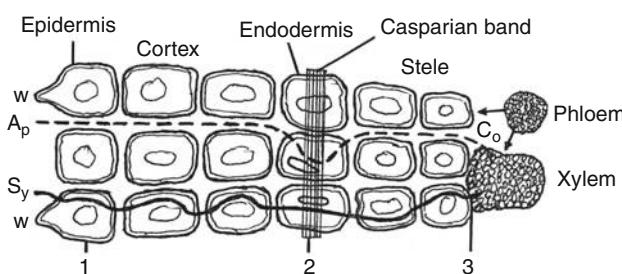

In general, it may be stated that in research practice we mainly deal with porous membranes. As is becoming increasingly well known, cell membranes are porous, too. Suffice it to say that cell membranes have various pores (channels), through which in a controlled manner various substances, including water can penetrate (Kargol, 2007; Stryer, 2000). Speaking about these pores, we also mean water channels, formed by certain transport proteins (called aquaporins). The porous structure of the cell membrane is also formed by ion channels through which (when open) not only ions but also water can pass. These channels have hydrophilic internal walls and are filled with water. Pores formed by some antibiotics, located in the lipid bilayer of the cell membrane, may also be permeable to water. Moreover, certain pores can occur directly in the lipid bilayer of cell membranes. All these pores vary from one to another in terms of their cross-section radius dimensions. They fulfill various specialized transport functions pertaining to permeability of water and various solutes through them.

Membrane ideas for explanation of water transport processes across the root

We shall now consider some basic issues related to agrobiophysical aspects of water intake from the soil by plants, and water transport across the root (Fiscus, 1975, 1986; Ginsburg, 1971; Kargol, 1994, 1995, 2007; Pitman, 1982; Steudle et al., 1987; Taura et al., 1987). The discussion of these issues will be preceded by an outline of the root structure.

Anatomical structure of the root

In the soil, the root must have particular contact with the water found therein. It is also important for the contact to occur mainly in the trichome zone of the root. This zone is the most capable of water intake. With a view to facilitating our discussion of the mechanisms of root water intake (as well as water movement to the xylem of the vascular cylinder), let us look at its main structural features. They have been shown schematically in Figure 3. The protoplasts of

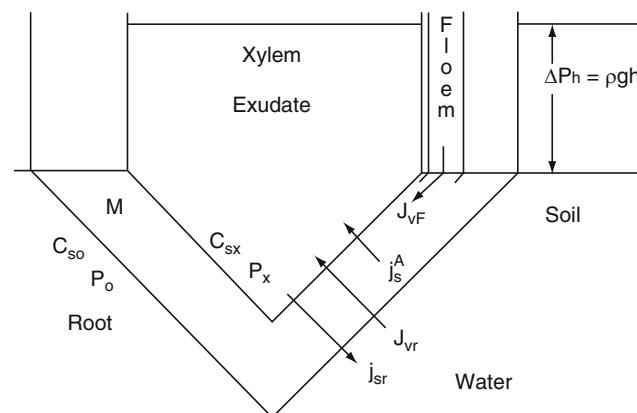

Membranes, Role in Water Transport in the Soil-Root-Xylem System, Figure 3 Fragment of root cross section, trichome zone (S_y , symplastic route; A_p , apoplastic route; w, w , trichomes; 1, 2 and 3, barriers).

primary bark cells are, as we know, joined with one another by means of cytoplasmic bridges (plasmodesmata). With the help of these bridges, they are also linked – on the outside – with epidermis cell protoplasts, and on the inside – with endodermis cell protoplasts. The protoplasts of the parenchyma cells of the vascular cylinder are similarly joined to the endodermis. Thus, the root symplast spreads from the epidermis to the xylem, forming a cytoplasmatic continuum. This continuum provides a symplastic water route. It is illustrated by Line (S_y).

Cell walls and intra-cell voids form the so-called apoplastic water route. This route is shown by the broken line (A_p) in Figure 3. Even though it stretches from the epidermis to the xylem, it still has in the endodermis layer a significant barrier (in connection with the existence of the Casparyan band therein). In general, in the root radial water route, three barriers can be distinguished. They have been marked with Figures 1, 2, and 3.

The Fiscus single-membrane theory of water transport across the root

Ascribing to barriers 1, 2, and 3 (cf. Figure 3) the status of membranes, several membrane models have been developed to emulate the root radial water route. The simplest of these is the single-membrane model, as proposed by Fiscus (Fiscus, 1975, 1986). In this model, shown in Figure 4, all the three above mentioned barriers have been replaced with one membrane M with the filtration coefficient L_{pr} , the reflection coefficient σ_r and the permeability coefficient ω_r . The membrane separates two solutions of the concentrations C_{so} and C_{sx} , that is, the soil solution and the exudate (the xylem solution). These remain under mechanical pressures P_o and P_x respectively. Basing on that model, it has been possible (on the basis of the KK equations) to determine experimentally the values of all

Membranes, Role in Water Transport in the Soil-Root-Xylem System, Figure 4 Single-membrane model of root radial route (M is the membrane; C_{sx} , C_{so} are concentrations; P_x , P_o and ΔP_h are mechanical pressures; J_{vr} and j_{sr} are passive flows; j_s^A is the active solute flow; J_{vf} is the phloem volume flow; ρ is density; g is gravitational acceleration; h is height).

the three transport parameters (L_{pr} , σ_r , and ω_r), for roots of various crop plants and for various solutes. Due to the determination of these parameters, it has been possible to describe transport properties (of the model root) by means of the KK equations thus written

$$\begin{aligned} J_{vr} &= L_{pr}\Delta P - L_{pr}\sigma_r\Delta\Pi \\ &= L_{pr}(P_x - P_o) - L_{pr}\sigma_rRT(C_x - C_o), \end{aligned} \quad (10)$$

$$\begin{aligned} J_{sr} &= \omega_r\Delta\Pi + (1 - \sigma_r)\bar{c}_s J_{vr} \\ &= \omega_rRT(C_{sx} - C_o) + (1 - \sigma_r)\bar{c}_s J_{vr}, \end{aligned} \quad (11)$$

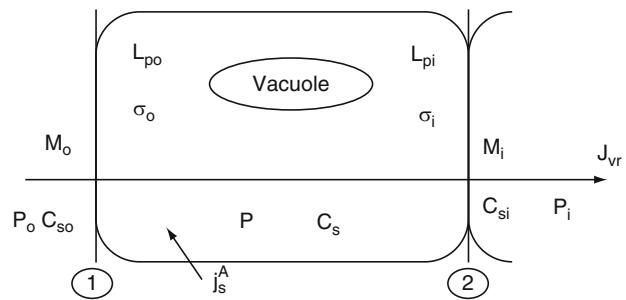

where J_v is the volume flow; j_s is the solute flow; $\Delta\Pi$ and ΔP are (mechanical and osmotic) pressure differences; $\bar{c}_s = 0,5(C_{sx} + C_o)$ is the mean concentration (of the concentrations C_{sx} and C_o); P_x and P_o are mechanical pressures in the xylem and the soil; R and T are the gas constant and temperature.

According to the model described with Equations 13 and 14, the flows J_{vr} and j_{sr} are determined (in their value and direction (sense)) by the values of pressure differences $\Delta\Pi$ and ΔP . This model appears to be rather far removed from the biological reality. Nonetheless, it has played a particularly important role in experimental and theoretical investigations pertaining to determination of transport properties of the root radial transport route in a variety of crop plants (Fiscus, 1975, 1986; Steudle et al., 1987; Kargol, 1994, 2007). Moreover, it explains to a large extent the agrobiophysical water transport mechanisms across the root as well as generation of the so-called root pressure. This pressure is expressed by the formula $\Delta P_\eta = \rho gh$, where ρ is density, g is gravitational acceleration; h is the height to which the root can pump water under that pressure.

According to this model, root pressure is osmosis driven, as the experimentally determined coefficient σ_r pertaining to the membrane M , which emulates the root radial water route takes the value of $\sigma_r > 0$. On the basis of this model (Fiscus, 1975, 1986) as well as Steudle and others (Steudle et al., 1987), experimentally determined the parameters L_{pr} , σ_r , and ω_r for many crop plant roots.

The Ginsburg double-membrane model, which explains radial water transport in the root

Another model, which emulates the radial water route is Ginsburg's double-membrane model shown in Figure 5 (Ginsburg, 1971). While constructing it, Ginsburg assumed that, in the radial segment of the root symplastic route, water encountered two barriers (1 and 2: cf. Figure 3). He gave these barriers the status of membranes M_o and M_i , and ascribed filtration coefficients (L_{po} and L_{pi}), as well as reflection coefficients (σ_o and σ_i) to them respectively. In this model, the membrane M_o separates solutions of the concentrations C_{so} and C_s , while the membrane M_i – solutions of the concentrations C_s and C_{si} , where C_{so} , C_s and C_{si} are the concentrations of the solution in the soil, between the membranes and in

Membranes, Role in Water Transport in the Soil–Root–Xylem System, Figure 5 Two-membrane Ginsburg model (description in text).

the apoplast of the vascular cylinder. With the use of the Kedem–Katchalsky equation for the flow J_v (i.e., Equation 1), Ginsburg demonstrated that transport properties of his model are thus formulated:

$$\begin{aligned} J_{vr} &= -LRT(\sigma_i - \sigma_o)C_s + LRT(\sigma_{si}C_i - \sigma_iC_{so}) \\ &\quad - L(P_i - P_o), \end{aligned} \quad (12)$$

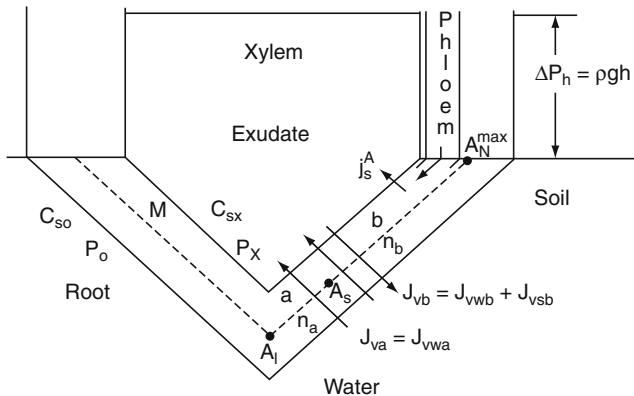

where J_{vr} is the volume flow; P_i and P_o are mechanical pressures in the soil and in the apoplast of the vascular cylinder; and $L = L_{po}L_{pi}(L_{po} + L_{pi})^{-1}$.

From an analysis of this equation, it follows that – depending on the value of the concentration C_s (which may be regulated with the active flow j_s^A of the solute (s)) – the flow J_{vr} may occur in accordance with the concentration gradient (at $C_{so} < C_{si}$), under iso-osmotic conditions (at $C_{so} = C_{si}$), as well as against the concentration gradient (at $C_{so} > C_{si}$). These conclusions, if referred to water transport across the root, are the main research achievement resulting from the Ginsburg model.

It must be added here that many membrane models have been developed to emulate the root radial water route, including multi-membrane models (Pitman, 1982; Taura et al., 1987; Kargol, 1995, 2007).

Single-membrane theory of two-way water transport along the root radial route

We shall presently consider the single-membrane model of the root radial water route, which we have developed (Kargol, 2007) on the basis of the MF formalism. Schematically, it has been presented in Figure 6. In this model, the assumption is that the membrane M is a heterogeneous porous structure, which emulates (in a manner analogous to the Fiscus model) the entire radial water route in the root. It contains the statistical number of N pores, which are permeable to water. Individual pores vary in areas (A) of their cross sections and are arranged randomly (arbitrarily). To facilitate our considerations, the pores have been arranged in one direction, from the smallest A_1 , to the largest A_N^{\max} . With reference to this membrane, it is possible to select such a solute (s), with the molecule

Membranes, Role in Water Transport in the Soil–Root–Xylem System, Figure 6 Single-membrane root model in which the membrane M is a heterogeneous porous structure (C_{so} , C_{sx} are concentrations; P_i , P_o are mechanical pressures; J_{va} , J_{vb} are volume flows; n_a and n_b are numbers of semipermeable and permeable pores; j_s^A is the active flow of the substance (s)).

cross-section area A_s , that the following relation will be satisfied: $A_1 < A_2 < \dots < A_s < \dots < A_N^{\max}$.

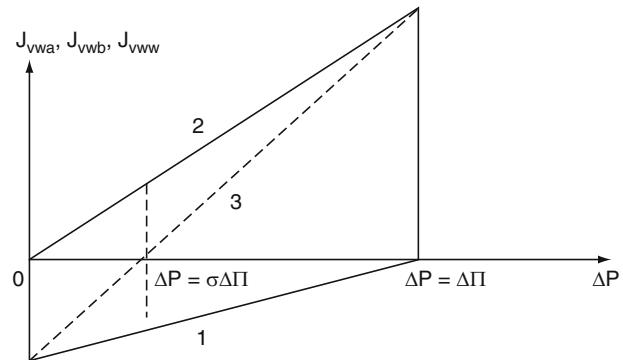

Under the circumstances, it is justified to divide the membrane M into Part (a) that contains n_a semipermeable pores and Part (b) that contains n_b permeable pores. These parts are to be ascribed the reflection coefficients $\sigma_a = 1$ and $\sigma_b = 0$ respectively. This membrane (according to Figure 6) separates the soil water with the solute (s) concentration C_{so} and the xylem solution (the exudate) with the solute concentration C_{sx} . Due to the occurrence of active transport j_s^A of the solute (s) in the root, it may be assumed that on the membrane M there occurs the pressure difference $\Delta C = C_{\text{sx}} - C_{\text{so}}$. Thus, there also occurs the osmotic pressure difference $\Delta\Pi = RT\Delta C = RT(C_{\text{sx}} - C_{\text{so}})$. As a consequence, within the pores n_a , the osmotic volume flow will be generated $J_{\text{va}} = J_{\text{vwa}}$ (which is in fact a water flow). This means, in turn, that the model root under consideration is able to generate root pressure $\Delta P_{\eta} = \rho gh$. In connection with the existence of this pressure, on the membrane at issue there also occurs, apart from the pressure difference $\Delta\Pi$, the mechanical pressure difference $\Delta P = P_x - P_o = \Delta P_h$. In the presented situation (according to the MF formalism), it may be written that [7]

$$\begin{aligned} J_{\text{vwa}} &= L_{\text{pa}}\Delta P - L_{\text{pa}}\Delta\Pi \\ &= L_{\text{pa}}(P_x - P_o) - L_{\text{pa}}RT(C_{\text{sx}} - C_{\text{so}}), \end{aligned} \quad (13)$$

where L_{pa} is the filtration coefficient of semipermeable pores n_a . Because $L_{\text{pa}} = L_{\text{pr}}\sigma_r$, the above equation, which describes the osmotic transport of water takes the following form:

$$J_{\text{vwa}} = L_{\text{pr}}\sigma_r(\Delta P - \Delta\Pi), \quad (14)$$

where L_{pr} is the filtration coefficient for the entire membrane (all N pores), and σ_r is the reflection coefficient of the membrane M.

Membranes, Role in Water Transport in the Soil–Root–Xylem System, Figure 7 Plots of relations of flows $J_{\text{vwa}} = f(\Delta P)$ and $J_{\text{vwb}}^{\Delta P} = f(\Delta P)$, obtained on the basis of Equation 13 – Plot 1, and Equation 16 – Plot 2. Plot 3 depicts the relation $J_{\text{vw}} = J_{\text{vwa}} + J_{\text{vwb}}^{\Delta P} = f(\Delta P)$.

In connection with the occurrence on the membrane M of the pressure difference ΔP , within its pores n_b the volume flow J_{vb} will be generated and given by the formula

$$J_{\text{vb}} = L_{\text{pb}}\Delta P = (1 - \sigma_r)L_{\text{pr}}\Delta P, \quad (15)$$

where $L_{\text{pb}} = (1 - \sigma)rL_{\text{pr}}$ is the filtration coefficient of the pores n_b . While analyzing Figure 5, it is easy to see that

$$J_{\text{vb}} = J_{\text{vwb}} + J_{\text{vsb}} = J_{\text{vwb}}^{\Delta P} + J_{\text{vwb}}^{\Delta\Pi} + J_{\text{vsb}}^{\Delta P} + J_{\text{vsb}}^{\Delta\Pi},$$

where J_{vwb} and J_{vsb} are the volume flows of water (w) and the solute (s); and $J_{\text{vwb}}^{\Delta P}$ and $J_{\text{vwb}}^{\Delta\Pi}$ are volume flows of water and the solute, driven by the pressure difference ΔP ; while $J_{\text{vsb}}^{\Delta P}$ and $J_{\text{vsb}}^{\Delta\Pi}$ are volume flows of water and the solute, driven by the pressure difference $\Delta\Pi$. The flow $J_{\text{vwb}}^{\Delta\Pi}$ may be expressed by the following formula (Kargol, 2007):

$$\begin{aligned} J_{\text{vwb}}^{\Delta P} &= (1 - \sigma_r)(1 - \bar{c}_s \bar{V}_s)L_{\text{pr}}\Delta P \\ &\approx (1 - \sigma_r)L_{\text{pr}}\Delta P, \end{aligned} \quad (16)$$

where \bar{c}_s is the mean concentration of the concentrations C_{sx} and C_{so} ; and \bar{V}_s is the molar volume of the substance (s). Equation 14 and the Formula 16 are the sought expressions that pertain to water transport along the root radial route. This transport is realized simultaneously in two opposite directions. Equation 14 formulates osmotic transport of water from the soil to the xylem of the vascular cylinder, and Equation 16 depicts water transport in the opposite direction. In order to clarify this, Plots 1 and 2 of these equations have been provided. They have been presented and explained in Figure 7. Plot 3, in turn, illustrates the relation of the net flow J_{vw} , given by the formula:

$$J_{\text{vw}} = J_{\text{vwa}} + J_{\text{vwb}}^{\Delta P} = L_{\text{pr}}\Delta P - L_{\text{pr}}\sigma_r\Delta\Pi. \quad (17)$$

From the discussion of the latter relation (Equation 17), two main conclusions follow. If $\Delta P = 0$,

then $J_{\text{vwa}} + J_{\text{vwb}}^{\Delta P} = -L_{\text{pr}} \sigma_r \Delta \Pi$. If $\Delta P = -\sigma \Delta \Pi$, then $J_{\text{vwa}} + J_{\text{vwb}}^{\Delta P} = 0$, which means that the amounts of water absorbed or removed by the root are the same.

Conclusions

- The above discussion of water transport across the plant root has demonstrated that the root is capable of generating root pressure. Under the influence of this pressure, water may be pumped through the stem xylem up to a certain height.
- The discussion has also demonstrated that the proposed single-membrane model of the root radial route (containing a heterogeneous porous membrane) displays the properties of simultaneous water transport in opposite directions (to the xylem of the vascular cylinder and out of the root – to the soil). This original investigation result is particularly important from the agrophysical viewpoint, particularly in terms of plants maintaining homeostasis.
- Due to this two-way water transport, the plant can also obtain necessary nutrients from the soil as well as simultaneously removing into the soil both water and superfluous (and frequently harmful) products of metabolism occurring in root cells. These unneeded products are food for many bacteria, which subsist in the direct vicinity of the root. Their superfluous metabolism products, in turn, may provide the plant with necessary nutrients.

MICROBES AND SOIL STRUCTURE

Vadakattu Gupta

Entomology, CSIRO, Glen Osmond, SA, Australia

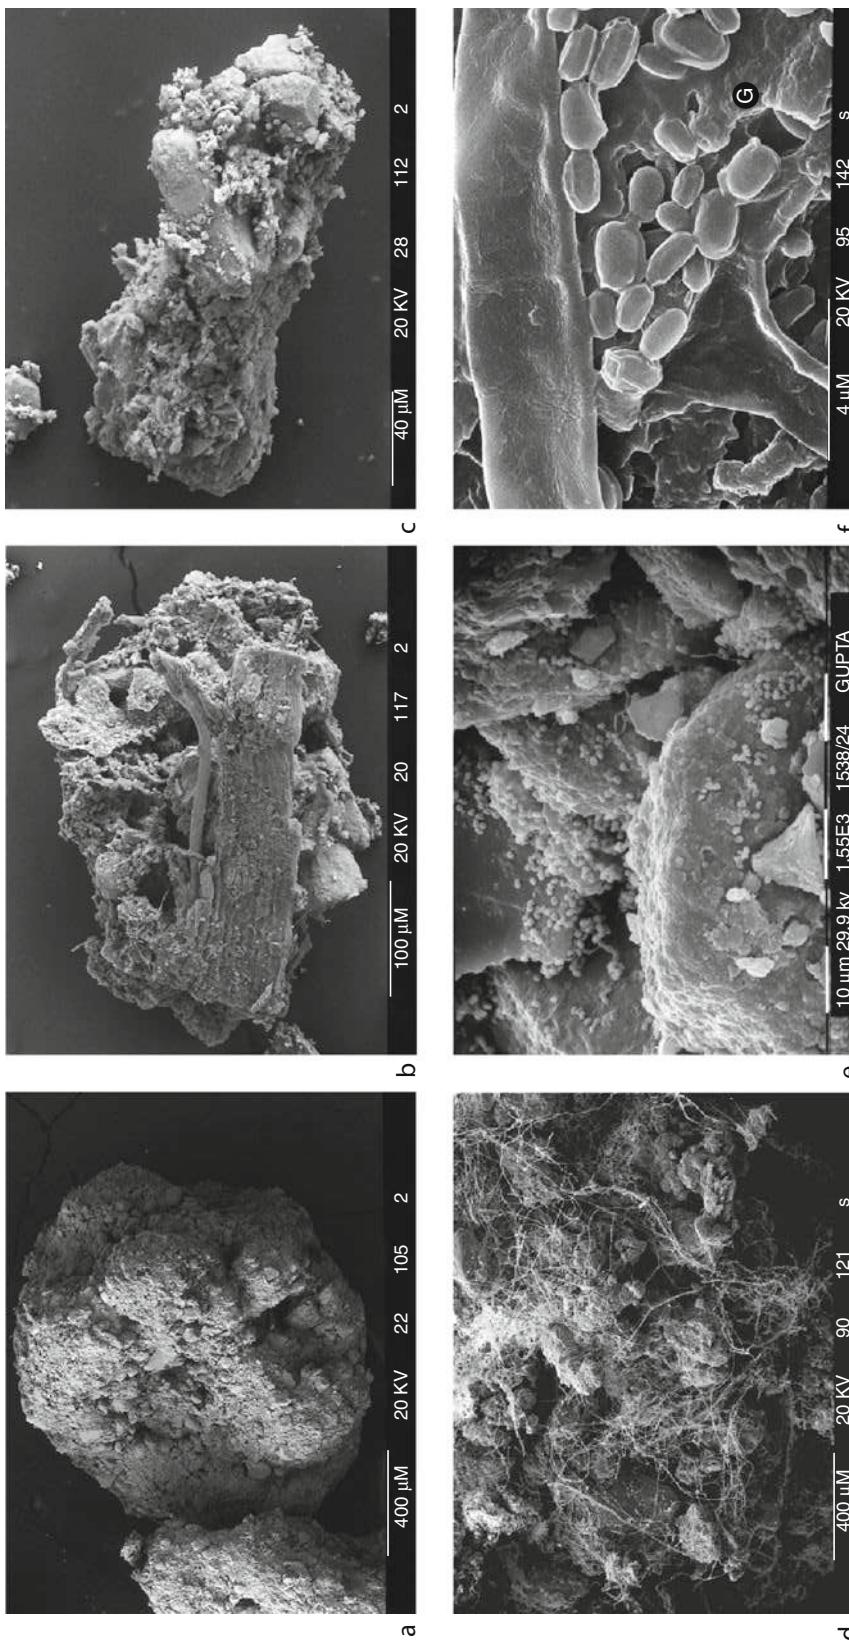

Definition

Microbes – Single and multicelled microorganisms that are microscopic in size (<100 µm in body width) including bacteria, fungi, algae, and protozoa.

Soil structure – The arrangement of primary soil particles and the pore spaces between them.

Soil particles are arranged together to form aggregates which are held together by organic matter and microbial agents (Tisdall and Oades, 1978). Aggregates that are stable to wetting are a key component of good soil structure as they help to maintain soil porosity and aeration at optimal levels for soil biota and plants.

Soil microorganisms play an important role in the formation and stabilization of aggregates. Bacteria and fungi produce a variety of mucilaginous polysaccharides, by utilizing the more easily available C substrates from fresh residues and roots, which act like glue and help them attach to clays, sands, and organic materials, resulting in the formation of new aggregates. Fungal hyphal networks facilitate the formation of macroaggregates (250–2,000 µm) through enmeshment of soil particles with organic debris (Gupta and Germida, 1988), whereas, decomposing plant residues and microbial debris encrusted with soil particles, by mucilages, form the core of microaggregates (20–250 µm) (Six et al., 2004). Both mycorrhizal and saprophytic fungi contribute to aggregate formation and stabilization. The influence of mucigels through their binding capacity is mostly seen at a scale <50 µm within the aggregates. As the decomposition of organic material progresses, microbial metabolites further permeate the surrounding mineral crust, increasing the interparticle cohesion and promoting the stability of aggregates. The production of hydrophobic

Microbes and Soil Structure, Figure 1 Scanning electron micrographs of soil aggregates: the backbone of soil structure: aggregates offer a diverse array of microsites for microbial colonization over short distances. Stable macroaggregates (a, b) are composed of decomposing crop residues (particulate organic matter), individual primary particles, microaggregates (c), pores of varying sizes, and biota remnants. Fungal hyphal networks (thread-like structures) hold soil particles and micro aggregates onto the surface of crop residues as part of the formation of macroaggregates (d). (e) Bacteria and fungi colonize the surfaces and small pores of macroaggregates (e). Organic compounds (glues, G) produced by bacteria (f) and fungi help bind the primary particles and plant debris to form stable aggregates.

substances by microorganisms increases the repellency of aggregates, which decreases the rate of soil wetting and influences aggregate stability. The relative importance of fungi vs. bacteria for aggregation is dependent on soil texture through its influence on porosity characteristics and nutrient availability (Figure 1).

Good soil structure provides an array of niches, i.e., in terms of redox potential and substrate availability, which can house diverse microbial communities. The distribution of bacterial and fungal communities and their function varies between different aggregate size classes (Gupta and Germida, 1988). Macroaggregates generally contain more labile organic matter with rapid turnover times and a greater proportion of fungal biomass. Mycelial networks of fungi help them exploit the heterogeneous soil matrix where carbon and nutrient resources are spatially separated (1) over extended distances at microbial scale and (2) in unconnected pore networks.

The coexistence of diverse bacterial communities within 1-cm³ area reflects the high degree of spatial heterogeneity in soil microniches. Bacteria often reside in pores and inner surfaces of aggregates as microcolonies of 2–16 bacteria each, and extensive colonization is restricted to microsites with higher C availability, e.g., rhizosphere and outer surfaces of freshly formed macroaggregates (Foster, 1988). Location of different phenotypic and functional groups of bacteria varies in different parts of aggregates, e.g., denitrifying bacteria and diazotrophs are generally located within inner parts of aggregates (Hattori, 1988; Mummy et al., 2006). However, location of aggregates in relation to roots, organic residues, and macropores is more important for determining the microbial community composition and their activity. Bacteria present within inner portions of larger aggregates, microaggregates, and micropores are protected from desiccation and grazing by protozoan predators. The turnover of these organisms is generally low compared to those located in macropores. Disturbance affects aggregation, aeration, and accessibility of substrates, thereby influencing diversity and activity of microbes in soil.

MICROBES, HABITAT SPACE, AND TRANSPORT IN SOIL

Karl Ritz

Natural Resources Department, National Soil Resources Institute, School of Applied Sciences, Cranfield University, Cranfield, UK

Definition

Microbes. Life forms that are nominally microscopic (not discernable with the unaided human eye) and typically comprised of one cell (unicellular).

Habitat space. Ecological or environmental volume, encompassing the physical, chemical, and biological environment that is inhabited by particular organisms, populations and communities.

Transport. Movement of entities (e.g., gases, liquids, solutes, particulates, organisms) from one region of a defined space to another.

Microbial life in soil

The living fraction of soils collectively known as the biomass, typically constitutes only a small percent of the total organic matter, but it is of great significance with regard to soil functioning (Paul, 2007). The biota play fundamental roles in delivering the majority of the ecosystem goods and services that soils provide, ranging from soil formation, carbon and nutrient cycling, modulating structural dynamics, regulating biotic populations, and providing biodiversity and genetic resources (Bardgett, 2005; Kibblewhite et al., 2008). Whilst the body size range of soil organisms spans several orders-of-magnitude from centimeters to micrometers (μm , 10^{-6} m), the majority of the soil biomass is always microbial, represented predominantly by bacteria, archaea, and fungi, plus to a lesser extent, protozoa. (Algal biomass in soils is generally present but relatively insignificant, except in some wetland rice systems in the tropics, and is then predominantly confined to the surface, since there is no light beyond a few millimeter depth in most soils, hence phototrophic organisms do not prevail beyond this zone. However, a small biomass does not necessarily mean algae are functionally unimportant in soil systems.) Multicellular organisms such as nematodes and the other soil fauna are not deemed microbial and hence are outside the scope of this entry. The soil microbial biomass typically ranges between different ecosystems from tens to thousands of

$\mu\text{g C g}^{-1}$ soil, depending upon the system and a wide variety of factors. However, there is generally a positive relationship between the concentration of organic matter in soil and microbial biomass, since carbonaceous material represents the primary energy source for the majority of the soil biota. Soil biodiversity is generally greater than in any other ecological compartment, particularly within microbial groups.

The soil habitat

The solid phases of soil are comprised of a diverse mixture of inorganic (“mineral” materials derived from the parent geology or glacial deposition) and organic (containing carbon) materials, made up of living matter (biota) or nonliving matter) components (Brady and Weil, 2002). Soils are produced by gradual processes of biogeochemical transformation, including “weathering,” a range of erosive chemical, physical, and biological mechanisms that produce a population of mineral particles of varying sizes. The small (nanometer), medium and large (millimeter) components are classified as the clay, silt, and sand fractions respectively. These mineral constituents eventually combine with organic components, predominantly originating from green plants, to form relatively thin “topsoils.” The inorganic and organic constituents of soil are arranged in space to form the so-called soil pore network. The origins of soil pore networks are that the fundamental sand-silt-clay components, mediated by organic materials, aggregate to form larger units (Tisdall and Oades, 1983). Generally, the forces binding such aggregates together are greater at smaller-size scales, and hence there tends to be a greater stability of soil structure at these smaller scales. These small units then aggregate further to create larger structures, with an associated hierarchy of scale and structural stability. Since the units are nonuniform, their packing creates a porous matrix, and since the constituents carry such a wide size range, the porous network is heterogeneous across a concomitantly wide range of scales. It is the pore network that comprises the physical, and primary, habitat for all soil organisms, representing a form of “inner space” in which the entirety of below-ground life inhabits (Figure 1). The nature of the pore network imparts a structural organization to soil communities and strongly influences the way they function and interact (Young and Ritz, 2005).

How soil structure affects microbial function

The exceptional heterogeneity of the soil pore network imparts some significant properties to the soil system from the perspective of the microbiota. First, it provides a huge surface area for potential colonization. Many soil bacteria are adapted to adhere to surfaces and occur as colonies on the surface of pore walls. Filamentous fungi are also well adapted to grow through soil pore networks by the process of hyphal elongation and branching, but also require some direct contact with substrates in order to absorb water and nutrients released by the action of the extracellular

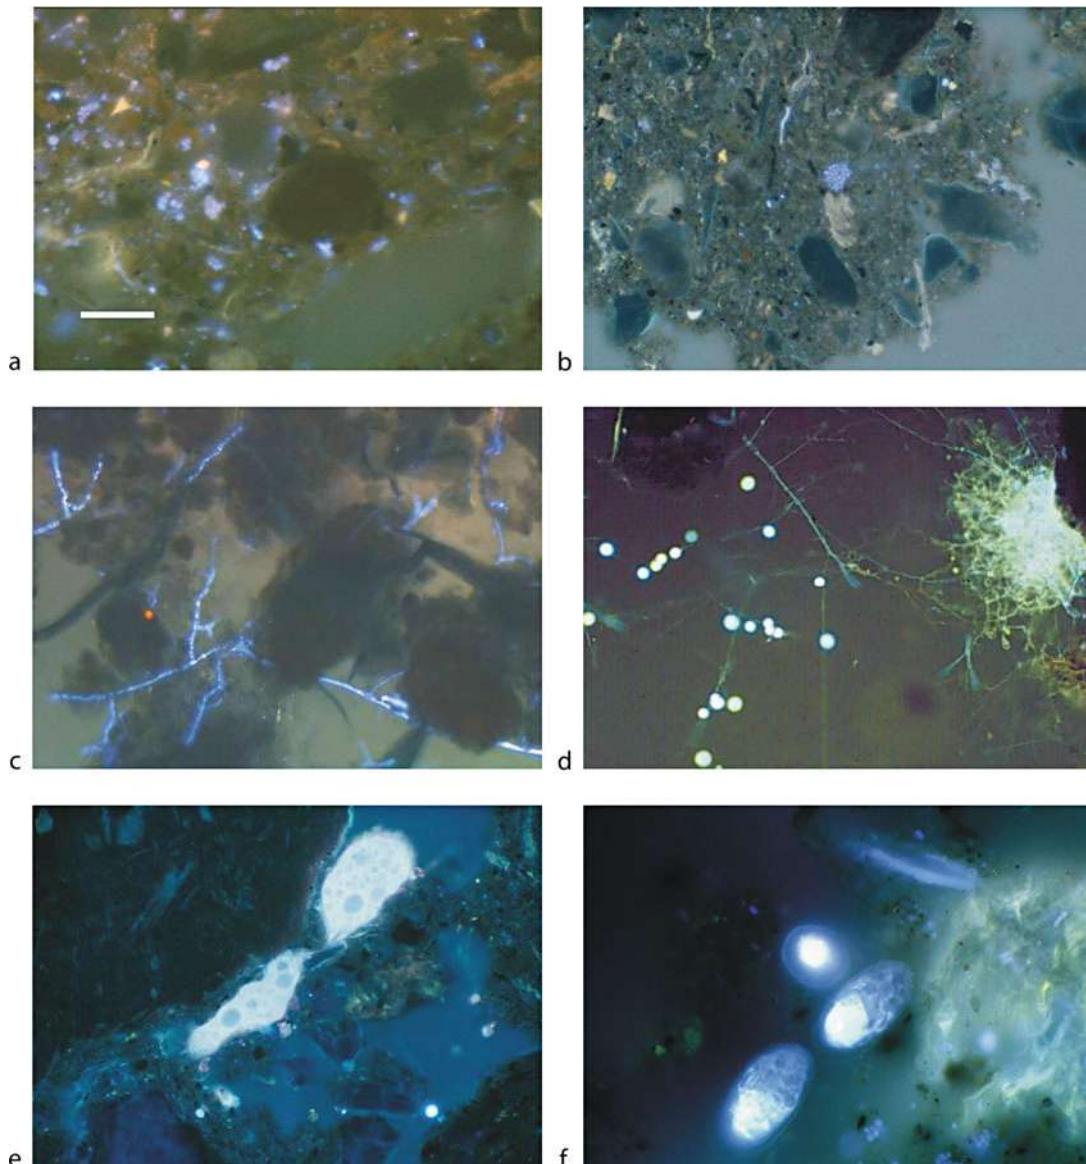

enzymes they produce. It is hypothesized that the extreme structural heterogeneity of soils is one basis for the exceptional diversity found in the soil microbiota, since it provides an extreme range of spatially isolated microhabitats which can lead to adaptive radiation (Zhou et al., 2002). Second, it governs the distribution and availability of nutrient resources to the biota. Unlike in aquatic systems, where most constituents are relatively well mixed by virtue of existing in a fluid matrix, the physical structure of soils essentially discretizes nutrient resources into spatially distinct patches, many of which will then be physically protected from being accessed by organisms. This can occur as a result of coating with soil minerals, or by being located in soil pores smaller than the physical size of potential consumer organisms. Such physical protection mechanisms can equally apply to dead organic matter, or potential prey in the case of active predators such as protozoa.

The connectivity and tortuosity of the pore network governs the movement of gases, liquids, and associated solutes, as well as particulates and organisms, through the matrix. Sessile organisms such as attached bacterial colonies rely upon the delivery of substrates to the colony, usually in water phases, as well as oxygen for aerobic respiration, via such pathways. The foraging distances taken by motile organisms when searching for substrate or prey – and hence the amount of energy consumed – will also be affected by path lengths for movement, which are related to these properties. There is a strong interaction between the pore network, water, and microbial activity, fundamentally linked to the relationships between the matric potential of a soil and the associated distribution of water between differently sized pores. Bacteria and protozoa require water films to move in, and their passage will be curtailed where there is no continuity in such features. Fungi are less constrained since hyphae can grow extended distances through air-filled pores.

As oxygen diffuses about 10,000 times more slowly in water than in air, water-filled pores – or narrow necks to larger pores – effectively act as valves, preventing the passage of oxygen and hence its availability to organisms for aerobic respiration. In these circumstances, many so-called facultative microbes can switch their metabolism to alternative biochemical pathways involving anaerobic processes.

How microbes affect soil structure

Whilst soil structure strongly affects the distribution and functioning of microbes and microbial communities, the microbiota also play important roles in soil structural dynamics (Brussaard and Kooistra, 1993). Microbes create soil structure by a number of direct and indirect processes, including (1) moving and aligning primary particles along cell or hyphal surfaces; (2) adhering particles together by the action of adhesives involved in colony cohesion, and other exudates, such as extracellular polysaccharides (EPS); (3) enmeshment and binding of

Microbes, Habitat Space, and Transport in Soil, Figure 1 Soil microbes in the soil habitat, visualized in thin sections of undisturbed soil, prepared appropriately to preserve biological tissue (cf. Nunan et al., 2001). (a) Bacterial cells in worm cast. (b) Bacterial colony embedded in soil matrix. (c) Mycelia of *Rhizoctonia solani* in sterilized soil. Note preferential growth in larger pores and apparent lack of penetration of denser masses of soil. (d) Unidentified mycelium in field soil, with abundant sporangia in main region of pore. aggregates by fungal hyphae and actinomycete filaments, and associated mycelia; and (4) coating pore walls with hydrophobic compounds, particularly by fungi which produce such polymers to insulate their mycelia, which have a relatively large surface area:volume ratio.

Soil structure is also destroyed by the action of microbes, since much of the organic material which serves to bind soil particles together is also potentially energy-containing substrate which microbes will

decompose if they can gain access to it. This is the reason why frequent soil disturbance, such as where repeated tillage is applied to soils, typically leads to a degradation of soil structure and a loss of soil C. Undisturbed soils have a high proportion of physically protected organic matter in them. When these are disturbed, such stabilizing material becomes available to microbial assimilation, is decomposed, and a proportion of the C is lost as respired CO₂.

Microbes and transport phenomena

Transport processes in soils are fundamentally affected by (1) the nature of the material being transported – gas, liquid, solute, colloid, particle, or organism; (2) the porosity, connectivity, and tortuosity of the pore network; (3) the exchange properties of the soil, and particularly their distribution in pore surfaces; (4) the distribution of water within the pore network; (5) interactions with the soil biota.

Microbial effects upon transport processes are generally indirect. Via their involvement with a plethora of elemental cycles, microbes transform the constitution and nature of compounds such that their propensity to be transported can be markedly altered, for example, by mineralizing elements from organic forms, or by altering the redox states of compounds, which can have profound effects upon transportability. Soil structure is affected by microbial actions as summarized above – and this in turn affects the moisture release curve, and hence distribution of water.

In relation to direct effects, bacterial movement through the soil matrix will result in a concomitant transport of elements bound in the bacterial cells, but given that the majority of bacteria in soils are sessile, this is not considered to be of great significance. Whilst motile, and hence prone to movement through the soil matrix, protozoan biomass is generally insufficient to likely influence nutrient transport phenomena directly. Protozoa can carry viable bacteria in their cells, including pathogenic forms, and hence may play a role in dispersal of such cells within soils. Fungi, however, have a much greater direct influence upon transport processes (Ritz, 2006). This arises as a result of the mycelium which is essentially a connected and integrated network, which is spatially isolated from the soil matrix. Materials can be translocated within mycelia by both active and passive processes, and are to some extent under the control of the fungal organism. Some primary nutrient elements which appear particularly prone to transport by filamentous fungi are C, N, P, K, S. Other elements, including some heavy metals and radionuclides, have been reported to be directly translocated by fungi. Of particular significance is the transport of P by mycorrhizal fungi to their host plants (Smith and Read, 2008).

Conclusions

Microbial activity creates soil structure which in turn affects the actual and potential function of such organisms. One way of conceptualizing the complex interplay between soil microbes – indeed, the entire soil biota – is that of “soil architecture,” which encompasses the notion of communities living in an appropriately physically structured environment, which allows, but modulates, a wide range of direct and indirect interactions which deliver the range of functions that lead to an integrated and sustainable system. An inappropriately structured soil (typically, one which has a low porosity) will be detrimental to the biota since there will be a compromised habitat,

manifest as inadequate space and a constrained potential for the dynamics of gases, liquids, solutes, and organisms. Without such dynamics, soil functioning will then inevitably also be impaired.

MICROSTRUCTURE OF PLANT TISSUE

Krystyna Konstankiewicz

Institute of Agrophysics, Polish Academy of Sciences,
Lublin, Poland

Synonyms

Microstructure; Structure

Definition

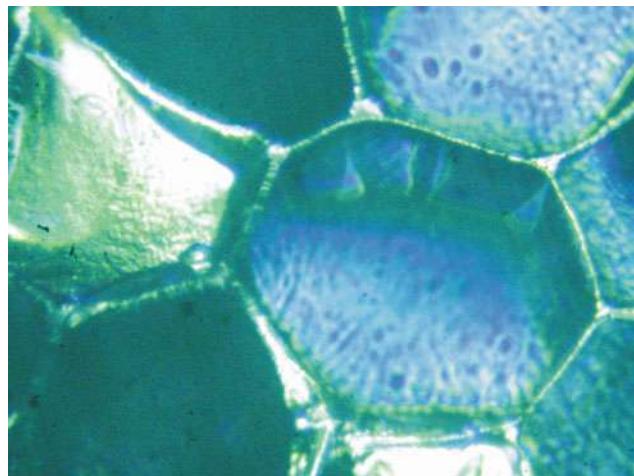

The *microstructure of plant tissue* is the geometric arrangement of cells as the fundamental elements of that structure. The packing of cells is not tight – between cells, surrounded by stiff cell walls, there are intercellular spaces. The system of plant microstructure is a three-phase one – the interior of the cells and of the intercellular spaces is filled with liquid and gas, while the cell walls are the solid phase. The shape and size of cells are determined by the cell walls which, due to their physical properties, play the role of “skeleton” of the whole object and affect its properties.

The *microstructure of plant tissue* is its fundamental material feature and determines its other properties – chemical, physical, and biological.

Introduction

The latest trends in research of plant tissues relate to the identification and description of the basic features of the material – on the microscale, and then to the search for their relations with the properties of whole objects, including their quality features (Mebatsion et al., 2008). One of the fundamental physical properties that characterize the material under study is its structure, which determines all of its other properties, for example, physical, chemical, and biological (Aguilera and Stanley, 1990). Material studies have a long tradition, supported by practical experience resulting from the production of a variety of materials (Kunzek et al., 1999). Based on the quantitative description of the structure of a material studied one can make comparisons between objects or record changes taking place within a single object as a result of, for example, a technological process, storage, or from non-homogeneity of the material (Wilkinson et al., 2000). Knowledge on the effect of structure on the properties of a material, in turn, can be utilized for controlling the technological processes so as to obtain materials with desired properties as well as for designing totally new materials (Bourne, 2002).

The fundamental structural element of plant tissue is the cell and that is the element to whose size relations of other properties of the material studied are sought (Konstankiewicz and Zdunek, 2005) (Figure 1).

Microstructure of Plant Tissue, Figure 1 Microstructure of potato parenchyma – preparation of sample: 1 mm sliced with a razor blade and washed with tap water. Image obtained with the Tandem Scanning Reflected Light Microscope (TSRLM), 0.47 mm × 0.65 mm.

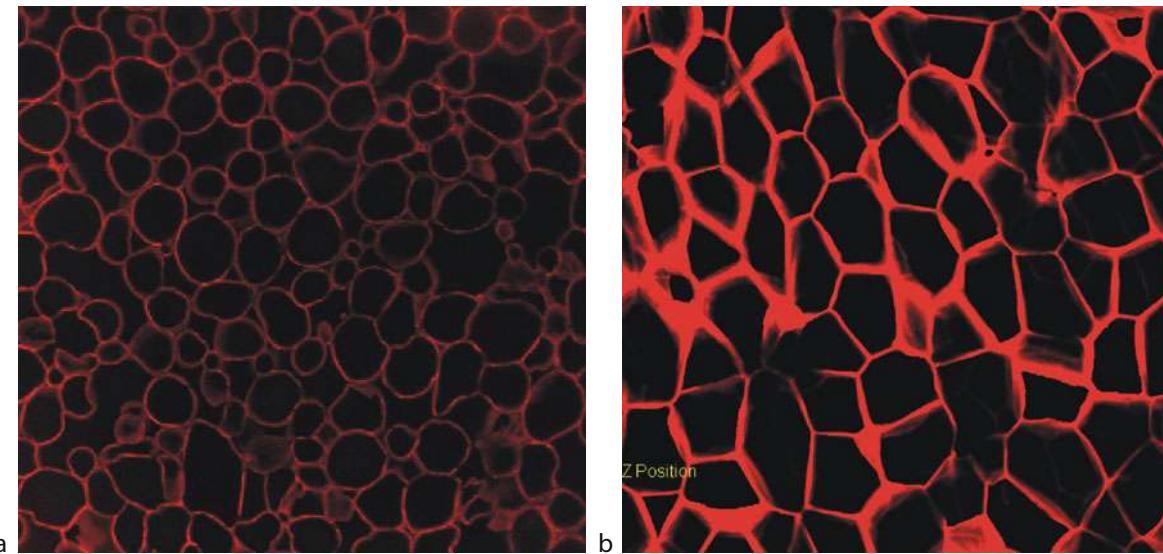

Many years of research in this field, including also my own, indicate that the cellular structure is a characteristic feature of plant tissues, and every conclusion may only be based on current results of quantitative analysis of structural parameters, especially those relating to cell size (Konstankiewicz et al., 2002; Zdunek and Umeda, 2005).

Microscope observations of cellular structures of plants

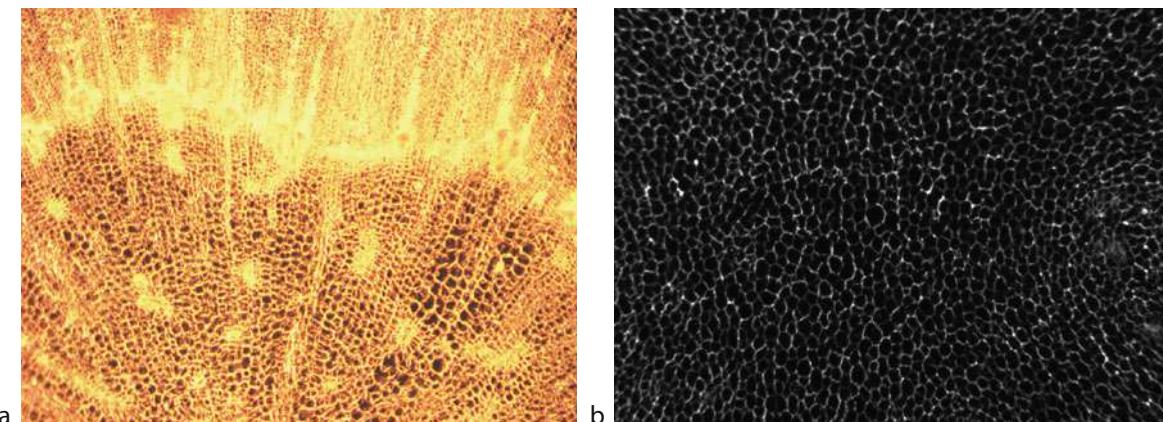

Microscope observations are the source of information on cellular structures. Commonly available and continually improved microscope methods permit the observation of cell structures at various rates of magnification, and digital techniques of recording the images obtained permit analysis of the information they contain. The broad array of microscopes of various types – optical, confocal, electron (scanning, transmission), acoustic, X-ray, atom force, Raman – with a variety of additional accessories and software, used for routine observations with very good results for various materials, provides a set of excellent research tools also with relation to plant tissues (Sargent, 1988; Pawley, 1989; Hemminga, 1992; Blonk and van Aalst, 1993; Kaláb et al., 1995; Davies and Harris, 2003; Konstankiewicz and Zdunek, 2005; Figure 2).

A separate group is constituted by methods of imaging of large sample areas – macrosopes, thanks to which it is possible to assess the spatial organization of structural elements, arrangement of cells, and to study identified directions and large zones of structural changes resulting from processes under study (Zdunek et al., 2007; Devaux et al., 2008; Figure 3).

The choice of suitable equipment is not easy, yet it frequently determines the successful solution of problems

Microstructure of Plant Tissue, Figure 2 Images of microstructure obtained with the Confocal Scanning Laser Microscope (CSLM), each one 1.4×1.4 mm (a) apple and (b) potato parenchyma, sample after preparation procedure.

Microstructure of Plant Tissue, Figure 3 Microstructure of carrot (a) and potato parenchyma (b) sample in natural state. Image obtained with the macroscope, $6 \text{ mm} \times 4.5 \text{ mm}$.

posed, and may also save time and cost. The objective of the research, that is, focusing on the significant elements of the structure and elimination of useless details while ensuring methodological correctness, is of fundamental importance. The location of specimen taking and the choice of the plane of observation are other significant elements. Whereas, the application of preliminary preparation of specimens, from simple slicing to the fixing of structure, may introduce disturbances in the structures under observation that have to be taken into account in subsequent examinations and in the formulation of conclusions (Sun and Li, 2003; Delgado and Rubiolo, 2005; Spector and Goldman, 2006; Otero et al., 2009).

In the studies on the physical properties of plant tissues, methods are sought for the obtainment of such images of

the structure that will provide distinct representation of cell walls that determine the overall dimensions of the cells, permit the measurement of those dimensions and then their correlation with other features of the tissue under study (De Smedt et al., 1998; Fornal et al., 1999; Konstankiewicz and Zdunek, 2001; Hepworth and Bruce, 2004).

For an image of a structure to be suitable for computer analysis, it must be of high quality, that is, primarily with a very good level of contrast. The structural elements of interest should be clearly defined, countable, and measurable. This is a difficult task in the case of plant tissues that have a low level of coloring, sometimes are even transparent, and additionally, due to their high content of water, tend to dry quickly and get deformed in the course of observation.

The quantitative description of a cellular structure requires the development of research methodology suitable for a given object. Even with well-developed procedures, the experience and knowledge of the observer are indispensable for correct interpretation of information contained in the images analyzed (Zdunek et al., 2004; Gancarz et al., 2007).

Image analysis of plant tissue microstructure

Good-quality microscope images of the structure of plant tissue can be subjected to detailed analysis leading to quantitative characterization of the object studied. Computer image analysis used for the purpose has been known since the beginning of the 1960s, and has undergone a violent development in the period of common availability of digital cameras and of various types (Serra, 1982; Serra, 1988; Kaláb et al., 1995; Abbott, 1999; Wojnar et al., 2002). Computers, cameras, and software are necessary equipment of every microscope set. The use of software for image analysis may appear to be a simple task, especially when there is easy access to professional offers and an abundance of promising results concerning other materials. It turns out, however, that the task is a complex one and requires good experience as well as knowledge not only about the object of study itself but also about the methods of image taking, acquisition, processing, and analysis. In spite of the continual advances of specialist knowledge in the field of image analysis, and the resultant occasional problems with its understanding, its possession at a basic level is a requirement for every user in order to avoid errors that may bring irreversible effects at the final stage of formulation of conclusions.

Computer image analysis is the most helpful when we need to make multiple computations or measurements, or when comparing images with one another. Such problems are encountered not only in research, but also in diagnostics or in quality control. These tasks require numerous replications and, most importantly, objectivity of the results obtained. For images with sufficiently good quality, it is possible to perform automatic analysis with the help of professional software (Bourne, 1981; Devaux et al., 2005; Cybulská et al., 2008). In practice, however, application of automated image analysis is not always possible even with good quality of the images, and very often image evaluation and manual corrections by an experienced observer are a necessity.

In a flat (2D) image, the size of a cell is defined by measured parameters: surface area, perimeter, diameters, and chords. However, the expected size of a cell as a spatial (3D) object should be its volume and shape and the dimensions of such a solid. Identification of a spatial structural element permits the modeling of the structure of the whole object.

The latest solutions propose highly specialized techniques of computer tomography for mathematic modeling of 3-D cell structures of plant tissues. Such models open

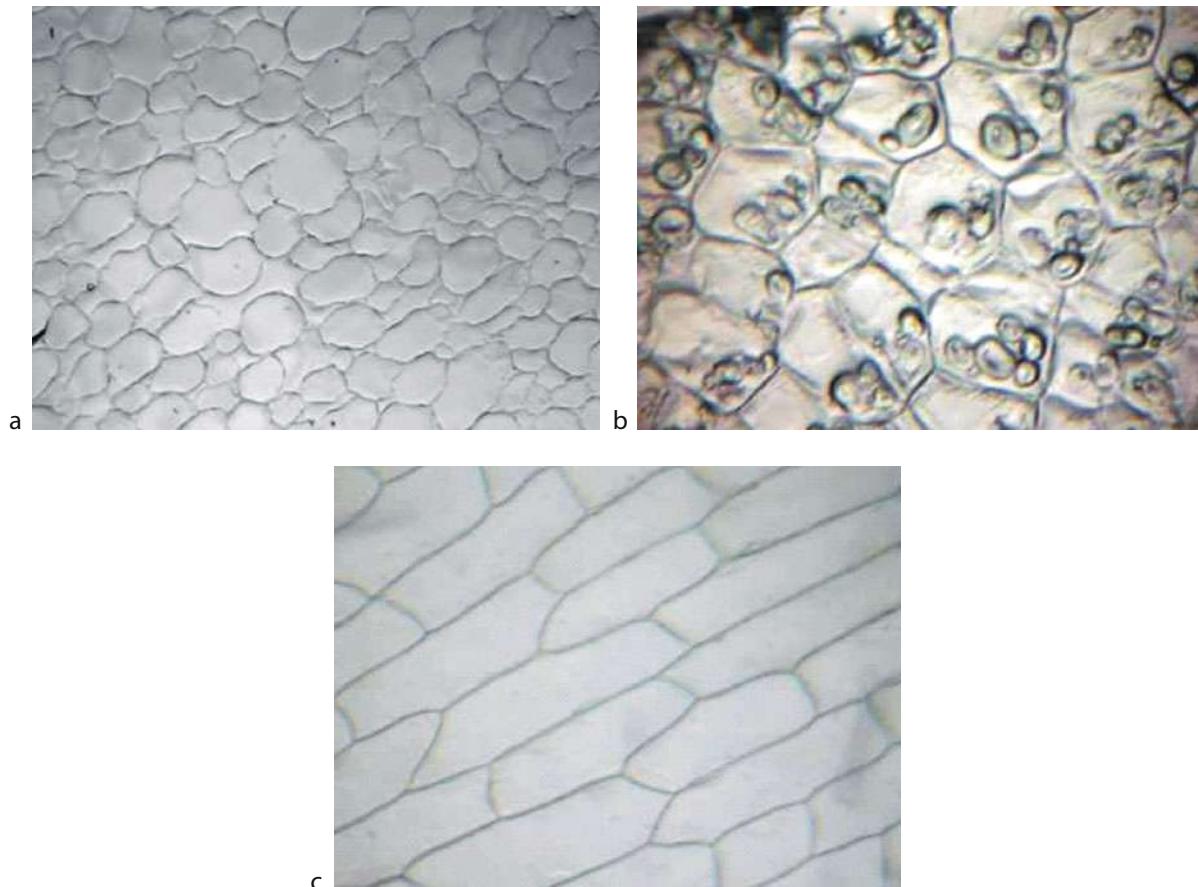

up new possibilities in the range of simulation studies on the transport of liquids and gases through the system of cell walls and intercellular spaces and on the processes of deformation under mechanical effects (Lee and Ghosh, 1999; Maire et al., 2003; Tijskens et al., 2003; Kuroki et al., 2004; Mebatson et al., 2006; Mebatson et al., 2009).

Stereological methods in studies on microstructure of plant tissue

The need for practical application of structural studies was at the root of the appearance of quantitative methods for structure description – the stereological methods (Underwood, 1970). The notable advance of theoretical stereology in recent years is related, among other things, with the development of microstructure observation techniques and precision sampling methods (Kurzydłowski and Ralph, 1995). It is the method of selection of objects to be studied that largely determines the systematic error of measurement. One of the fundamental errors is to conduct estimations of structure on the basis of a single cross section of a sample or a single selected area of the specimen. That is the erroneous assumption of homogeneity and isotropy of a medium (Ryś, 1995). Plant tissues have a nonhomogeneous and unstable cellular structure, with frequent discontinuities of notable dimensions (Haman and Konstankiewicz, 2000; Konstankiewicz et al., 2002). The morphology of their structure is a resultant of many factors – cultivar, object size and shape, type of tissue, method of cultivation, time of harvest, postharvest processing, and many others. Information on the heterogeneity of structure is obtained on the basis of microscope observation of natural or fixed specimens (Figure 4).

This permits the selection of characteristic areas in the section of the object – heterogeneity of position, as well as finding whether there occurs spatial orientation of elements of the structure – anisotropic heterogeneity (Gao and Pitt, 1991). Such a preliminary assessment determines the choice of the place and direction of taking specimens, as well as of their number, and in consequence determines the correctness of the final result. It is also important whether the results are to describe a specific area of the object studied or the object as a whole. Large areas of uniform structure permit the taking of specimens with sizes sufficient not only for microscope observation but also for other determinations, for example, of mechanical properties (Zdunek et al., 2004). This is important in the study of relations between the geometric parameters of the structure and other properties of plant tissue. In case of doubt as to the homogeneity of studied areas within the object, for example, the type of tissue or anisotropy features, specimens should be taken from various zones – close to the surface, from the center, and also from intermediate areas, varying the directions of specimen taking.

Based on the analysis of large sets of microscope images, it is possible to determine the minimum number of cells representative for the whole population

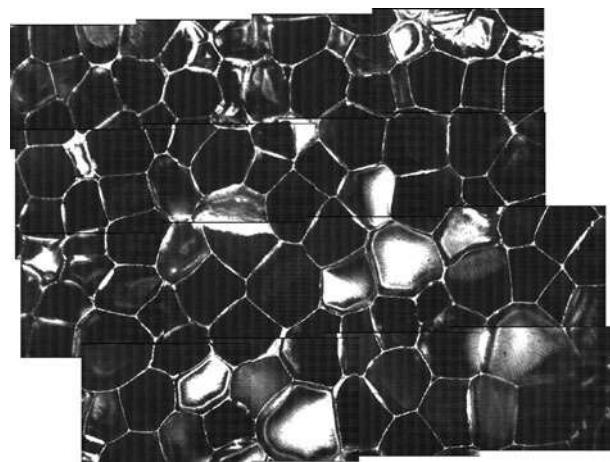

Microstructure of Plant Tissue, Figure 4 Cellular structure of apple (a) potato – cells with starch (b) and onion (c), respectively. Images obtained with optical microscope, samples after preparation, each one $1\text{ mm} \times 0.8\text{ mm}$.

(Maliński et al., 2000). As an example, for the parenchyma tissue of potato tuber the minimum number of cells cannot be less than 300, with high repeatability of results for several independent observers. Properly chosen number of cells under analysis permits the determination of not only the mean values of the geometric parameters of the cell but also their distributions within the object studied (Maliński et al., 1991; Figure 5).

Determination of parameters describing a cellular structure requires the development of suitable research methodology for a given object.

Due to the extensive range of variability of plant cell sizes, a microscope image may contain an insufficient number of whole objects. In such situations, it may be necessary to merge images so that the side of the resultant image be severalfold larger than the mean cell diameter.

The procedures relating to the choice of object, specimen, and area in the specimen for microstructure observation, have a significant effect on the final result and determine the weight of the relationships obtained.

Microstructure of Plant Tissue, Figure 5 Microstructure of potato parenchyma. Example for an image obtained by composing 16 images – TSRLM, $1.5 \times 1.2\text{ mm}$.

Summary

Structure is an important material feature of plant tissue. Investigation of the microstructure of plant tissue is difficult due to the large biological diversity of the material and to the necessity of simultaneous consideration of the effect of a large number of factors resulting from the complex conditions of cultivation and storage and from the increasingly demanding technological processes. Such complex materials, with the rapid development of measurement techniques – microscopes, image analysis – require particularly precise selection of proper measurement methods, preceded with fundamental studies. In most cases, there is no possibility of adaptation of measurement systems commonly used in studies on other materials, and the new research methods being developed require constant improvement due to the rapid development of measurement techniques and to the changing cultivar requirements related with the destined application of agricultural raw materials and products, and with the increasing expectations of the consumers. The utilization of knowledge on plant tissue structure in the process of plant production is the best method of obtaining, in a reproducible manner, materials with expected properties, and of rapid estimation of the quality of plant materials and products.

All the methods for the investigation of the structure, together with other properties, of plant tissues have potential for development, both due to the originality of methodological solutions and to the considerable potential of future practical applications.

Introduction

Soil minerals, organic matter, and microorganisms are interacting with each other. These interactions play an important role in creating soil structure, controlling biogeochemical processes, and turnover of organic and inorganic substances in soil.

A great role of clay minerals in the formation of complexes with soil microorganisms and organic substances of microbial origin and new quantitative approaches and hypothesis to the studies of interactions between mineral soil solid phase and microorganisms are pointed out.

Minerals, organic matter, and microorganisms have significant higher-order interactions in terrestrial ecosystem. These reactions exert strong control over soil physical, chemical, and biological processes. Soil mineral surfaces play a vital role in catalysis of abiotic formation of humic substances. Soil minerals, especially noncrystalline minerals, have the ability to chemically stabilize soil organic matter. Organic substances also act as binding agents to promote and stabilize aggregation. There are distinct interactive mechanisms between soil minerals, organic matter, and microbes, which should have a direct influence on the stability and cycling of C, N, P, and S (Huang et al., 2005).

Emerson (1959) presented a physical aspect of the microstructure of a soil aggregate. Assuming that a soil aggregate is composed mainly of clay and quartz, these particles may be linked directly by organic matter or through two or more domains which are themselves linked by organic matter.

A mineral soil solid phase more or less easily adsorbs bacteria on the surface. Negatively charged adsorbents repel rather than attract bacteria of negative charge. An attention of scientists has been drawn to the fact that the type of microorganisms is more significant than the type of adsorbents. For instance, gram-positive, immobile microorganisms are characterized by the highest absorbing affinity to soil particles.

A particle-size fractionation of soils is commonly used to quantify the content of soil organic matter and microbial biomass in different particle-size fractions.

A great role of clay minerals is known in the formation of complexes with soil microorganisms and organic substances of microbial origin (Chenu, 1993; Golchin et al., 1995; Schnitzer et al., 1988). The formation of complexes between extracellular polysaccharides and montmorillonite decreases the rate of microbial decomposition of these polysaccharides and other labile organic matter. Therefore, clay soils have a greater capacity for the protection of biomass of microorganisms within the soil matrix than sand soils (Hassink et al., 1993).

The role of interactions of soil minerals with soil microorganisms and their metabolites in the formation of soil aggregates was being studied for a long-term period (Harris et al., 1966; Bossuyt et al., 2001; Six et al., 2004). An ability of fungi and bacteria to participate in aggregate formation is dependent on soil texture, its composition, and availability of C and N. Compared to bacteria, fungi play a dominant role especially in water-stable macroaggregation of light-textured soils with a poor fertility (Guggenberger et al., 1999).

Hattori and Hattori (1976) observed the physical environment in soil microbiology and undertook an attempt to extend the principles of microbiology to soil microorganisms. A formation of complexes was studied between *Escherichia coli* cells and loam soil particles of different mineralogical origin. Pyrophyllite and kaolinite complexes being combined with *E. coli* cells, showed an adhesion to loam particles and formed microaggregates. The “cell-loam particle” complexes treated with sodium ions were stable in acidic medium and unstable in alkaline medium. The loam particles treated with Cu⁺⁺, Co⁺⁺, or Fe⁺⁺ demonstrated stronger adhesion with bacterial cells than loam ones treated with Na⁺, and the complexes were stable in alkaline medium but labile in acidic medium (Hattori, 1970).

Three hypotheses have been proposed concerning mechanisms of the adsorption of the mineral's molecules on the surface of bacterial cells (Marshall, 1971):

- (a) Adsorption of the molecules could proceed through on the surfaces of bacteria and mineral particles (“face-to-face adsorption”).
- (b) Adsorption of the molecules could proceed through on their edges (“edge adsorption”).
- (c) Adsorption could result from both mentioned mechanisms (“mixed adsorption”).

Adsorption of sodium bentonite was studied on *Bacillus subtilis* cells (Lahav, 1962). The effect of sodium bentonite (molecules smaller than the bacterial cells) on the electrophoretic mobility of *Bacillus subtilis* was tested in solutions of sodium chloride and of sodium phosphate with different concentrations of hydrogen ions and ionic force. It was noted that the adsorption of sodium bentonite on bacteria was a reversible process. Bacterial population consisted of two types of microorganisms. The addition of bentonite affected the electrophoretic mobility of one bacterial type, while the other one was not affected. The first type represented bacteria-adsorbing bentonite, whereas the second one included bacteria not adsorbing bentonite on their surface. Moreover, the presence of both bacterial types was found only in the presence of bentonite. The effect of bentonite on bacterial mobility depended on pH, ionic force, and contents of electrolytes. The lower were the pH values and the higher was the ionic force, the more effective was the effect of bentonite.

Among different types of bacteria, for instance, the influence of the bacterial biomass of *Arthrobacter* sp. on the formation and stabilization of water-stable macroaggregates in the soil was studied after the addition of plant residues, mineral fertilizers (NPK, Ca), and bentonite (Dąbek-Szreniawska, 1974). The introduction of the bacterial biomass of *Arthrobacter* sp. resulted in an increased amount of water-stable macroaggregates (>250 µm). The highest increase in the water-stable aggregation was induced by a combined influence of bacterial biomass and plant residues during a 3-month incubation. Application of bentonite generally increased the water stability of aggregates. Application of mineral NPK fertilizers caused a decrease in the water stability of aggregates as a result of changes in the activity and the composition of soil microbial community.

New quantitative approaches to the studies of interactions between mineral soil solid phase and microorganisms give an opportunity to get more detailed information about structure and function of soil microbial community in micro- and macroaggregates (Väistönen et al., 2005).

Conclusions

The distinct interactive mechanisms between soil minerals, especially clay minerals, which form complexes with microorganisms and organic substances are confirmed. They affect the stability and cycling of soil chemical components and have a positive effect on soil microstructure and aggregation.

Definition

Thermal conductivity of foods. The bulk property of food products describing their ability to conduct heat resulting from a gradient of temperature. It is measured in Watts per Kelvin per meter ($\text{W K}^{-1} \text{ m}^{-1}$).

Frozen foods. Foods with their aqueous solutions converted into ice and then stored at a temperature below freezing point.

Thermal conductivity models. Equations describing the material ability to conduct heat.

Introduction

A large variety of foods (meat, fish, poultry, fruits, vegetables, bakery, dairy foods, etc.) require refrigeration (chilling and/or freezing) to maintain their high quality, edibility, and nutritive values. Solid foods are capillary, porous, colloidal materials consisting of water, solid constituents (e.g., carbohydrates, fats, proteins, vitamins, or minerals), and in some instances, air (bakery products, ice cream, cheese, etc.). The majority of fresh natural foods (meat, fish, fruits, vegetables) are fully saturated with aqueous solution (solid food components dissolved in water). During a freezing process, food water is converted into ice and the solution concentration increases; consequently, the food initial freezing point (T_f) decreases below 0°C . Good knowledge of frozen food thermophysical properties, particularly thermal conductivity (λ), is required in the design of freezing/thawing equipment and analysis of chilling, freezing, storage, and thawing processes. This property describes food's ability to distribute heat strictly by a conduction mode. It is very difficult to measure and also to estimate as it is influenced by numerous parameters such as initial water content, temperature (T), density, food composition, anisotropy, ice fraction, measuring techniques, etc. Available experimental data usually do not cover a full T range encountered during freezing, storing, and thawing processes; often λ data are contradictory and incomplete (missing measurement details, T , composition data, a sample preparation procedure, and uncertainty analysis). Therefore, there is a strong demand for the use of λ models in computer analysis of food freezing, storing, and thawing processes.

Thermal conductivity of food components

Water and ice are two main components of frozen foods. Thermal conductivity of water (λ_w) is approximately double that of other solid constituents, while with respect to ice it is approximately four times smaller. There is a weak λ_w dependence on T . On the contrary to water, the thermal conductivity of ice (λ_{ice}) increases considerably with decreasing T . As a result, ice has a dominant effect on the frozen food's ability to conduct heat. Several predictive equations, $\lambda_{ice}(T)$, λ_{ice} in W/m K and T in °C, have been published over the last 30 years (Sakazume and Seki, 1978; Yen, 1981; Choi and Okos, 1986; U.S. Army Corps of Engineers 1996).

$$\begin{aligned}\lambda_{Choi-Okos} &= 2.2196 - 0.0062489 \cdot T + 0.00010154 \cdot T^2 \\ \lambda_{Sakazume-Seki} &= 2.2156 - 0.0100456 \cdot T + 0.00003445 \cdot T^2 \\ \lambda_{Yen} &= 6.727 \cdot \exp[-0.0041 \cdot (T + 273.15)] \\ \lambda_{US-Army} &= 2.21 - 0.011 \cdot T\end{aligned}\quad (1)$$

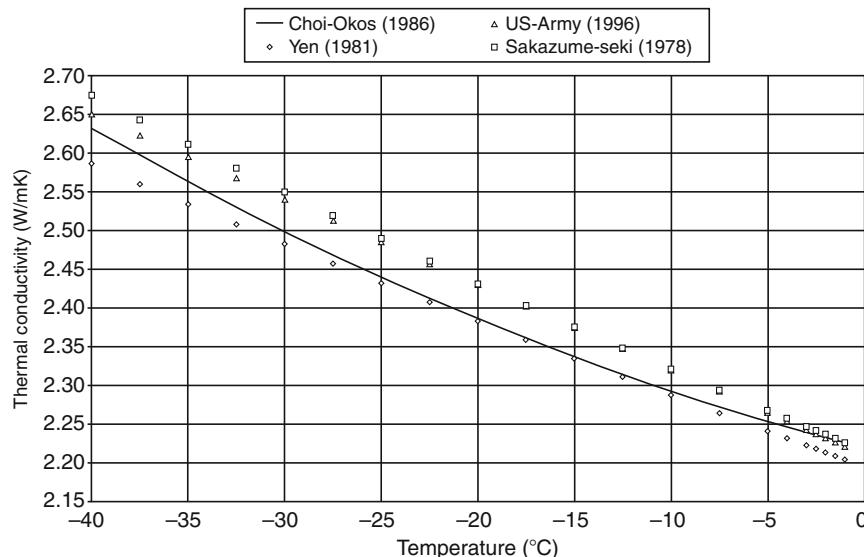

Fukusako (1990) reviewed available $\lambda_{ice}(T)$ data and fitting correlations and concluded that variations among the reported data were caused mainly by differences in sample purity, sample preparation, methods of measurement, and reproducibility of experimental data. The difference in predicted λ is on average below 0.05 W/m K (Figure 1). The predictive λ_{ice} equation by Choi and Okos (1986) is commonly used in food engineering for modeling λ of frozen foods within a range of T from −40°C to 0°C; λ_{ice} increases by about 18.6% as T decreases from −1°C to −40°C. Therefore, λ_{ice} dependence on T may strongly influence the λ of lean frozen foods that usually contain a large amount of ice. Thermal conductivities of remaining basic food components (including water) are

also estimated from equations given by Choi and Okos (1986) and in comparison to ice, λ shows a weak dependence on T .

$$\begin{aligned}\lambda_{water} &= 0.57109 - 0.0017625 \cdot T + 0.00000607036 \cdot T^2 \\ \lambda_{protein} &= 0.17881 - 0.0011958 \cdot T + 0.0000027178 \cdot T^2 \\ \lambda_{fat} &= 0.18071 - 0.00027604 \cdot T + 0.00000017749 \cdot T^2 \\ \lambda_{ash} &= 0.32962 - 0.0014011 \cdot T + 0.0000029069 \cdot T^2 \\ \lambda_{carbohydrates} &= 0.2014 - 0.0013874 \cdot T + 0.0000043312 \cdot T^2 \\ \lambda_{fiber} &= 0.18331 - 0.0012497 \cdot T + 0.0000031683 \cdot T^2\end{aligned}\quad (2)$$

Thermal conductivity of frozen foods

Two measuring techniques of λ are commonly used for frozen foods, namely: steady and transient state. The steady-state technique (a guarded hot plate) requires a long time to reach the equilibrium T of tested foods and therefore it is prone to moisture migration and spoilage. The transient state technique offers a smaller size of equipment, much shorter measuring times, smaller food samples and consequently, it is currently a preferable choice for λ measurement. Thermal conductivity probes, however, lack thorough verification at $T < T_f$ and latent heat of ice may considerably alter measured λ (Wang and Kolbe, 1990). Besides, thermal conductivity measurements are based on a highly simplified assumption that foods are homogeneous and isotropic materials. In fact, fibrous foods usually conduct different amount of heat in a perpendicular and parallel direction to fibers; this difference could be up to about 15% for frozen beef (Heldman, 2003). As a result, experimental data gathered may be burdened with errors of unknown magnitude. Fat has a very

Modeling the Thermal Conductivity of Frozen Foods, Figure 1 Thermal conductivity of ice as a function of temperature.

low λ (0.2–0.5 W/m K) and therefore, its increasing content has a decreasing effect on the frozen food's λ . The majority of frozen foods show a strong λ dependence on decreasing T . Figure 2 displays experimental λ data of selected foods, by Pham and Willix (1989) and Willix et al. (1998), undergoing freezing from -1°C to -40°C ; within this T range λ increases by a factor of 2–3.

Predicting ice fraction in frozen foods

Thorough knowledge of ice fraction in frozen foods is crucial for obtaining good λ estimates. One of the most frequently used m_{ice} models was proposed by Schwartzberg (1976).

$$m_{\text{ice}} = (m_w - m_b) \cdot \left(1 - \frac{T_f}{T}\right), \quad (3)$$

where m_w = mass fraction of water at T_f in $^{\circ}\text{C}$, m_b = mass fraction of bounded water, and T = temperature of frozen food in $^{\circ}\text{C}$. For example, for meat products, $T_f \approx -0.9^{\circ}\text{C}$ and $m_b = 0.4 \cdot m_{\text{protein}}$ (Pham and Willix, 1989).

The above equation gives good estimates for highly diluted solutions, i.e., T_f is close to 0°C .

Golovkin and Tchizov (1951) provided an empirical relation for ice fraction that follows closely experimental m_{ice} data of a variety of foods such as meat, fish, milk, eggs, fruits, and vegetables. Their experimental m_{ice} , from -1°C to -65°C , was refitted and coefficients of the original empirical relation were slightly adjusted.

$$m_{\text{ice}} = \frac{1.133}{1 + \frac{0.339}{\log[1+|T-T_f|]}} \quad (r^2 = 0.996). \quad (4)$$

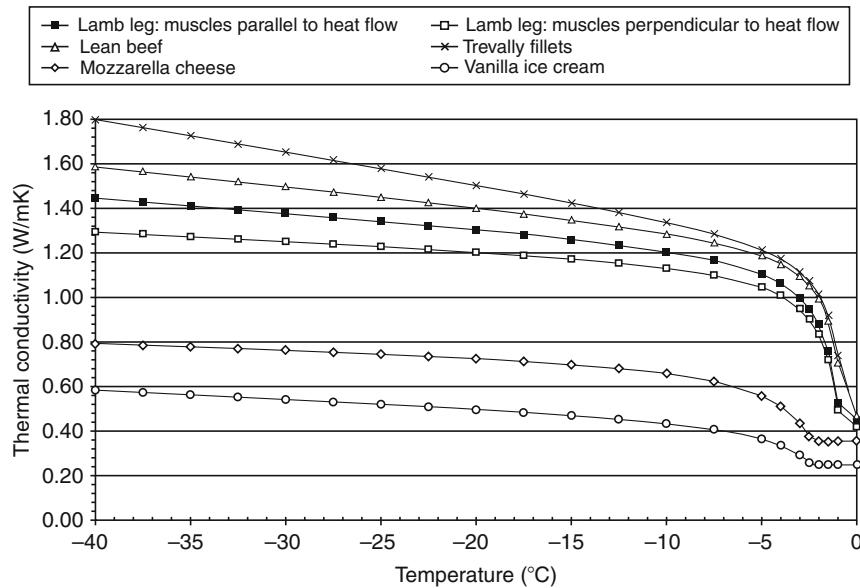

The initial freezing point is a key parameter in the above Equations 3 and 4; its value, however, is difficult to predict or measure. In general, T_f for fish, meats, fruits, and vegetables varies from -2°C to -0.5°C ; a summary of T_f predictive models for a variety of foods was published by Sun (2006). A comprehensive summary of m_{ice} modeling approaches was given by Fikiin (1998) and Rahman (2001).

Models predicting thermal conductivity of frozen foods

For modeling purposes, solid foods are often subdivided into two groups, namely: fully saturated with water (fish, meat, fruits, vegetables, etc.) and partly saturated with water (bread, butter, ice cream, etc.), i.e., food pores are filled with water and/or moist air, respectively. Measuring λ of porous saturated/unsaturated materials undergoing freezing is difficult, error prone, time consuming, laborious, and equipment expensive. Therefore, several predictive models of λ for frozen fully saturated porous systems (e.g., food and soils) were proposed in the past. In the majority of cases, these models are based on a system composition data and λ of their components. The models for saturated solid foods consider that heat is being distributed by conduction only, while for unsaturated foods more complex modeling attempts are required to take into account simultaneous phenomena of water evaporation, condensation, and ice formation. A concise review of selective predictive models is given below.

Maxwell–Eucken (Maxwell–E) model

Maxwell (1873) published a model for predicting electrical conductivity of randomly distributed and noninteracting

Modeling the Thermal Conductivity of Frozen Foods, Figure 2 Thermal conductivity of frozen foods vs. temperature.

homogeneously dispersed spheres (d) in a homogeneous continuous medium (con); and distances between spheres were assumed to be considerably larger than spheres' radii. Eucken (1932) extended this model to conduction heat flow in porous media and provided the following weighted average relation.

$$\lambda = \frac{k_{\text{con}} \cdot \theta_{\text{con}} \cdot \lambda_{\text{con}} + k_d \cdot \theta_d \cdot \lambda_d}{k_{\text{con}} \cdot \theta_{\text{con}} + k_d \cdot \theta_d}, \quad (5)$$

$$k_d = \frac{1}{3} \sum_{x=a,b,c} [1 + (\delta - 1) \cdot g_x]^{-1} \quad \delta = \frac{\lambda_d}{\lambda_{\text{con}}}, \quad (6)$$

where $k_{\text{con}} = 1$, θ are respective volume fractions, g_x is a shape factor for each particle's dimension in the dispersed phase. For solid spherical particles, $g_x = 1/3$ is applied to all three dimensions.

Levy model

Levy (1981) modified the Maxwell–E model by replacing the volume fraction of a dispersed phase, θ_d , by a new function F that eliminates a dilemma of phase designation.

$$F = \frac{1}{\sigma} - \frac{1}{2} + \theta_d - \frac{1}{2} \sqrt{\left(\frac{2}{\sigma} - 1 + 2 \cdot \theta_d\right)^2 - 8 \cdot \frac{\theta_d}{\sigma}} \quad (7)$$

$$\sigma = \frac{(\delta - 1)^2}{(\delta + 1)^2 + 0.5 \cdot \delta}.$$

In reality, porous media such as foods, however, are not necessarily composed of solid spheres and they may not be isolated from each other.

deVries model

Further modification of the Maxwell–E model was done by deVries (1963), who replaced a spherical shape of solid grains by rotated oblate ellipsoids dispersed in the continuous medium (water, air, ice), generating the following relation.

$$\lambda = \frac{k_{\text{con}} \cdot \theta_{\text{con}} \cdot \lambda_{\text{con}} + \sum_{j=1}^N k_j \cdot \theta_j \cdot \lambda_j}{k_{\text{con}} \cdot \theta_{\text{con}} + \sum_{j=1}^N k_j \cdot \theta_j}, \quad (8)$$

where N is the number of solid components; each solid grain component (j) has the same weighting factor k_j and the same thermal conductivity λ_j .

$$k_j = \frac{1}{3} \sum_{x=a,b,c} \left[1 + \left(\frac{\lambda_j}{\lambda_{\text{con}}} - 1 \right) \cdot g_x \right]^{-1}, \quad (9)$$

where g_x is a solid particle ellipsoidal shape factor for each of three ellipsoid axes (a , b , c); $g_a + g_b + g_c = 1$, $a = b = p \cdot c$, where p is a shape value; thus, $g_a = g_b$, while $g_c = 1 - 2 \cdot g_a$.

The models by Maxwell–E, Levy (Equations 5–7), and deVries (Equations 8–9) are at first sight, identical in form, but in fact a different shape of solid particles (sphere vs. rotated ellipsoid) is used in these models. The shape value for spheres is known ($p = 1$), while for rotated ellipsoid the p is usually obtained by fitting the model to experimental data. Consequently, the model by deVries is rarely used in food engineering.

Mascheroni model

Mascheroni et al. (1977) assumed that solid frozen meats are made of partially dehydrated fibers (f), surrounded by ice and/or water randomly dispersed in a continuous matrix of the remaining food tissue. The first version of the model considers that heat flow is perpendicular (\perp) to meat fibers:

$$\lambda_{\perp} = \frac{\lambda_{\text{ice}} \cdot \lambda_f \cdot (1 - \xi_{\text{ice}})}{\xi_{\text{ice}} \cdot \lambda_f + \lambda_{\text{ice}} \cdot (1 - \xi_{\text{ice}})} + \lambda_{\text{ice}} \cdot \xi_{\text{ice}}, \quad (10)$$

where $\xi_{\text{ice}} = 1 - \sqrt{1 - \theta_{\text{ice}}}$, $\theta_{\text{ice}} = m_{\text{ice}} \cdot \frac{\rho_b}{\rho_{\text{ice}}}$, ρ_b = food bulk density, ρ_{ice} = density of ice.

The second model option assumes that heat flow is parallel (\parallel) to the meat fibers:

$$\lambda_{\parallel} = \lambda_{\text{ice}} \cdot \xi_{\text{ice}} + (1 - \xi_{\text{ice}}) \cdot \left[\lambda_{\text{ice}} \cdot \xi_{\text{ice}}^2 + \lambda_f \cdot (1 - \xi_{\text{ice}})^2 + \frac{4 \cdot \xi_{\text{ice}} \cdot (1 - \xi_{\text{ice}})}{\frac{1}{\lambda_f} + \frac{1}{\lambda_{\text{ice}}}} \right]. \quad (11)$$

Gori model

Gori (1983) assumed that frozen meats (also used for frozen soils) are composed of cubic cells, each having a concentrically located cubicle, representing all solid food components (s), surrounded with the continuous medium (unfrozen water [w], ice [i], or a mixture of both [wi]). The first version of the model considers the horizontal parallel isotherms in the cubic cell.

$$\frac{1}{\lambda} = \frac{\beta - 1}{\lambda_{\text{wi}} \cdot \beta} + \frac{\beta}{\lambda_{\text{wi}} \cdot (\beta^2 - 1) + \lambda_s} \quad \beta = \sqrt[3]{\frac{1}{1 - \theta_{\text{wi}}}} \quad (12)$$

The second version of the model takes into account a vertical parallel heat flux in the cubic cell.

$$\lambda = \frac{1}{\frac{\beta \cdot (\beta - 1)}{\lambda_{\text{wi}}} + \frac{\beta}{\lambda_s}} + \lambda_{\text{wi}} \cdot \frac{\beta^2 - 1}{\beta^2}. \quad (13)$$

Effective medium theory (EMT) model

The EMT model was adapted to predicting λ of vegetable foods by Mattea et al. (1986).

$$\sum_1^n \theta_j \cdot \frac{\lambda_j - \lambda}{\lambda_j + 2\lambda} = 0. \quad (14)$$

For frozen foods, three phases were considered:

$$\begin{aligned}\lambda_1 &= \lambda_w \quad \theta_1 = \theta_w \quad \lambda_2 = \lambda_{ice} \quad \theta_2 = \theta_{ice} \\ \lambda_3 &= \lambda_s \quad \theta_3 = 1 - \theta_w - \theta_{ice}\end{aligned}$$

Modified resistor series model

Cleland and Valentas (1997) proposed a modified resistor series model for calculating λ of frozen foods, which may also contain bounded water (b).

$$\frac{\theta_w + \theta_b + \theta_s}{\lambda} = \frac{\theta_w + \theta_b}{\lambda_w} + \frac{\theta_s}{\sum_{j=1}^n \frac{\theta_j}{\lambda_j}}. \quad (15)$$

Geometric mean model (GMM)

The GMM was successfully used in predicting λ of frozen soils by Johansen (1975).

$$\lambda = \lambda_s^{\theta_s} \cdot \lambda_{ice}^{\theta_{ice}} \cdot \lambda_w^{\theta_w}. \quad (16)$$

Parallel model (/)

It assumes parallel configuration of the system components in the direction of heat flow.

$$\lambda_{//} = \frac{\sum_i^n \theta_i \cdot \lambda_i}{\sum_1^n \theta_i}. \quad (17)$$

Series model (Σ)

It assumes series configuration of the system components in the direction of heat flow.

$$\lambda_{\Sigma} = \frac{\sum_{j=1}^n \theta_j}{\sum_{j=1}^n \frac{\theta_j}{\lambda_j}}. \quad (18)$$

Pham (1990) carried out a comprehensive analysis of seven physical predictive models and one set of empirical equations for λ of frozen foods and concluded that the model by Levy (1981) was the most accurate followed by the effective medium theory (EMT) model and the Maxwell–Eucken model. Tarnawski et al. (2005) analyzed and compared eight models (deVries, Levy, Mascheroni, Maxwell–Eucken, Gori, geometric mean, effective medium theory, modified resistor) and their 54 versions, developed for frozen foods and soils, against λ data of 13 meat products (Pham and Willix, 1989) in T ranging from -1°C to -40°C . The thermal conductivity of ice and other food components were assumed to be T independent; the fraction of ice was modeled using a relation given by Schwartzberg (1976). The models by

deVries, Levy, and Mascheroni produced results very close to experimental data. In general, relatively small differences in predictions were observed, i.e., Relative Root Mean Squared-Error (RRMSE) was ranging from 5% to 7%; it was probably due to meat anisotropy, constant λ_{ice} , varying composition, measuring errors, and limitation of predictive models. A similar analysis carried out by Tarnawski et al. (2007) for T -dependent λ_{ice} showed that the models by Mascheroni et al. (1977) are marginally better than the other remaining models. Carson (2006) published a comprehensive review of models applied to unfrozen and frozen foods. Wang et al. (2006) verified 31 predictive models by comparing them with λ conductivity data for 22 meat and seafood products (Willix et al., 1998; Pham and Willix, 1989), with T ranging from -40°C to $+40^{\circ}\text{C}$. The results obtained showed that the best 15 models had RRMSE varying from 11.5% to 16.4%. van der Sman (2008) modeled thermophysical properties of frozen meat products using their composition data, $\lambda(T)$ for water and ice, with the ice fraction estimated by a relation given by Schwartzberg (1976). The λ model by Torquato and Sen (1990) was extended to ternary systems (frozen meats) by modeling two existing phases (unfrozen water and muscle fiber) as one continuous medium and handling ice crystals as the dispersed phase. The model introduces a factor dependent on the structure and orientation of protein fibers. This modeling attempt was compared with experimental λ data by Pham and Willix (1989) and Willix et al. (1998), and predictions with an error of 10% were reported. In the past, comprehensive reviews on modeling λ of foods were also given by Sweat (1985) and Sanz et al. (1989).

In terms of frozen unsaturated food products (internal pores filled in with moist air), λ modeling is much more intricate as porosity of foods and filling mediums (water, air) have to be considered. Cogné et al. (2003) measured λ of ice creams using a hot-wire probe technique. The measured λ was affected by T and the ice cream's apparent density. For λ modeling, ice cream was considered as a heterogeneous and multiphase system composed of a frozen concentrated continuous liquid phase matrix (carbohydrates, proteins, lipids, and unfrozen water) filled in with ice and air. The dispersed phase (liquid water and solid components) λ was estimated by a parallel model and then together with $\lambda_{ice}(T)$ was applied to de Vries model for obtaining λ of a standard mix at different T ; then, this λ with a value of λ_{air} was applied to Maxwell–Eucken model to obtain the overall λ . Jury et al. (2007) carried out λ measurements of bread with T ranging from -20°C to 80°C . Bread was assumed to be composed of dry fraction (proteins, carbohydrates, lipids, mineral salts, etc.) and pores containing moist air, both surrounded by water. When this system is exposed to $T < T_f$, very complex simultaneous heat and moisture transfer phenomena (evaporation–condensation effects, ice formation, etc.) take place (Hamdammi et al., 2004). Consequently, measuring and estimating effective λ for unfrozen and frozen breads still remains a very complex issue (Hamdammi et al., 2003).

Conclusions and recommendations

Accurate λ predictions for frozen foods are difficult due to a large number of modeling parameters involved, such as initial water content, temperature, density, food structure, anisotropy, initial freezing point, rate of ice formation, temperature-dependent thermal conductivity of ice, etc. Frozen foods are often considered as a mixture of homogeneous solid components being dispersed in continuous phase (ice, water, or water+ice). There are, however, still some dilemmas with a proper selection of a continuous medium and therefore, further studies are needed. A choice of water+ice as the continuous phase is promising as it improves λ predictions and eliminates discontinuity at the initial freezing point T_f , but nevertheless it requires further comprehensive testing. Temperature-dependent λ_{ice} has a strong influence on predicted λ of frozen lean meats; but, there are some unanswered concerns regarding the equations currently used for λ_{ice} estimation, as λ_{ice} also depends on ice structure and a freezing process for both water solution and pure water. Taking into account these issues and the enormous complexity of foods and the freezing process, developing an accurate mechanistic λ model for frozen foods is rather unrealistic. Review of frozen food literature reveals that Levy model and Mascheroni's equations produce very close results to experimental data (within approximately 10% error). The model by Mascheroni, however, is simpler in form, accounts for food fiber orientation, does not require any fitting, and it produces close predictions for low-fat meats. For high-fat meats, Levy's model gives better λ estimates, but the model structure is too complex and therefore it is not easy to use. Highly complex predictive models are difficult to handle when applied to food products of uncertain food structure, composition, and unknown thermal conductivity, because numerous rough assumptions have to be made. Besides, it is still unclear what the real impact of highly accurate λ predictions will have on the analysis of freezing processes and designing freezing/thawing equipment, due to a variety of foods having very diverse physical properties. It appears that, the demand for sophisticated and difficult to use λ models may not be fully justified and more attention should be paid to the use of simple models (e.g., geometric mean, series-parallel, etc.) applied to a wide variety of foods.

MONITORING PHYSICAL CONDITIONS IN AGRICULTURE AND ENVIRONMENT

Wojciech M. Skierucha

Department of Metrology and Modeling of Agrophysical Processes, Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland

Definition

Monitoring physical conditions in agriculture and environment is a collection and processing of data that allow to determine temporal and spatial variation of these conditions to make proper decisions in the future for the benefit of sustainable food production.

Introduction

Agriculture has both positive and negative influence on environment. Its primary function is meeting the growing demand for food. Agriculture creates habitats not only for humans but also for wildlife and plays an important role in sequestering carbon, managing watersheds, and preserving biodiversity. But agriculture degrades natural resources causing soil erosion, introducing unrecoverable hydrological changes, contributing in groundwater depletion, agrochemical pollution, loss of biodiversity, reducing carbon sequestration from deforestation, and carbon dioxide emissions from forest fires (Doran, 2002).

Physical conditions in agriculture and environment can be defined as physical properties and processes involved in mutual relation between the processes of food and fiber production and the impact of these processes on natural agro-environment. They include topography, surface water and groundwater distributions, heat-temperature distributions, wind direction changes, and intensity.

The measures of physical conditions in agriculture and environment should include a minimum number of measurable physical indicators, that can provide sufficient data not only for decision making in the production of food and fiber but also in ecosystem function and the maintenance of local, regional, and global environmental quality.

Agricultural sustainability and environmental quality are determined by the health of soil, which is a thin layer of the earth surface forming the interface between agriculture and environment. Soil quality, which can be described

by the combination of its physical, chemical, and biological properties and contamination by inorganic and organic chemicals is critical to environmental sustainability (Arshad and Martin, 2002). The physical properties of soils play a major role in controlling mass and energy transport in the subsurface environment.

The basic physical soil quality indicators recommended or used by soil researchers are as follows (Schoenholtz et al., 2000): texture (influence retention and transport of water and nutrients), soil depth and topsoil depth (major factor in total nutrient, water, and oxygen availability), bulk density (decides about root growth, rate of water movement, soil volume expression), soil water content, soil temperature, available water holding capacity (informs about plant available water, erosivity), soil roughness (erosivity, soil tilth), saturated hydraulic conductivity (water and air balance, hydrology regulation), resistance to penetration (root growth), porosity (water/air balance, water retention, root growth), and aggregate stability and size distribution (root growth, air/water balance).

The need for monitoring physical conditions in agriculture and environment is increasing, because of increasing pressure on natural resources, sustainability, and exhaustion of nonrenewable resources. Advances in sensors, computers, and communication devices result in great amounts of temporal and spatial information that should be processed in real-time (or near real-time) to produce unambiguous information for the decision-making stage.

Robust, low-cost, and preferably real-time sensing systems are needed for monitoring physical conditions in agriculture and environment. Commercial products have become available for some sensor types. Others are currently under development, especially in the field of precision agriculture.

Selection of the monitoring method

Monitoring is a series of measurements (or observations) done in a planned fashion in order to assemble a more complete view of existing conditions through time. Single observations or surveys are made at a point in time to record the current condition. Monitoring, in a formal sense, is a series of surveys.

The goals, applied sensors, data collection strategies, and methods of analysis used in monitoring must be defined in detail and in advance before taking further steps that sometimes require formal, technical, and financial arrangements. These elements and their relationship depend on the temporal and dimensional scale of planned observations. There are technical means to measure minute quantities of chemicals in the environment. At the other end of the dimensional scale, there are space-based satellite sensors routinely scanning and mapping the earth surface several times a day.

The choice of mass and volume of the sampled material, size of measurement probes, and temporal and spatial

locations should be chosen for assuring the measured sample to be representative of the target component. This is especially important for soil because it is not homogeneous both in space and in time.

The investigation of the agricultural and environmental physical conditions sometimes requires physical removal of samples from the environment, for example, collecting soil cores in the vadose zone disrupt soil profiles and can create preferential flow paths. Measurements involving unrecoverable destruction of the measured medium are called destructive. Nondestructive measurements or monitoring is becoming increasingly important with the technological miniaturization as well as the development of sensors, electronics and telecommunication. The example of nondestructive monitoring is by means of satellite-based sensors to measure topography, plant cover, or top-soil temperature.

Selectivity

The key feature of the applied measurement method is its selectivity, that is, the lack of sensitivity of the conversion function (calibration) on the influence from the factors other than the measured one. Proper selectivity liberates the user from frequent, specific for each soil, *in situ* calibrations.

The solution to the problem of electric measurement of the physical quantity in selective way is to find such an electric property of the medium conditioning it, which is specific to the considered medium. For example, the specific property of molecular oxygen in electrolyte ("soil water") is small activation energy of electrode reaction of its reduction. It can be concluded that electric measurement of oxygenation may be based on the ammetric measurement of the current of electrode reaction of oxygen molecules reduction (Malicki and Bieganowski, 1999).

Concerning the problem of electric soil moisture measurement, the medium conditioning moisture is water and its specific property is the polar structure of water molecules. Polarity of water molecules is the reason that dielectric permittivity (dielectric constant) of water is much higher than permittivity of soil solid phase (the relative dielectric constant of water in the electric field of frequency below 18 GHz and at room temperature is about 81, while the relative dielectric constant of solid phase is 4–5 at the same conditions). The dielectric constant of soil strongly depends on its water content, therefore it may be concluded that electric measurement of soil moisture should be based on the measurement of its dielectric constant.

Similarly, concerning the issue of electric measurement of soil salinity, the media conditioning salinity are salts present in soils and the specific property is their ionic form. The ability to transport electric charge by the ions in "soil water" allows the soil to conduct electric current. Therefore, the electric measurement of soil salinity should be based on the measurement of its electric conductivity.

Status of water as significant issue of agrophysics

Increasing demands of water management result in the continuous development of its tools. One of the most important, besides the simulation models of water balance, is monitoring of water status in porous materials defined as a space-temporal recording of the water properties that stimulate the phenomena and processes observed in the soil–plant–atmosphere system.

Concerning agrophysics, water status in porous materials is the issue of first priority, because each phenomenon or process examined in its scope depends on water status.

Monitoring of water status is accomplished using digital systems. The digital data acquisition systems react only on electric signals and the applied sensors must convert the measured value into the proportional electric signal.

Water status of soil, as a porous material should be expressed by minimum five variables: amount of water in the soil (i.e., soil moisture), soil potential, salinity, oxygenation, and temperature (Malicki, 1999).

The most difficult are the electric measurement of soil water potential and soil water content (soil moisture); therefore, they are the subject of permanent research. It is assumed here, that the method successfully verified for soils will be also applicable for other porous agricultural materials because their structure is not as complex as soil.

Monitoring physical conditions in agriculture and environment is done by sampling, automatic ground measurement systems or remote sensing with the use of planes or satellites.

Sampling

There are several soil basic physical properties that cannot be measured automatically and the necessary information about their variability in time and/or space is gathered by means of traditional sampling. Soil mechanical properties, that is, soil texture and soil density or porosity, which is functionally dependent on soil density, do not change in time in uncultivated areas because they present the effect of long-term geological processes.

Sampling strategy in agro-environmental monitoring depends on the objectives, which include increase agriculture productivity (yield indicators), optimize water use in irrigation systems, or increase carbon sequestration. Also, it depends on observation scale from the geographical or administrative point of view: an experimental plot, field, landscape, watershed, farm, district, or whole country. Spatial and temporal variability must also be taken into account in constructing time schedule and sampling locations to be representative.

Sampling usually affects the environment, that is, this type of measurement maybe destructive to the tested object or its immediate vicinity. Drilling a deep well to collect groundwater does not affect the groundwater environment but the geological profile is irreversibly damaged. Soil cores collected in the vadose zone disrupt soil profiles and can create preferential flow paths.

Ground monitoring systems with automated data acquisition and processing

The technological progress in material science, electronics, telecommunication, and informatics effects in the development of new sensing devices that can be adopted in examining objects of agricultural and environmental studies. They include Time Domain Reflectometry (TDR) and Frequency Domain Reflectometry (FDR) probes for the simultaneous measurement of soil moisture, electrical conductivity, and temperature (Skierucha et al., 2006). There sensing devices include sensors and transducers, where the former detects the signal or stimulus and the latter converts input energy of one form into output energy of another form. An example of the sensor is thermistor giving the change of resistance as the function of temperature. This sensor associated with electrical circuitry forms an instrument, also called a transducer, that converts thermal energy into electrical energy.

Another important element of a ground monitoring system is a data acquisition and processing unit, which monitors the output signal of the transducer and processes the resulting data into a form that can be understood by the end user. The basic features of this unit include user-friendly interface for the operator, large storage memory, physical communication interfaces preferably with serial transmission from the instrument to the operator's notebook. Telemetry with the application of wireless networks is becoming popular especially for distant ground monitoring systems (Wang et al., 2006).

Monitoring stations must meet strong requirements concerning power consumption. The hardware designers should use low-power electronic circuits and apply sleep mode operations whenever possible. Also, charging the internal battery is accomplished with a solar panel.

Remote sensing

Remote sensing in agriculture and environment is the acquisition of biological and geochemical information about the condition and state of the land surface by sensors that are not in direct physical contact with it. The transmission of this information is in the form of electromagnetic waves reflected from the land surface either in passive mode – when the source of energy is the sun and/or the Earth, or in active mode – when the source energy is artificially generated. The analyzed signal reflected from the land surface is composed with different wavelengths over the electromagnetic spectrum (Artiola et al., 2004a). Today a large number of satellite sensors observe the Earth at wavelengths ranging from visible to microwave, at spatial resolutions ranging from submeters to kilometers and temporal frequencies ranging from minutes to weeks or months (Rosenqvist et al., 2003).

The remote sensed data provide information about ecosystem stability, land degradation and desertification (Artiola et al., 2004b), carbon cycling (Rosenqvist et al., 2003), erosion and sediment yield, soil moisture

(Wigneron et al., 1998; Kerr, 2007), and plant and weeds cover (Thorp and Tian, 2004).

Conclusion

Monitoring physical conditions in agriculture and environment can be done in various temporal and dimensional scales and with the application of numerous instruments and methods reflecting the current development of technology. The received and processed data increase our knowledge for the benefit of social, political, and economic sustainable development as well as for better understanding the nature.

Definition

Mulch. Mulch is any material, other than soil, placed or left at the soil surface for soil and water management.

Mulching. In agriculture and gardening, mulching is the practice of leaving crop residues or other materials on the soil surface for soil and water conservation and keeping favorable and stable environments for plant growth.

Introduction

Mulching is a form of conservation tillage consisting of leaving a layer of crop residues (CR) or other materials on the soil surface. Mulch helps to preserve high and sustainable yields by increasing the soil organic matter (SOM) content and therefore improving soil physical quality. Mulch tilling is also a form of minimum tillage and a cost-efficient alternative for high-yield conservation agricultural practice.

Leaving CR or other substances on the soil surface is a traditional practice for protecting soil from erosion and enhancing fertility (Lal and Stewart, 1995). It has been reported that conventional agricultural practices, based

on intensive fertilization and chemical amendments, often lead to degradation processes, such as erosion (see entry *Tillage Erosion*), acidification, and the emission of greenhouse gases (see entry *Greenhouse Gases Sink in Soils*). Current global problems such as population growth, greenhouse effect, malnutrition, water quality, reduction of agricultural land, and soil degradation (see entry *Desertification: Indicators and Thresholds*) require the implementation of conservation tillage practices to address the problem of sustainability, food security, and environmental quality.

Materials used as mulch

A wide variety of materials can be used as mulch. Most of mulches are organic materials (e.g., CR, litter, straw, leaves, or weed biomass), but other inorganic or industry-derived materials can be also used (plastic film, gravels, or geotextiles). The election depends in both availability and objectives.

Organic mulches must be weed free, easy to apply, and readily available by farmers. The mulch decomposition time can vary greatly. Depending on the amount and type of mulch, varying quantities of nutrients and organic matter enter the soil during the decomposition process. In agriculture, the most commonly used organic mulches are crop/plant residues, produced on-site or off-site and left on the soil surface after cropping (e.g., wheat straw). A large quantity of residue is produced annually, so that it constitutes a renewable and easily available resource. Other mulches used in agriculture and gardening are wood chips, pine bark, and pine needles. Some wastes, such as shredded or composted clipped grass, litter, and small branches can also be used.

Inorganic materials such as geotextiles can be used as mulch. Some of the advantages of using geotextiles is the prevention of weed growth (at least in a great proportion), and the normal aeration and water exchange. Rock fragments and gravels can be used as inorganic mulch materials. They show low decomposition rates and do not require annual replacement, but cannot be suitable for all crops. Plastic films help control most weeds and contribute to water conservation. Plastic films are used predominantly in extensive crop areas, but show some problems: interruption of air, water, and nutrients flow between the topsoil and the atmosphere, as well as other environmental problems such as disposal of plastic materials.

Effects on soil physical properties

Soil structure and aggregate stability

Soil structure is extremely important for the maintenance of soil quality and productivity. Aggregate stability (AS) affects root density and elongation (see entry *Root Responses to Soil Physical Limitations*), air and water flow and erosion (Amézketa, 1999). Some of the main factors affecting soil aggregation are SOM content (see entry *Soil Aggregates, Structure, and Stability*), texture and moisture content, but external factors as crop type, tillage practices, or microfauna are also important. Long-term tillage affects AS (Angers et al., 1993; Unger et al., 1998; Álvaro-Fuentes et al., 2008), as tillage destroys aggregates leading to a decrease in aggregate size and pore clogging by fine particles. It has been reported that decomposition rates of SOM are lower with minimum tillage and residue retention, and consequently it increases over time (Loch and Coughlan, 1984; Dalal, 1989).

AS is determined by the cohesive forces between particles. Therefore, it can be used as an index of structure and physical soil stability. Soil texture, clay mineralogy, cations, and the quantity and quality of SOM are key factors controlling aggregation. Plant roots (see entry *Plant Roots and Soil Structure*), microorganisms (especially fungi), and organic substances are also involved in the formation of aggregates and AS. AS may vary seasonally (Hillel, 1998) or during tilling. After mulching, increased SOM content contributes to enhance aggregation, as it has been reported under a diversity of climate areas (Mulumba and Lal, 2008; Jordán et al., 2010) even in the short term (Hermawan and Bomke, 1997).

Inorganic mulches (e.g., plastic film) show limited or no effect on soil structure. Zhang et al. (2008), for example, reported that under no tillage, the increase in SOM content and AS in soils under straw cover was higher than under plastic film; in this case, soil quality under plastic mulch was similar or even lower than in non-covered soils. In contrast, geotextiles may increase SOM content, improving topsoil structure and AS (Bhattacharyya et al., 2010).

Bulk density and porosity

The effects of CR on soil bulk density (BD; see entry *Bulk Density of Soils and Impact on their Hydraulic Properties*) are highly variable. Although high BD has been observed under mulch relative to conventional tillage (Bottenberg et al., 1999), decreased bulk densities have also been reported by Oliveira and Merwin (2001) and Ghuman and Sur (2001). In other cases, there is no relationship between mulch rate and BD. This variability may be due to differences in management practices, soil type, and the type of mulch material used in the experiments. However, Mulumba and Lal (2008) found that BD increased for mulching rates between 0 and 5 Mg ha⁻¹ wheat straw mulch, but strongly decreased for higher rates.

Pores of different size (see entry *Pore Size Distribution*), shape, and continuity are created by abiotic and biotic factors (Kay and VandenBygaart, 2002). Mulumba and Lal (2008) found that total porosity increased significantly with increase in mulch rate after an 11-year treatment in the USA. Increased porosity due to mulch application has been also reported after shorter periods (Oliveira and Merwin, 2001; Jordán et al., 2010).

Penetration resistance

Many studies have reported greater penetration resistance in soils under no-tillage practices than in other conventionally tilled soils in the upper centimeters, and, generally, penetration resistance is higher under reduced tillage systems with residue cover. Mulch application has a significant effect on penetration resistance but only at certain stages of the crop production. After an experiment with Polish Luvisols under reduced and no-tillage practices, penetration resistance increased in the growing season, causing reduced plant growth and crop yield (Pabin et al., 2003). In this case, straw mulch did not counteract the negative changes in the parameters of the soil strength. According to Bielders et al. (2002), differences in penetration resistance after different treatments are mostly due to differences in intrinsic soil properties (e.g., cohesion, BD).

Crusting and sealing

Plant residues on the soil surface protect it against crusting (Sumner and Stewart, 1992), improving AS and infiltration rates (see entry *Soil Surface Sealing and Crusting*). Le Bissonnais and Arrouays (1997) observed that increasing SOM content decreased soil surface sealing. After a study in western Niger, Bielders et al. (2002) observed low permeability erosion crusts and discontinuous structural crusts with partially exposed clay skins in soils under conventional tillage, in contrast to mulched soils. As it has been reported in stone-covered soils (Martínez-Zavala and Jordán, 2008; Zavala et al., 2010), gravel mulch helps to avoid soil sealing and crusting (Poesen and Lavee, 1994).

The use of plastic film mulches has spread considerably as a way to reverse the low crop yields (e.g., Zhang and Ma, 1994), increasing the risk of crust formation (Li et al., 2005).

Soil temperature

Temperature affects the rate of soil biological and chemical processes (see entry *Temperature Effects in Soil*). The amount of energy entering the soil depends strongly on soil color, aspect, and the vegetative cover. CR on the soil surface can affect or completely modify the soil temperature regime by reducing the amount of energy entering the soil by the interception of radiation, shading the soil surface, and buffering temperature variations.

Soil temperature range is usually narrower in mulched than unmulched soils. Wheat straw has a higher albedo and lower thermal conductivity than bare soil, and therefore it reduces the input of solar energy (Horton et al., 1996). On the other hand, during colder periods, wheat straw mulch on the soil surface insulates it from the colder atmosphere (Zhang et al., 2009).

Results after application of inorganic mulches vary depending on the mulch material. After field experiments in the UK, Cook et al. (2006) demonstrated that soil temperature reduced with higher mulching rates. In contrast, the use of inorganic mulches can increase soil temperature. Nachtergael et al. (1998) reported that gravel mulch

increased soil temperature and decreased evaporation (see entry *Evapotranspiration*) in vineyard soils in Switzerland. Organic geotextiles can also attenuate extreme temperature fluctuations, reducing water loss through evaporation. Inorganic materials such as plastic mulches are often used to increase soil temperature in horticulture, leading to high yields. Apart from other environmental problems, intensive use of plastic mulches for increasing soil temperature shows some limitations. Enhanced mineralization rates can lead to exhaustion of SOM, affecting long-term soil physical and chemical fertility (Li et al., 2004).

Soil water

Mulching has a great impact on soil water and surface water. Mulching decreases runoff by improving infiltration rate and increases water storage capacity by improving retention (see entry *Field Water Capacity*). In addition, reduced evaporation rates help to extend the period of time during which soil remains moist.

Mulching improves considerably soil water characteristics, although different results have been reported. Organic mulches on the soil surface induce optimal soil conditions for plant growth, enhancing soil water retention and availability, and increasing macroporosity (Martens and Frankenberger, 1992). Much research has shown that use of mulch can increase infiltration and decrease evaporation, resulting in more water stored and reduced runoff rates (e.g., Smika and Unger, 1986).

Wheat straw mulch is considered the best way of improving water retention in the soil and reducing soil evaporation. High available water capacities have been reported under high mulching rates and reduced or no till practices. Mulumba and Lal (2008) and Jordán et al. (2010) found that even low mulch rates have a strong impact on the available water content. Contrasting data have been reported by Głab and Kulig (2008), who found no effect in available water content after applying mulch and different tillage systems. Results can also vary between the upper and lower layers of the soil profile.

Soil erosion risk

Many researchers have reported low or negligible soil losses in mulched soils in comparison with conventional soil tillage (see entry *Water Erosion: Environmental and Economical Hazard*). The hydrological/erosional response of mulched soils depends largely on the mulching rates applied during the crop period. It has been reported that the erosive consequences of moderate storms in the Mediterranean area could be strongly reduced by using just $5 \text{ Mg ha}^{-1} \text{ year}^{-1}$ mulching rates (Jordán et al., 2010). A mulch layer increases the roughness and the interception of raindrops, delaying runoff flow and favoring infiltration (García-Orenes et al., 2009). Low erosive responses of mulched soils have been reported from diverse climate areas of the world. In contrast, Jin et al. (2009) suggested that the relation between mulching rate

and interrill soil detachment is not unique and can vary depending on rainfall intensity. Increasing cover rates reduce infiltration and lead to an increasing net flux, which becomes deeper and faster in its concentrated flow part. In this case, ponding is faster and deeper, thus the water column pressure is greater and thereafter infiltration takes place more quickly and penetrates more deeply. However, this response can be overridden under moderate rainfall intensity by a dense soil cover or thick mulch layers.

Plastic mulches substantially accelerate runoff generation in slopes (Wan and El-Swaify, 1999). According to Bhattacharyya et al. (2010), the use of geotextiles is an effective soil conservation practice, but its efficiency decreases in large areas. Despite synthetic geotextiles dominating the commercial market, geotextiles constructed from organic materials are highly effective in erosion control and vegetation establishment (Ogbobe et al., 1998) and can be an ecological alternative for farmers (Giménez-Morera et al., 2010). Anyway, experimental studies under natural and simulated rainfall have demonstrated that cotton geotextiles reduce soil losses but increase water losses, probably due to water repellency of cotton. Although soil erosion can be severely reduced by geotextiles at the pedon or meter scale, surface runoff may result in high erosion rates at slope and watershed scales as more runoff will be available (Giménez-Morera et al., 2010).

Summary

During the last decades, conservation tillage techniques have displaced conventional tillage in many areas of the world. The use of CR left on the soil surface improves soil quality and productivity through favorable effects on soil physical properties. Mulch farming is a form of conservation tillage that preserves soil quality and the environment. Mulch affects soil physical properties by improving SOM content, increasing soil porosity and AS. Indirectly, mulching also regulates soil temperature, and increases water retention capacity.

An organic mulch layer serves as a protecting layer against rainfall-induced soil erosion by reducing drop impacts and modifying the hydrological response of the exposed surface. CR and other organic mulches intercept rainfall and contribute to decrease runoff rates and enhance infiltration, protecting soil from erosion. Inorganic mulches as geotextiles, gravels, or plastic films show a range of erosional responses to rainfall.

MYCORRHIZAL SYMBIOSIS AND OSMOTIC STRESS

Juan M. Ruiz-Lozano
 Departamento de Microbiología del Suelo y Sistemas Simbióticos, Estación Experimental del Zaidín (CSIC), Granada, Andalucía, Spain

Definition

The term Mycorrhiza comes from the Greek words “mycos,” meaning fungus and “rhiza,” meaning root and applies to a mutualistic symbiosis between roots of most higher plants and a group of soil fungi belonging to the phyla Glomeromycota, Basidiomycota or Ascomycota. By this mutualistic association, the plant receives soil nutrients (especially phosphorus) and water, while the fungus receives a protected ecological niche and plant-derived carbon compounds for its nutrition (Varma, 2008).

The term Osmotic Stress refers to all the environmental conditions that induce a water deficit in the plant tissues, limiting plant growth and development. It generally includes drought, cold and salinity, which directly decreases the plant water content due to an also low soil water content (drought) or which difficult the right uptake of water from soil due to the diminution of soil water potential (cold and salinity).

Eco-physiological studies investigating the role of the mycorrhizal symbiosis against osmotic stresses have demonstrated that the symbiosis often results in altered rates of water movement into, through, and out of the host plants, with consequent effects on tissue hydration and plant physiology (Augé, 2001). Thus, it is accepted that the mycorrhizal symbiosis protects host plants against the detrimental effects of water deficit, and that this protection results from a combination of physical, nutritional and

cellular effects. Several mechanisms have been proposed to explain these effects. The most important are: direct uptake and transfer of water through the fungal hyphae to the host plant, better osmotic adjustment of host plants, enhancement of plant gas exchange through hormonal changes, and protection against the oxidative damage generated by drought. Modulation by the mycorrhizal symbiosis of plant genes involved in the response of plants to water deficit have also been described, with special emphasis on the role of aquaporins (Ruiz-Lozano et al., 2006). Results obtained so far show that the mycorrhizal symbiosis up- or down-regulates aquaporin genes depending on the own intrinsic properties of the osmotic stress. In any case, the induction or inhibition of particular aquaporins by mycorrhizal symbiosis results in a better regulation of plant water status and contribute to the global plant resistance to the stressful conditions, as evidenced by the better

growth and water status of mycorrhizal plants under conditions of water deficit (Ruiz-Lozano and Aroca, 2009).

NANOMATERIALS IN SOIL AND FOOD ANALYSIS

Subramanian Viswanathan

Requimte, Grupo de Reacções e Análises Químicas,
Instituto Superior de Engenharia do Porto, Porto, Portugal

Synonyms

Nanomaterials application in soil and food testing

Definition

Nanomaterials: generally referring to materials with the size of 0.1–100 nm.

Carbon nanotube: allotropes of carbon with a cylindrical nanostructure.

Biosensor: a device for the detection of an analyte that combines a biological component with a physicochemical detector component.

Introduction

The Food and Agriculture Organization (FAO) is the main United Nations agency specializing in all aspects of food quality and safety, and in all the different stages of food production, harvest, postharvest handling, storage, transport, processing, and distribution. Food analysis is the discipline dealing with the development, application, and study of analytical procedures for characterizing the properties of foods (Nielsen, 2003). These analytical procedures are used to provide information about a wide variety of different characteristics of foods, including their composition, structure, physicochemical properties, and sensory attributes. This information is critical to our rational understanding of the factors that determine the properties of foods, as well as to our ability to economically produce foods that are consistently safe, nutritious, and desirable and for consumers to make informed choices about their diet. One of the most

important reasons for analyzing foods from both the consumers and the manufacturers' standpoint is to ensure that they are safe.

Precision farming has been a long-desired goal to maximize output (i.e., crop yields) while minimizing input (i.e., fertilizers, pesticides, and herbicides) through monitoring environmental variables and applying targeted action. A soil analysis is used to determine the level of nutrients found in a soil sample. Quality crops with high yields require a sufficient supply and maintenance of nutrient elements. As nutrients are utilized by one crop and not replaced for subsequent crop production, yields will decrease accordingly. Accurate monitoring of nutrient before and after crop production and soil analysis results will help the efficient management of fertilizer applications. Soil analysis can also help to reduce agricultural waste and thus keep environmental pollution to a minimum. Researchers are exploring to come up with sensors for detection of soil nutrients, pesticides, pollutants up to very minute fractions by exploiting novel properties of nanomaterials.

The definition of nanomaterial is based on the prefix “nano,” which is from the Greek word meaning “dwarf.” The word nanomaterials is generally used when referring to materials with the size of 0.1–100 nm; however, it is also inherent that these materials should display different properties from bulk (or micrometric and larger) materials as a result of their size (Rao et al., 2004). These differences include physical strength, chemical reactivity, electrical conductance, magnetism, and optical effects. The potential of nanomaterials to revolutionize the health care, textile, materials, information and communication technology, and energy sectors has been well publicized. In fact, several products enabled by nanomaterials are already in the market, such as antibacterial dressings, transparent sunscreen lotions, stain-resistant fabrics, scratch-free paints for cars, and self-cleaning windows.

Nanomaterials such as nanotubes (NTs), nanowires (NWs), and nanoparticles present new opportunities as sensing platforms for biological and environmental applications. Having micrometer-scale lengths and nanometer-scale diameters, NTs and NWs can be manipulated with current microfabrication, as well as self-assembly techniques to fabricate nanoscale devices and sensors (Rao et al., 2004). Examples of different nanomaterials-based analytical techniques for the detection of major families of environmental pollutants, i.e., organic contaminants, heavy metals, and air pollutants are reported. Application of the nanomaterials in the field of soil and food analysis is promising. This article covers the recent developments and issues in electrochemical biosensors for food analysis such as ease of preparation, robustness, sensitivity, and realizations of mass production of the detection strategies. This article also emphasizes the current development of electrochemical biosensors combined with nanotechnology.

The synthesis, characterization, and utilization of nanomaterials are part of an emerging and rapidly growing field. Nanomaterials may be grouped under nanoparticles (the building blocks), nano-intermediates, and nanocomposites. Nanostructured materials are synthesized by supramolecular chemistry yielding nanoassemblies (Rao et al., 2004). The nanoparticles serve as the building blocks of nanomaterials and devices. They include nanocrystalline materials such as ceramic, metal and metal oxide nanoparticles; fullerenes, nanotubes, nanorods, and related structures; nanofibers and wires, and precise organic as well as hybrid organic–inorganic nanoarchitectures such as dendrimers and polyhedral silsesquioxanes, liposomes, or nanosomes, respectively.

Nanocrystalline materials

Included here are ceramics, metals, and metal oxide nanoparticles. These materials are assembled from nanometer-sized building blocks, mostly crystallites. The building blocks may differ in their atomic structure, crystallographic orientation, or chemical composition. In other words, materials assembled of nanometer-sized building blocks are microstructurally heterogeneous, consisting of the building blocks (e.g., crystallites) and the regions between adjacent building blocks (e.g., grain boundaries). One of the primary applications of metals in chemistry is their use as heterogeneous catalysts in a variety of reactions (Rao et al., 2004). Due to their vastly increased surface area over macroscale materials, nanometals and oxides are ultrahigh activity catalysts. Nanometals and oxides are also widely used in the formation of nanocomposites. Aside from their synthetic utility, they have many useful and unique magnetic, electric, and optical properties.

Carbon nanotubes

Carbon nanotubes (CNTs) are hollow cylinders of carbon atoms. Their appearance is that of rolled tubes of graphite

such that their walls are hexagonal carbon rings and are often formed in large bundles. Generally speaking, there are two types of CNTs: single-walled carbon nanotubes (SWCNTs) and multi-walled carbon nanotubes (MWCNTs) (Rao et al., 2004). As their names imply, SWCNTs consist of a single, cylindrical graphene layer, whereas MWCNTs consist of multiple graphene layers telescoped about one another. CNT-based nanodevices are a hot research area at the moment. Applications could include novel semiconducting devices, chemical sensors, and ultrasensitive electromechanical sensors (Wang, 2005).

Nanocomposites

Nanocomposites are materials with a nanoscale structure that improve the macroscopic properties of products. Typically, nanocomposites are clay, polymer or carbon, or a combination of these materials with nanoparticle building blocks. Nanocomposites, materials with nanoscale separation of phases can generally be divided into two types: multilayer structures and inorganic/organic composites. Multilayer structures are typically formed by gas phase deposition or from the self-assembly of monolayers. Inorganic/organic composites can be formed by sol–gel techniques, bridging between clusters (as in silsequioxanes), or by coating nanoparticles, in polymer layers for example.

Biosensors

Biosensors are molecular sensors that combine a biological recognition mechanism with a physical transduction technique. They provide a new class of inexpensive, portable instrument that permit sophisticated analytical measurements to be undertaken rapidly at decentralized locations. The sampling component of a biosensor contains a bio-sensitive layer that can either contain bioreceptors or be made of bioreceptors covalently attached to the transducer. The interaction of the analyte with the bioreceptor is designed to produce an effect measured by the transducer, which converts the information into a measurable effect, for example, an electrical signal. There are four major types of transducers: electrochemical (electrodes), mass (piezoelectric crystals or surface acoustic wave devices), optical (optrodes) and thermal (thermistors or heat-sensitive sensors). Among the various types of biosensors, the electrochemical biosensors are the most common as a result of numerous advances leading to their well-understood biointeraction and detection process (Egging, 2002).

The state of the art of nanomaterials and nanotechnologies represents a new trend in the development of sensors and electronic chips that will have a big impact on the future of nanoscience. It is essential to distinguish between nanotechnology and nanomaterials, because in the first case nanotechnologies represent new possibilities for sensor construction and for the developing of novel methods. In the second case, nanomaterials have been widely used

to immobilize enzymes, antigens, and nucleic acids on transducer surfaces, to promote the direct electron transfer reactions, and to amplify and orient the analytic signal of the bio-recognition events.

Applications

In chromatography

Separation science, based on chromatographic and electrophoretic techniques, has achieved many advances employing nanomaterials. Separation media and channels in the above two approaches have sizes and shapes comparable to those of nanomaterials, which makes the latter useful for specific applications in separation science on a micro- and nanometer scale. Nanomaterials have played various roles (e.g., modifier, stabilizer, and stationary phase) in chromatography. The effective pi–pi interactions between fullerenes and phenyl group have utilized to develop fullerene-based stationary phases for the separation of solutes with phenyl moieties in their structures. The conjugated pi- electron system on the surface of SWCNT as well as surface functionalization provides an opportunity to synthesize a stationary phase with good selectivity (Zhang et al., 2006). Nanoparticles, including silica nanoparticles, gold nanoparticles, titanium oxide nanoparticles, polymer nanoparticles, molecularly imprinted polymers, molecular micelles, and dendrimers, used as pseudostationary phases in CEC, have been reviewed by Nilsson et al. (2006).

In optical sensors

Nanomaterials-based optical sensors have been much interested to the trace detection of analytes of interest in the agriculture and food industry. The changes in the optical properties of nanomaterials such spectral absorbance, photoluminescence (PL), and chemiluminescence (CL) phenomena induced by the interaction between nanomaterials and various analytes is utilized to the determination of chemical and biochemical analytes (Shi et al., 2004). Quantum dots (QDs) are nanocrystals of inorganic semiconductors that are somewhat restricted to a spherical shape of around 2–8 nm diameter (Smith and Nie, 2004). Their fluorescent properties are size-dependent and therefore they can be tuned to emit at desired wavelengths (between 400 and 2,000 nm) if synthesized in different composition and size. In this way, QDs of different sizes can be excited with a single wavelength and emission controlled at different wavelengths, thus providing for simultaneous detection. These, together with their highly robust emission properties, make them more advantageous for labeling and optical detection than conventional organic dyes (Patolsky et al., 2006). Their high quantum yields and their narrow emission bands produce sharper colors, lead to higher sensitivity and the possibility of multiplexing of analysis (Tully et al., 2006). The unique optical properties of plasmonic nanoparticles have led to the development of label-free chemical and environmental sensor since the surface plasmon resonance (SPR) is

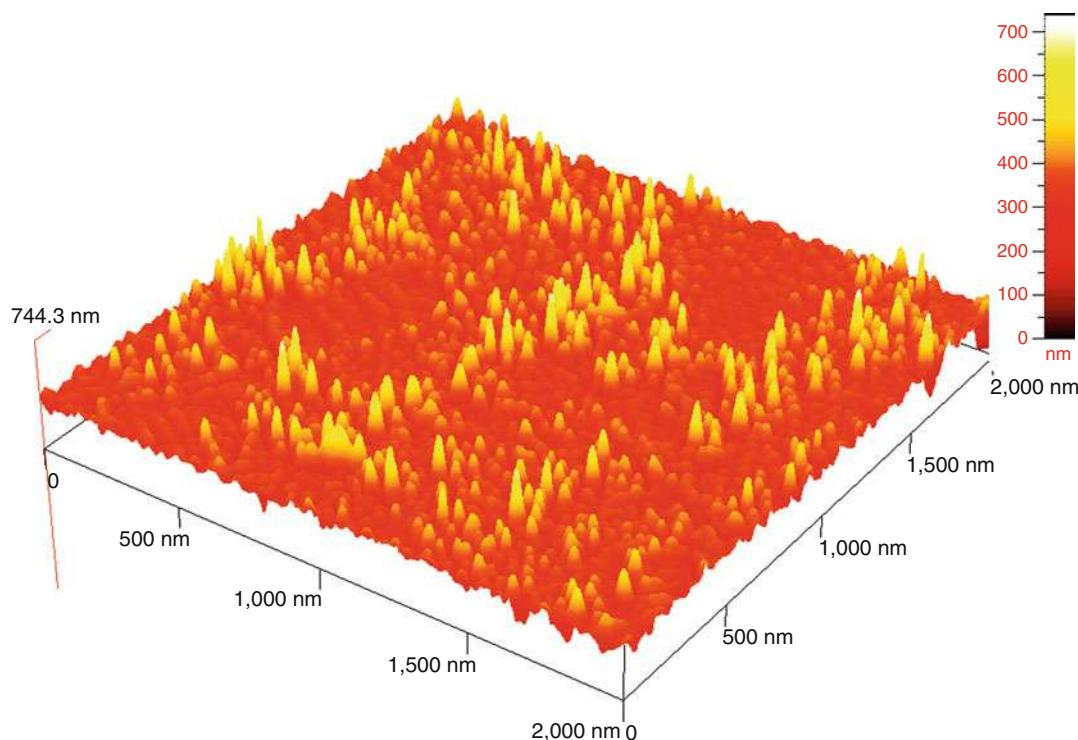

sensitive to the local environment. Some research groups are exploring biosensors based on the SPR exhibited by metal nanoparticles (Haes and Van Duyne, 2002).

In electrochemical biosensors

One-dimensional (1-D) nanostructures, such as CNT and semiconductor- or conducting polymer nanowires, are particularly attractive materials for working electrode in biosensors. Nature of biosensing surface is very important, namely, the prolonged use of the sensor and an anticipated extended storage and working stability. High surface-to-volume ratio and electron transport properties of CNT opens the possibility of developing superior electrochemical sensing devices, ranging from amperometric enzyme electrodes to label-free DNA hybridization biosensors (Zhang et al., 2009). The possibility of direct electron-transfer between enzymes and electrode surfaces could pave the way for superior reagentless biosensing devices, as it obviates the need for co-substrates or mediators and allows efficient transduction of the bio-recognition event. “Trees” of aligned CNT in the nanoforest, prepared by self-assembly, can act as molecular wires to allow electrical communication between the underlying electrode and redox proteins covalently attached to the ends of the SWCNT (Gooding et al., 2003). Viswanathan et al. (2009) demonstrated that vertically aligned SWCNT on gold electrode for pesticides determination (Figure 1). Arrays of nanoscopic gold tubes or wires have been prepared by electroless deposition of the metal within the pores of polycarbonate particle track-etched membranes (Marc and Sophie, 2003). A sensitive and selective genomagnetic assay for the electrochemical detection of food pathogens based on in situ DNA amplification with magnetic primers reported by Lermo et al. (2007). Liposomes are microscopic, fluid-filled, pouches with endless walls that are made of layers of phospholipids identical to the phospholipids that make up cell membranes. Electroactive marker encapsulated immuno liposomes are typically used as signal amplifier for electrochemical immunoassays (Viswanathan et al., 2006). Chitosan (CS) is the second abundant polysaccharide and a cationic polyelectrolyte present in nature. Chitosan nanoparticles are promising biometarials for various analytical applications. Ferrocene-conjugated chitosan nanoparticles were used as the electroactive indicator of hybridization (Kerman et al., 2008).

Electronic tongue

Electronic tongue systems are hybrid micro or nanoarrays of electronic sensors that measure and compare tastes. E tongue is mainly based on potentiometric, voltammetric, ion-selective field-effect transistor (ISFET), piezoelectric, and optical sensors with pattern recognition tools for data processing. The information given by each sensor is complementary and the combination of all sensors results generates a unique fingerprint. Most of the detection thresholds of sensors are similar or better than those of

Nanomaterials in Soil and Food Analysis, Figure 1 Atomic force microscopic image of ssDNA-wrapped single-walled carbon nanotube (SWCNT) self-assembled monolayer on Au(111) surface (Viswanathan et al., 2009).

human receptors. The electronic tongue appeared to be capable of distinguishing between different sorts of beverages: natural and artificial mineral waters, individual and commercial brands of coffee, flesh food, and commercial and experimental samples of soft drinks containing different sweeteners (Scampicchio et al., 2008). Ciosek and Wroblewski (2007) have reviewed about recent developments of multisensor array based electronic tongue for food and soil analysis.

Electronic nose

Electronic nose is a specific kind of semiconducting sensor arrays that can mimic the natural olfaction sense, according to the electronic response (e.g., voltage, resistance, conductivity) arising from the different gas sensors, usually metal-oxide chemosensors. After exposure of the volatile compounds to the sensor array, a signal pattern is collected and results are evaluated with multivariate analysis or processed by an artificial neural network. Arrays of these nanosensors are able to detect molecules on the order of one part per million, sniffing molecules out of the air or taste them in liquid, suggesting applications in foods and food industry. A novel hybrid chemical sensor array composed of individual In_2O_3 nanowires, SnO_2 nanowires, ZnO nanowires, and single-walled carbon nanotubes with integrated micromachined hotplates for sensitive gas discrimination was demonstrated by

Chen et al. (2009). Mycotoxins are secondary metabolites that mold produce naturally from some fungal species. Many researchers have reported efficient e-nose application such as mycotoxins analysis in grains (Falasconi et al., 2005), *Salmonella typhimurium* in stored beef (Zhang et al. 2008).

Mass-sensitive sensors

Researchers have taken advantage of the unique coupled semiconducting and piezoelectric properties of metal oxide nanowires to create a new class of electronic components and devices that could provide the foundation for a broad range of sensor applications. Plata et al. (2008) reported the microcantilever-based sensor for the determination of total carbonate in soil.

Conclusions

Soil and food analysis has become a very important and interesting area of research because of the rapid expansion of food trade and awareness of organic farming. Quality food is important both for consumer protection and also for the food industry. Nanomaterials such as nanoparticles, nanowires, and nanotubes open a new door as sensing platforms for sensor applications. They have allowed introducing novel strategies in sensors and bio-sensor technology. In particular, the development and application of nanomaterials in soil and food analysis are discussed, with focus on sensors, separation and

extraction techniques, including the use of nanomaterials as transducer elements for sensors. Although not fully implemented yet, tiny sensors and monitoring systems enabled by nanotechnology will have a large impact on future precision farming methodologies. The prediction is that nanotechnology will transform the entire food industry, changing the way food is produced, processed, packaged, transported, and consumed.

NATURE CONSERVATION MANAGEMENT

Tadeusz J. Chmielewski

Department of Landscape Ecology and Nature Conservation, University of Life Sciences, Lublin, Poland

Biological resources management

Definition

Nature conservation management (NCM) is a system of actions aimed at permanent conservation and sustainable use of the resources and values of the natural environment.

The main elements of NCM system

The growing scale of anthropogenic transformation of the environment causes that NCM is becoming an increasingly important field of human activity and requires higher and higher qualifications. At present, the NCM system (NCMS) comprises the integrated functioning of five subsystems (Chmielewski, 2007): (1) subsystem of diagnosis (DS); (2) planning subsystem (PS); (3) decision-taking subsystem (DTS); (4) subsystem of tasks realization (TRS); (5) certificate and control subsystem (CCS).

- (1) For rational management of nature conservation we must first acquire knowledge about the functioning of natural ecosystems and about their responses to various human actions (Pullin, 2007; Wu and Hobbs, 2007). Organization for economic co-operation and development (OECD) presents the organization of the system of natural environment diagnosis as the following sequence: Drivers – Pressures – State – Impact – Response, referred to by the abbreviation DPSIR model (Watt and Young, 2007). **Driving forces** are anthropic activities and processes that cause pressures production (agriculture, industry, transport, etc.), consumption, recreation, etc. **Pressures** are described as direct stress from the anthropic system on the natural environment: release of polluting substances, radiation emissions, use of soil, intake of natural resources, and other changes of the natural environment. **State** – means conditions and tendencies in the natural environment, air, water and soil quality, global temperature, loss of biodiversity, etc. The description of the state of the environment is not easy: it should comprise at least four stages: (a) retrospection, that is, analysis of changes that have taken place in the environment over the last several decades; (b) inventory of nature resources; (c) valuation of nature resources; and (d) analysis of the potential of the natural environment (Chmielewski, 2001). **Impacts** are effects on the anthropic system due to changes in the natural environment: negative consequences on human health, economic loss in production activities, floods, etc. **Responses** are actions of the anthropic system aimed at solving environmental problems (prevention, pollutants elimination, biodiversity conservation, ecosystem restoration, ecological compensation, etc.) (Fiedler and Jain, 1992). The “**Responses**” element, however, is not a typical element of the diagnostic system as it comprises elements of three further subsystems of the NCMS (2–4).
- (2) The results of diagnosis of the state of the natural environment constitute the basis for initiating the planning subsystem, the main element of which are *nature management plans* (or nature conservation plans) for the most valuable areas: national parks, nature reserves, Natura 2000 sites, landscape parks, etc., as well as the *sustainable development strategies* and *local development plans* for the various levels of hierarchy of administrative organization of the country.

Nature management plans are mostly worked out by the governmental nature conservation services; however, in the process of their preparation local government representatives take part as well. Achievement of compatibility and agreement of the provisions of the nature conservation plans with the local development plans are of key importance for smooth management of resources of the natural environment.

- (3) On the basis of these two types of plans, the administrative decisions concerning nature conservation actions as well as land-use changes, housing and road construction, development of services, and other activities are undertaken. They may pertain, for example, to water damming, stand reconstruction, moor plant succession control, but also to the architecture style of buildings, tourist facilities, and creating tourist routes and educational paths. All administrative decision should contain relevant provisions concerning the conservation of natural values, sustainable utilization of nature resources, and harmonious scenic beauty design. Unfortunately, many decisions – particularly those concerning new economic investments, neglect the ecological conditions or marginalize them.
- (4) and (5) Observance of the provisions contained in administrative decisions is of fundamental importance for nature conservation and landscape quality. This purpose is served by a system of certification, control, standards, and indexes of quality of the environment (Keulartz and Leistra, 2008; Schmidt et al., 2008). However, losses observed in the resources and values of the natural environment indicate that in many regions that system is not effective. For a better nature conservation management it is necessary to develop urgently a network of biodiversity and landscape diversity monitoring as well as urban monitoring. It is also necessary to systemize the gathering of these data, by a common introduction of Spatial Information Systems based on advanced computing technologies. Such systems are one of the key instruments facilitating effective protection and sustainable management of resources and unique natural values areas on the world scale.

Key instruments for effective functioning of the five subsystems of NCMS

Each of the five subsystems of the NCMS has at its disposal specialist instruments that should ensure its effective functioning. Of key importance for the subsystem of diagnosing, the state of the natural environment is the financing and organization of research and of the network of monitoring of the natural environment. For better understanding of the functioning of nature and for the purpose of development of effective methods of nature resources management theories are constructed as well as models for conservation and wildlife management (Samson and

Knopf, 1996; Harris, 2007). For the quality of the planning subsystem, of fundamental importance is the legal system, the quality of education of landscape ecologists, landscape architects, space planners and engineers, as well as the operating conditions of design companies and offices. The quality of administrative decisions depends primarily on the quality of the relevant legislation and on the level of professionalism of administration officers and on the quality of internal audit. In the process of realization of the plans and decisions, that is, in the course of the practical utilization of nature resources, highly important is the ecological policy of the particular countries, their legal systems, ecological education of the people, education of the administrative cadre, organization of the system of certification and audit. At all levels of organization and at all stages of implementation an important instrument of the NCMS should be the cost-effectiveness analysis, permitting to identify which NCM methods and techniques should be applied for the invested funds and undertaken organization activities to bring the best ecological effects (Wätzold, 2005).

Conclusion

NCM is becoming a more and more extensive and highly specialist branch of knowledge and a broader and broader forum of practical activity. The NCM system has an extensive infrastructure and numerous instruments that should ensure its effective operation. In spite of all this, we are still witnessing many processes unfavorable for nature, such as the shrinking of the ecological space, landscape structure fragmentation, and loss of biodiversity. These challenges necessitate further intensive work on the ecological education of the society and on the development of the NCM system at the level of regions, countries, continents, and the whole biosphere.

Artificial Intelligence; Artificial Neural Network; Neural Network

Definition

Artificial neural network (ANN) – a mathematical model, based on the calculations made by the network of interconnected artificial neurons or perceptrons. Neural networks are a subclass of wider range of calculation techniques called *soft learning techniques*.

Introduction

First ideas concerning artificial neural networks are dated back to 1940s, when for the first time model of an artificial neuron was formulated (McCulloch and Pitts, 1943) and basic methods of neural networks training was developed (Hebb, 1949). Further theoretical developments and first practical applications of neural networks took place in 1950s and 1960s. The first image classification system was built (Rosenblatt, 1958). A new effective method of network learning-supervised training was developed (Widrow and Hoff, 1960). The multipurpose neural networks ADALINE and MADALINE, used for weather forecasting, in adapting control systems, and for image recognition, was built (Widrow, 1962). After initial period of rapid developments, works on neural networks stagnated some, until 1980s, when performance of computational systems increased enough, to allow for new ANN applications. New types of neural networks were

discovered and a new type of training algorithm was developed (Hopfield, 1982; Kohonen, 1984). From 1980s period of rapid theoretical developments and increasing practical applications started.

Nowadays artificial neural networks emerged into one of the wider used soft learning techniques. The artificial neural networks are used in scientific developments and in wide range of practical applications. Many agrophysical objects and processes may be modeled by artificial neural networks.

Basic concepts of neural networks

Artificial neural networks are mathematical models which allows for data processing or information storage. These mathematical models consist of neural network themselves and algorithms or methods for neural network training and evaluation of its performance. Concept of artificial neural network was taken from organization of biological brain. Neural network is a set of interconnected artificial neurons and links between them.

Artificial neurons, called also in ANN nomenclature a perceptron, have properties similar to real brain's biological neuron. It has many inputs, called *dendrites*, and only one output – *axon*. In fact, behavior of the perceptron is modeled by simple nonlinear function of the form [Equation 1](#):

$$y = f_{\text{act}} \left(w_0 + \sum_{i=0}^n w_i x_i \right) \quad (1)$$

where y – is an output signal from neuron considered, x_i – are input signals from other neurons, w_i – are weights specific for i -th dendrite of artificial neuron, w_0 – is a constant bias signal used in many neural networks types (called also inhibitory input), finally f_{act} – is a so called activation function. Based on this equation, the output of each neuron is simply a weighted sum of input signals, processed by additional activation function.

There are many types of activation functions used in ANN developments. Some of them commonly used are grouped in [Table 1](#).

In neural networks, output from one neuron is connected to inputs of other neurons. This net of interconnected neurons has parallel data processing capabilities, and may be used to store the information.

There are many neural networks topologies, but in agrophysical research two of them are commonly used. For applications based on evaluation of the output, based on input variables, multilayer neural networks are used.

Neural Networks in Agrophysics, Table 1 Sample activation functions

Binary (0,1)	Log-sigmoid	Hyperbolic	Linear
$f_{\text{act}}(z) = \begin{cases} 0, & z < 0 \\ 1, & z \geq 0 \end{cases}$	$f_{\text{act}}(z) = \frac{1}{1 - e^{-z}}$	$f_{\text{act}}(z) = \frac{e^z - e^{-z}}{e^z + e^{-z}}$	$f_{\text{act}}(z) = z$

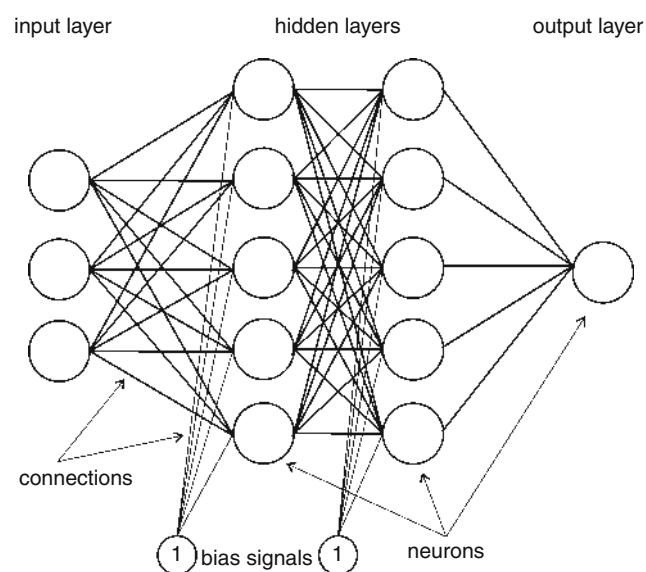

These neural networks are mainly feedforward neural networks, but some applications utilize feedback neural networks also. If modeled problem is based on some kind of classification, self-organizing map (SOM) neural networks are typically used.

The wider range of applications uses single layer or multilayer feedforward network. Such network has layered architecture, see [Figure 1](#). The first neuron layer consists of input neurons. These neurons are used to enter processed data into the network. Following input layer are one or more hidden layers. The last is the output layer, values of neurons from this layer represent results generated by neural network for specific input values. Outputs of neurons in feedforward networks from one layer are connected to inputs of neurons in the next layer. This allows for trained network to evaluate its output for input variables.

Common feature of feedback neural networks is its recurrence. Due to this, outputs of neurons from one layer are connected to input of the same layer. This kind of neural network may be used for modeling of processes, because of calculated output values changes for each subsequent evaluation.

Training of the neural networks

Neural network consists of neurons and weights describing connections between neurons. While number and type of neurons for specific neural network is fixed, weights for each connection may be changed. Processes of adjustment of weight values have a crucial role for applications of neural networks, and it is called neural network training. There are many algorithms/methods used for ANN training. Generally each neural network topology has specific

Neural Networks in Agrophysics, Figure 1 Feedforward neural network.

training method. Training methods may be generalized into two categories: supervised training and unsupervised training.

In most of agrophysical applications, where feedforward or feedback neural networks are used, proper method of network training is some kind of supervised training technique. Supervised training assumes knowledge of proper output responses for set of inputs. The origin of this dataset is application dependent, but the most frequent source of training data is some kind of experiment, survey, or measurement. The basic idea of supervised neural network training is to compare results/outputs generated by neural network for inputs, for which proper output values are known. Based on difference between evaluated by network output results and known outputs from training dataset, called training error, weights of neural network are subsequently adjusted.

Data which are used for learning neural network are commonly divided into two disjointed datasets: training dataset and testing dataset. Training dataset is used for training of the neural network, while on the testing dataset performance of trained neural network is evaluated. The aim of neural network training is to adjust neural network weights in such way that error for testing dataset, called test error, will be minimal. The smaller the test error is, the better generalization properties the neural network has, and will better perform for new, unknown input data.

Presentation of training data to the network and weight adjustments are repeated many times, until neural network performs well. Generally, training error decreases in subsequent neural network training procedure repetitions. However testing error, which is the criterion for neural network evaluation, in some circumstances, may remain at constant level, or even grow up slightly after initial decrease. This phenomenon is known as over learning that occurs especially when training dataset is too small in comparison to number of neurons in the neural network. When over learning happens, testing error increases for subsequent steps of learning, while training error decreases.

Agrophysical applications

Basic tool for scientific development utilizing artificial neural networks methodology is appropriate software. There are many commercially and freely software packages available. Beside many others, some freely available software is worth to mention: SNNS (Zell et al., 1995) and its successor JavaNNS. EMERGENT (Aisa et al., 2008), and program R (R Development Core Team, 2010) with appropriate modules are free multiplatform neural network solutions.

Neural networks may be used in many fields of agrophysical developments. Typical applications include: modeling of transport processes in the soil medium, modeling of hydrophysical properties of soils, soil classification based on different criteria, crop production modeling, or food quality evaluation. These applications

of neural networks can be generalized into two categories: problems based on prediction of some property and problems based on some kind of classification.

Soil science

One of the fields where neural networks are extensively used is pedotransfer functions (PTF) development. Pedotransfer functions are mathematical models, which allow for approximating difficult measurable soil parameters, based on some easily measurable input information. Typically, soil water retention curve and hydraulic conductivity of soils are evaluated by PTFs. For PTF development many techniques may be used (Wösten et al., 2001), from legacy regression models (Walczak et al., 2006) to neural networks and beyond (Lamorski et al., 2008).

For PTFs development feed forward neural networks are used, as these applications are based on approximation. Typically among others input parameters for PTFs evaluating retention curve are: particle size distribution, soil porosity, bulk density, and organic carbon content. Some PTF models use as input parameter measured water content for one specific value of water potential. The output of neural network is a retention curve approximation. There are numerous models used for evaluating soil water retention curve, which may be divided into two classes: models which evaluate water content for selected values of water potential (Lamorski et al., 2008; Pachepsky et al., 1995) and models which evaluate parameters of some kind of retention curve approximation function, mainly in the form of Mualem and van Genuchten approximation (Schaap and Leij, 1998; Minasny and McBratney, 2002).

The other usage of ANN to evaluation of hydrological properties of soils are PTFs for soil hydraulic conductivity approximation. Soil hydraulic conductivity is one of parameters which influences soil water transport phenomena. For many purposes approximations of value of hydraulic conductivity may be used instead of measured values. One of the method, which may be used for soil hydraulic conductivity approximation, is to use neural network modeling. This approach includes models for saturated hydraulic conductivity evaluation (Merdun et al., 2006; Schaap et al., 1998). Unsaturated soil hydraulic conductivity may be approximated by neural networks also (Schaap and Leij, 2000).

Soil classification is the other application of ANN to soil science. One of the commonly used soil classification systems are texture based classification systems. They allow for determination to which class soil belongs, based on its granulometric distribution. For other purposes, different classification criteria than soil texture may be used. The common problem in soil classification systems is that one wants to determine some kind of qualitative in nature soil parameter. In soil surveys such parameters evaluation are made by properly trained and experienced researcher. It is not easy task to map such soil features from a set of quantitative, easily measurable soil parameters, but there are attempts to build such

expert systems. One of important soil properties is its aggregation structure. Soil aggregation is a qualitative parameter which cannot be directly connected to soil quantitative parameters. Although there were attempts to classify soil to one of three aggregate classes (granular, blocky or massive) based on soil granulometric composition and organic carbon content using feed forward neural networks (Levine et al., 1996).

Crop production and food quality

The other field of investigations where artificial neural networks are used is crop production, especially with precision agriculture relying on advanced monitoring, measurement ([Precision Agriculture: Proximal Soil Sensing](#)) and modeling techniques. Fertilization is one of the key practices used in crop production, proper dosage of fertilizer, appropriate for current field conditions may be determined by neural networks (Yu et al., 2010). Prediction of crop growth is another example of usage of neural network. There are ANN models which allow for crop yield prediction based on some input parameters (Green et al., 2007). Irrigation is a common agricultural technique. Effective usage of water is an important objective; artificial neural networks may be also used in optimization of water usage (Morimoto et al., 2007). Food quality is very important and may be influenced by many external factors, during crop harvesting, storage, and processing. Some properties of crops important for food quality may be modeled by ANN. Example applications include method of estimation of sorption isotherm for rice (Amiri-Chayjan and Esna-Ashari, 2010), which is important factor influencing rice storage conditions and has impact on rice quality. Chemicals are commonly used in tillage practice, for crop fertilization, or protection against pests. Unfortunately, if inappropriately used, chemical compounds may accumulate in crops and influence quality of food produced. The key point is to prevent food contamination, by optimization of chemicals usage (Du et al., 2008). In some circumstances toxins may be introduced to food in naturally occurring phenomena. One of application of ANN allows for predicting contamination of peanuts by aflatoxin produced by naturally occurring mildew (Henderson et al., 2000) in dependence of plant growth conditions.

Modeling approaches

Processes occurring in agrophysical objects may be modeled using strict mathematical, physical, or chemical methodology. In such approach phenomena are modeled exactly. Although in some practical applications rigorous modeling methodology is not needed. Artificial neural networks are the tool which may be used in such circumstances. The main idea of learning based modeling is to build and train ANN which will predict approximated values, based on previously registered values. Forecasting neural networks may be used for modeling wide range of agrophysical processes. Possible applications include

forecasting of soil moisture, soil temperature, or contaminant concentration. There is a known model (Raju, 2001) utilizing ANN to evaluate soil temperature and evaporation, based on air relative humidity, wind speed, and air temperature. The other study (Han and Felker, 1997) describes method of estimation daily soil water evaporation, where neural network input factors are: air humidity, air temperature, wind speed, and soil water content. Soil moisture predictions are also possible (Liu et al., 2008), neural network was used for prediction of future soil moisture at specified depth, based on previous values of soil moisture readings from the same depth. Also they are successfully used for modeling of post-harvest drying process ([Neural Networks in the Modeling of Drying Processes](#)).

Summary

Proper description of processes occurring in the soil–plant–atmosphere continuum has a crucial role in agrophysical development. Artificial neural networks are useful for a range of agrophysical applications, including estimates of soil water retention, movement, evaporation, temperature, crop growth, post-harvest drying process, and food quality. ANN descriptions are particularly useful when strict measurement or modeling methods cannot be used.

Artificial intelligence modeling

Definition

Neural network (NN) is an artificial intelligence method in order to determine the relationship between the moisture distribution in the material bed to be dried and the physical parameters of the drying air temperature, humidity, and airflow rate. During its application, an emphasis should be given on the selection aspects of neural network structure and specifically to the influencing parameters as sampling time, randomized training, different training algorithms, number of hidden neurons, number of linked data series, and type of validation data. A properly selected structure of neural network model can be used to determine the moisture distribution in the drying bed. It can also be stated that besides other factors the selection of training and validation input data for NN model has a strong influence on the applicability.

Introduction

Concerning the postharvest processes, besides the energy consumption impacts, the quality issues remain the most determining factor. The main problem in the grain drying process is to determine the moisture content in the material bed. Overdrying requires excessive energy and even can damage the quality of the dried material, especially in case of seed. On the other hand, the grain will be vulnerable to mildew if the moisture content remains high. There is an option to determine the moisture content in the drying bed by measurement but the accuracy of this approach is probably not satisfactory. Weather conditions and dust have a great effect on the accuracy, as well. Another way to determine the moisture distribution is to calculate the moisture content based on drying air parameters using physically based or black-box models. Physically based models give a moderately good result in most cases but it normally takes a great effort to identify their parameters and also to solve the model itself. Derivation of the

classical black-box models seems to be an uncomplicated approach. However, the application of such models is mainly limited to process control.

The artificial neural network is a well-known tool for solving complex problems and it can give reasonable solutions even in extreme cases or in the event of technological faults (Lin and Lee, 1995). Huang and Mujumdar (1993) created a neural network in order to predict the performance of an industrial paper dryer. The neural network model by Jay and Oliver (1996) was used for predictive control. Trelea et al. (1997) successfully used explicit time and recurrent neural networks for modeling the moisture content of thin-layer (5 cm) corn during the drying process and for wet-milling quality at constant airflow rate and absolute humidity and variable temperature. Thyagarajan et al. (1997) modeled an air heater plant for a dryer using a neural network. Sreekanth et al. (1998) predicted psychometric parameters using various neural network models. Kaminski et al. (1998) used a neural network for data smoothing and for modeling material moisture content and temperature. The literature cited clearly encourages further study of the application of artificial neural networks to modeling of postharvest and within that the drying process. However, application of neural networks for drying processes takes a significant consideration to the influence of sampling time, randomized training, different training algorithms, number of hidden neurons, number of linked data series, and type of validation data. The structure of the NN is to be selected to include all the inputs and outputs of the drying system.

Modeling approaches

As a classical way of modeling, the physically based models (PBM) are normally used to determine the performance evaluation of drying process. However, the PHBs make some difficulties in setting up the most appropriate equations, to determine the accurate values of their parameters, and to find the most efficient methods for the solution. At the same time, there is a good option of the use of NN for modeling purposes along with their uncertainties and difficulties in determination their optimal topology and parameters for the given problem, for example, postharvest technology this time. Sometimes, in order to provide input data for training the neural network a well-identified physically based model are considered to use instead of full-scale or laboratory measurements.

Several NN topologies could be considered for the use of modeling the drying process as it was suggested by Farkas et al. (2000a). The choice of a topology depends on careful selection of the input system variables and the controlled output variables, for example, moisture contents in the different layers of the material bed. It should be stated that the selection of NN topology is an essential step.

Training the neural networks

Input data used for training the neural network of different structure should be the same. The drying air

temperature, airflow, and absolute humidity have to be changed randomly to train higher order dynamics, as well. The outlet air temperature and absolute humidity in the layers could be calculated on the basis of an appropriate physically based model because of its difficulty in measurements. In each training loop, each data record can be trained, for example, with back-propagation algorithm (Lin and Lee, 1995). One training step means to calculate the error between the network output and the desired output and to modify the weight of the neural network. During the training process, all the introduced neural network structures have different training speed, for example, the number of calculation loops in order to reach the required accuracy. The cost function expresses the stop condition of the training. The selection of training input data for NN model has a strong influence on the applicability.

Validation the neural networks

For validation purposes, constant and multi-flow data are normally chosen because of the real industrial drying processes. The validation data for multi-flow dryer are taken from outside weather parameters. The airflow is switched between two states to simulate intermittent drying, the air temperature, and humidity considered based on weather condition. The selection of validation input data for NN model has a strong influence on the applicability. During the validation calculation beside the correlation coefficients the average and maximal deviation could be used to estimate the behavior of the neural network model.

Sensitivity of the neural networks

Extensive studies on validation of the NN model have been carried out along with the influences different parameters as the sampling time, the randomized training, the different training algorithms, the number of hidden neurons, the number of linked data series, and the type of the data as it was suggested by Farkas et al. (2000b). In this experiment, a three layer feed-forward neural network with six hidden neurons was used. The NN contained also delayed feedback from the output to the input.

It was found that increasing the time step decreases the average deviation between the original training points and the outputs of the NN. It can be observed that the fluctuations are larger at the beginning of the drying if small sampling time is selected, because of the large number of points. The explanation of this effect can be that the back-propagation algorithm minimizes the difference between one input-output training pair in one step, and then it modifies the network weights based on the calculation point by point. In such a way, the neural network partly "forgets" the behavior of the process at the beginning. The more points are used the higher fluctuation will be at the beginning of the process. Randomized training can be used for reducing this effect

when the points are randomly selected to train the neural network.

In order to avoid high fluctuation at the beginning of the process, the training pairs are randomly selected from the entire drying period. Using randomized training pairs for back-propagation algorithm caused considerable improvement in the results even in case of a large number of training pairs. The result shows furthermore that there is no fluctuation effect at the beginning of drying process, so using randomized training pairs is to be recommended for real applications.

Preliminary studies showed that the original back-propagation algorithm could be slightly improved after some modifications. The first changing was to introduce an adaptive learning constant during the training. Another modification was changing the weights. After such experiments it can be concluded that there is almost no influence caused by the modifications, so it can be concluded that the original algorithm could be efficiently used without any modification.

A sensitivity study was performed in order to determine the influence of the number of hidden neurons in the NN. The sampling time was selected as 120 s along with randomized training pairs and the original back-propagation algorithm. From the results, it can be concluded that the best approximation was achieved when the number of hidden neurons was between 3 and 5. So the number of neurons in the hidden layer could be optimized in any special application cases.

As it was said before, it has been realized that a single data series is not reasonably enough for training the NN. Training with one data series, validation results can be unsatisfactory in case of changing in input data. To achieve better performance in neural network modeling it seems a good idea to link together different number of data series as one virtual drying process. The result shows that increasing the number of linked data series for training increases the accuracy of the NN model. Fast random signals caused the largest fluctuation at low number of linked data series.

There were several trials to validate the NN with different (constant, slow, and fast random) type of data. It can be observed that the case of slow random training gives reasonable good result for both constant and fast random validations. Constant training gives the worse result for the case of fast validation signal.

Summary

Neural network modeling is a reliable tool for determining the moisture and temperature distribution in the course of drying process. In order to set up an appropriate model, sufficient number of measurements should be available for training the neural network. The sensitivity aspect of the neural network model should be taken into account during the training and validation. Generally saying, the NN can be successfully applied especially for process control purposes.

Nondestructive measurement of fruit quality

Definition

Technologies used to measure quality parameters in fruit of not destructive form.

Introduction

Nondestructive testing was, and still is, a priority research area for specialty crops; its aim is to assess or quantify product properties and characteristics for the purpose of quality and safety monitoring and control. Sensors have been widely recognized for their potential to identify product properties, and they have been translated into industrial technologies, as evidenced by thousands of engineering research publications during the past 50 years.

Fruit quality is related to both internal variables (firmness, sugar content, acid content, and internal defects) and external variables (shape, size, external defects, and damage). Increasing consumer demand for high-quality fruit has led to the development of optical, acoustic, and mechanical sensors that determine this quality (Nicolai et al., 2006). Fruit packing companies need to measure these quality variables, but they need to do so in a nondestructive manner. Manufacturers and research groups have understood this complexity and are currently developing sensors with this aim.

The development of sensors to measure fruit internal and external quality variables on a nondestructive way is one of the challenges of postharvest technology. These include static and online sensors that use different technologies for determining fruit quality parameters. Although many techniques are under development, some companies already market instruments that determine the internal quality of fruit.

Internal fruit quality parameters

Fruit firmness

Fruit firmness is one of the most important quality variables; it is an indirect measurement of ripeness and its accurate assessment allows appropriate storage periods and optimum transport conditions to be established.

Traditionally, fruit firmness has been estimated in a destructive manner by means of the Magness Taylor test. This can be performed in the laboratory or with portable equipment, and is based on the introduction of a cylindrical head into the flesh of a peeled fruit to measure the maximum penetration force. Depending on the equipment used, other variables can be measured such as maximum force, deformation, and the values for different relationships between force and deformation. However, the Magness Taylor test has three main drawbacks: it is destructive, measurements are highly variable (by up to 30%), and it cannot be used in online situations. Nevertheless, this technique is well accepted and used for classifying fruit by many packing companies and quality laboratories.

Technical advances over the last few decades have led to the development of nondestructive devices capable of measuring fruit internal variables (Delwiche et al., 1996). Originally, these devices were developed for use in the laboratory, but have been adapted for online use (as have weight or diameter-measuring devices).

Fruit firmness can be estimated by different techniques including the measurement of variables extracted from force-deformation curves, the analysis of impact forces, the rebound technique, the measurement of acoustic responses to vibrations and impacts, the measurement of optical properties, and nuclear magnetic resonance (Garcia-Ramos et al., 2005).

Sugar content, acid content, and internal defects

The interaction between light and fruit tissues can be used to measure fruit internal quality (Nicolaï et al., 2007). An optical sensor consists of a light source and a receiver that records the optical signal. The optical signal has different wavelengths. According to the light pathway inside the sample, there are two main optical techniques: reflectance (incident light penetrates the external tissues and exits toward the sensor near the entering point) and transmittance (incident light goes through the tissues and hits the sensor on the opposite side of the fruit – or at least 90° away from entrance point).

The technology more used is the near infrared reflectance spectroscopy (NIR). This technique, which measures the reflected spectrum of a sample lit with halogen light is closely related to that employed by optical equipment (e.g., cameras). Much research effort is currently being made in this area.

Commercial, online, optical devices based on NIR spectroscopy are available. Some devices were developed for use with melons but have been successfully used with pears, apples, peaches, and Sharon fruit. These sensors can handle 2–5 fruits/s depending on the species. The internal variables measured are sugar content plus an indirect measurement of firmness (“ripeness”).

External fruit quality parameters

Shape and size

The estimation of the size and form of the fruit is realized by means vision systems in the range of the visible and near infrared spectrum (Moreira et al., 2009). Nevertheless, commercial vision systems do not yield in general the high precision volume estimates required for density sorting, because they compute volume from two-dimensional (2D) images. Nowadays, three-dimensional (3D) machine vision systems are beginning to be introduced in some food industries. This trend could eventually spread to fresh produce packinghouses, where 3D cameras could be used, apart from calculating accurate volume, shape sorting, and surface area.

Weight

Fruit weight estimation is commonly performed with an electronic weight sizer. These sensors are implemented in commercial fruit packing lines and can be recalibrated for different weight groups. The accuracy achieves ± 1 g working at speeds of 1 m/s (until 10 fruits/s).

Color

Light in the visible region (approximately 400–780 nm) can provide color and/or pigment information about horticultural products. Skin color may be indicative of maturity for some horticultural products such as banana, mango, and tomato (Edan et al., 1997). However, for many other horticultural products, skin color is not a good and reliable indicator of their maturity/quality. Color more directly relates to product appearance, which is important to the consumer perception of product quality (Abbott, 1999). Hence, color vision technology is widely used in the horticultural industry to ensure consistent product items in size, shape, and color.

Summary

The increasing demand of fruit quality by consumers makes necessary the development of technology to achieve this goal. Most of the fruit packing lines already have equipments capable of quantifying the parameters of external quality of a fruit (size, weight, and color) in line and of not destructive form. During the recent years, the enterprises and research groups have developed technologies for the nondestructive measure of internal quality parameters (sugar content, acids content, firmness, etc.). These include static and online sensors that use different technologies for determining fruit quality parameters. Although many techniques are under development, some companies already market instruments that determine the internal quality of fruit.

NONDESTRUCTIVE MEASUREMENTS IN SOIL

Wojciech M. Skierucha

Department of Metrology and Modeling of Agrophysical Processes, Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland

Definition

Nondestructive measurements in soil are a wide group of techniques used in science and agriculture and applying ground-installed sensors to evaluate the properties of soil without causing damage.

Nondestructive and destructive measurements

Contrary to destructive measurements in soil, where the original physical, chemical, or biological properties of the measured object cannot be recovered, in nondestructive testing the measured object can function correctly after the measurement process. For example, the standard thermogravimetric method for the measurement of soil volumetric water content is destructive, while TDR (time-domain reflectometry) method is nondestructive. In thermogravimetric method, the soil sample is permanently removed from its original location and during the process of drying its structure and biological components are destroyed. In TDR method, after one-time installation disturbance in a fixed location, repeated and automated measurements are allowed without causing any damage to any soil constituent.

Nondestructive measurements or tests should be distinguished from noninvasive ones, which include diagnostics, that is, procedures that do not involve tools breaking the soil structure (see [Noninvasive Quantification of 3D Pore Space Structures in Soils](#)) and the skin or physically enter the body (ultrasound, X-rays, endoscopes, computer tomography). The noninvasive measurements that do not use sensors installed in the soil include: NIRS (near infrared reflectance spectroscopy) for determination of soil texture and carbon content, airborne and satellite remote sensing for characterizing soils for plant available water capacity and topsoil properties (Schmidhalter et al., 2008), GPR (Ground Penetrating Radar), electromagnetic induction for collecting information about field heterogeneity of soil texture and soil water content, NIRS (near infrared spectroscopy) for determination of soil texture and carbon content. Their primary application is precision agriculture and site-specific soil treatment to achieve optimal plant production under sustainable agricultural and environmental conditions.

These methods usually require additional and traditional ground measurements for calibration purposes.

Nondestructive measurement techniques are commonly used in industry because they do not permanently alter the article being inspected saving both money and time in product evaluation, troubleshooting, and research.

Elements of nondestructive measurements in soil

Agrophysics as an applied and interdisciplinary science adopts nondestructive measurement techniques from other fields of science and industry. The fundamental elements

for successful nondestructive measurements in soil apart from a sensor, usually working in the indirect measurement mode, are: data-logging features of the applied measurement equipment, battery supply (frequently supported by charging solar panel) powerful enough to work without replacement for at least one measurement season, and communication option (preferably wireless) to transmit measured data as well as the experiment configuration in both direction between the field location and the operator's computer. **Table 1** presents the selection of the most popular nondestructive measurements in soil, which are used for the measurement of soil water status.

Nondestructive Measurements in Soil, Table 1 Selection of the most popular nondestructive and noninvasive soil water status measurements methods

Measurement method	Directly measured quantity, physical principle, soil property measured, and references	Remarks
TDR (time domain reflectometry)	Velocity of propagation of electromagnetic wave (step or needle pulse) along the metallic parallel or coaxial waveguide (TDR probe) fully inserted into the soil. It is very well correlated with the real part of the soil complex dielectric permittivity as well as the amount of water in soil. (Topp et al., 1980; Noborio, 2001) Attenuation of the electromagnetic wave during its travel in the TDR probe, which results mainly from the soil electrical conductivity-dependent ion conduction. Signal attenuation is correlated with the soil bulk electrical conductivity and soil salinity defined as electrical conductivity of soil extract. (Malicki and Walczak, 1999; Robinson et al., 2003)	<ul style="list-style-type: none"> – Commonly recognized alternative for the thermogravimetric method – Instruments are still very expensive – Usually no site calibration required
FDR (frequency domain reflectometry)	Phase shift (dependent on soil bulk dielectric permittivity) and amplitude attenuation (dependent on soil salinity) of a probe inserted into the soil treated as a lossy capacitor. Measurement is done in single frequency generated by the probe internal probe oscillator (50–150 MHz). (Veldkamp and O'Brien, 2000)	<ul style="list-style-type: none"> – Not applicable for very saline soils and long probe rods – Limited accuracy caused by the possible change of the TDR probe geometry
Neutron scattering	Number of slow neutrons that are produced from the collision of fast neutrons with hydrogen molecules in soil, which is linearly related to the soil volumetric water content. Fast neutron generator and the counter are installed in the vertical access tube for the measurements in different layers of soil. (Evett and Steiner, 1995)	<ul style="list-style-type: none"> – Requires soil site calibration – Probes and meters are commercially available and cheaper than TDR instrumentation – Low power consumption as compared to TDR technique – Requires soil-site calibration – Precise but expensive – Additional cost with special licensing, operator training, handling, radiation materials waste disposal – Health hazard – Limited range of work (down to about –85 kPa) – Require frequent servicing (air bubbles) – In drought conditions water moves from the tensiometer to the soil – Sensitive to soil salinity and temperature – Requires soil-specific calibration – Very economic and field installations can work for several years – Supplementary to tensiometers in the range up to –1,500 kPa
Tensiometry	Suction force or pressure exerted on a pressure transducer in a water-filled tube connected with soil matrix by a porous cap. The measured physical quantity is a matrix potential of soil water, which is a basic element of the total potential of water in the soil. (Mullins, 2001; Sisson et al., 2002)	
Electrical resistance blocks	Electrical resistance, measured with an alternating current bridge (usually \approx 1,000 Hz) of electrodes encased in some type of porous material (gypsum, nylon fabric, fiberglass) that within about 2 days will reach a quasi-equilibrium state with the soil. This method determines soil water content and water potential as a function of electrical resistance. (Hillel, 1998; Spaans and Baker, 1992)	
Nuclear magnetic resonance (NMR) spectroscopy	Structure and composition of soil, soil organic matter and nutrients (Randall et al., 1997), plant nitrogen metabolism. (Mesnard and Ratcliffe, 2005)	<ul style="list-style-type: none"> – High spectral resolution – Problems with equipment availability
X-ray computed tomography	Description and quantitative measurements of soil structure elements, especially of soil pores and pore network features, investigation the hydro-physical characteristics of the soil, in a functional and temporal manner, analysis of the biotic factor influence on soil. (Taina et al., 2008; Peth et al., 2008)	<ul style="list-style-type: none"> – High spatial resolution (\sim 1 μm) – Lack of unity, not only in the utilized methods, but also in terminology

There is a tendency to construct noninvasive integrated sensors that measure more than one physical soil property at the same time and in the same soil volume, for example, TDR or FDR soil water content and soil salinity integrated with an easy to implement temperature sensor (Skierucha et al., 2006), bulk density, and water content using low- and high-energy sources for CT scanning (Rogasik et al., 1999; Lipiec and Hatano, 2003), penetrometers with TDR probe sensors (Young et al., 2000; Vaz and Hopmans, 2001) and with thermal sensors (Marczewski et al., 2004), combined measurements system of TDR and tensiometry (Malicki et al., 1992; Walczak et al., 1993; Whalley, 1993), thermo-time domain reflectometry probe for measuring soil thermal properties and water content (Ren et al., 2003; Usowicz et al., 2006).

Summary

Nondestructive measurement methods in soil and other environmental objects develop rapidly following the technological advances in electronics, informatics, and materials engineering. They are on the application front of modern technology developments. Agrophysics should take advantage of the progress of nondestructive methods of measurements in medicine, satellite, and others branches of science financially supported by governmental and private funds and look for the new applications in the field of food quality and environmental protection.

Definitions

Noninvasive research facilitates the understanding of physical, chemical, and biological processes in soils and their dependency on soil structure. The most commonly employed method or device used for noninvasive examinations of porous materials and their 3D architectures is X-ray Computed (Micro)Tomography (XCT, μ CT), which can be either based on synchrotron radiation (SR- μ CT) or microfocus tube sources (MF- μ CT).

Introduction

Soil pore spaces are of interest to soil researchers for various reasons where the traditional soil science disciplines usually take different perspectives. The soil physicist, for example, treats soil pore spaces mostly with respect to water, gas, and solid particle movements, while the soil biologist and soil chemist understands pore spaces predominantly as an environment for root growth and microbial activity and a pathway to access and retain nutrients or contaminants, respectively. Recent research on the soil-microbe system emphasizes that the interaction of physical, biological, and biogeochemical processes occurring within soil pore space structures deserves more appreciation (Young and Crawford, 2004). Soil scientists now begin to recognize that the physical heterogeneity of soil structures controls both abiotic and biotic functions within soil habitats with feedback loops between the two. In other words, soil structure and its dynamic functional properties regulate soil biodiversity (Crawford et al., 2005; Ettema and Wardle, 2002) while soil microbes in turn can alter soil structure and hence pore spaces (Six et al., 2004). Detailed insights into pore space realms are important not only from a soil microbial habitat perspective. Given that the interacting mechanisms operate across scales virtually all soil environmental processes (from transport

to sorption and turnover) maintaining biogeochemical cycling in the pedosphere depend on pore space structures.

How to study soil pore space structures

Past research on soil structure and its associated pore space was strongly based on traditional techniques, which can be distinguished into direct (e.g., thin section analysis) and indirect (e.g., water retention function) methods. Despite profound conceptual understanding on soil structure formation and stability has been achieved the major drawback of this traditional approach is that the techniques are either destructive (e.g., preparation of thin sections) or that results refer to statistical values averaged over a bulk volume (e.g., pore size distribution) lacking detail on the spatial configuration of pores. Another problem is that soil structure is inherently three dimensional and that 2D analysis from thin sections bears some risk for inaccurate interpretations of structural morphologies. When we consider the soil pore space as a dynamic, three-dimensional, interconnected network of voids with a complex hierarchical organization we have to acknowledge that traditional methods are insufficient for deriving an adequate quantitative characterization of pore space morphologies. Noninvasive imaging techniques have made significant progress in the last decade ([Nondestructive Measurements in Soils](#)) promising to overcome some of the limitations involved in studying dynamic 3D soil pore spaces.

Applications of X-ray computed tomography in soil structure analysis

X-ray computed tomography (XCT) is the most widely used noninvasive imaging technique to study soil structure. The technique was introduced in the discipline of soil science by the pioneering work of Petrovic et al. (1982) investigating soil bulk density and later followed up by Crestana et al. (1986), who studied the spatial distribution and temporal dynamics of water in soil. Both used medical scanners achieving a voxel resolution in the submillimeter range. Later efforts were made to extend the noninvasive visualization of pore spaces beyond larger macropores ($>50 \mu\text{m}$) toward smaller pore sizes down to the mesopore range ($<10 \mu\text{m}$). However, because of the strong X-ray attenuation of the mineral soil components, resolution is generally limited by the distance the X-ray beam has to travel from the entry to the exit of the specimen and hence decreases with increasing sample size. As a rule of thumb, the resolution achieved is in the range of 1/1,000 of the sample thickness. A main limitation of conventional medical scanners for analyzing small samples at high resolution, however, is that because they are built for larger objects (human bodies) they do not reach the required precision in terms of angular rotation of the detector and sample positioning during image acquisition.

With synchrotron radiation sources becoming more accessible to the scientific community, the potential of this high energy radiation for X-ray microtomography of

environmental samples was recognized. Pioneering work on synchrotron radiation-based X-ray microtomography (SR- μ CT) was conducted by Flannery and colleagues about 20 years ago (Flannery et al., 1987). They introduced SR- μ CT as a “new form of microscope” that produces three-dimensional images with a spatial resolution comparable to that of a light microscope ($\sim 1 \mu\text{m}$). The use of SR- μ CT for analyzing soil pore spaces at micrometer resolution was introduced by Spanne et al. (1994) but surprisingly only recently the technique was applied to study small-scale soil structure of natural undisturbed soils (Altman et al., 2005; Feeney et al., 2006; Nunan et al., 2006; Peth et al., 2008a; Peth et al., 2008b). Synchrotron radiation sources offer a variety of special techniques (fluorescence, absorption, diffraction, infrared) providing excellent perspectives for plant and soil research with a superior performance in terms of sensitivity, speed, and resolution (Lombi and Susini, 2009). Recent developments of high-resolution laboratory μ CT systems, however, will make X-ray computed microtomography (μ CT) a more readily available tool in soil structure analysis allowing for the visualization and quantification of soil pore architectures at a resolution down to a few microns with a quality that is very close to what is obtained from SR facilities (Brunke et al., 2008).

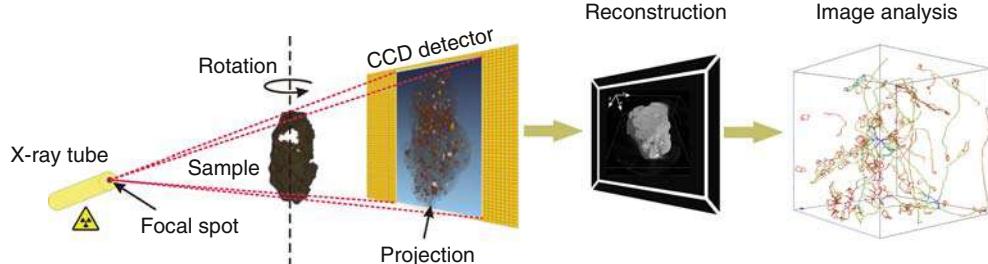

Principles of X-ray computed tomography

X-ray computed tomography is based on the differences in X-ray attenuation where an incident beam of intensity I_0 is absorbed by the internal components of the radiated object resulting in a transmitted beam with reduced intensity (I). This relationship is described by Lambert-Beer’s law:

$$I = I_0 \exp(-\mu D) \quad (1)$$

where μ is the overall linear attenuation coefficient (L^{-1}) and D is the sample thickness (L^{-1}). The linear X-ray attenuation coefficient (μ) is a function of density and atomic number of the components as well as the X-ray energy used. For porous media consisting of different phases (solid, water, and air) Equation 1 must be extended accounting for the different phase specific attenuation coefficients to

$$I = I_0 \exp\left(-[(1 - \theta_p)\mu_s\rho_s D + \theta_p S_w \mu_w \rho_w D]\right) \quad (2)$$

Noninvasive Quantification of 3D Pore Space Structures in Soils, Figure 1 Typical layout of a tomography experiment with a laboratory X-ray computed microtomography (μ CT) system.

where ρ_s and ρ_w are the densities and μ_s and μ_w the linear attenuation coefficients of solid matter and water, respectively. S_w denotes the water saturation and θ_p the total porosity. Due to the low linear attenuation of air, the contribution of the gaseous phase to the overall attenuation is considered negligible and therefore omitted in Equation 2.

The incident fan-shaped X-ray beam is generated in a high vacuum X-ray tube and transmitted through the sample, which is mounted on a precision rotation table (Figure 1). The sample is rotated at 0.25–0.50° steps between 0° and 360° and at each angular step the integral attenuation of the X-ray beam transmitting the sample is recorded by the CCD detector. The measured angular projections of the sample are finally reconstructed into a 3D linear attenuation coefficient map. Commonly, attenuation coefficients are converted to grayscale values ranging from [255] for the highest attenuation coefficient to [0] for the lowest attenuation coefficient. Reconstructed images finally contain the spatial configuration of soil voids and soil components with sufficient attenuation contrast. Hence, the architecture of soil pore networks is available in digital format and can be analyzed quantitatively with 3D image analysis algorithms.

A readable introduction to principles of computerized tomography is given by Kak and Slaney (1988).

Visualization and quantification of soil pore space structures in 3D

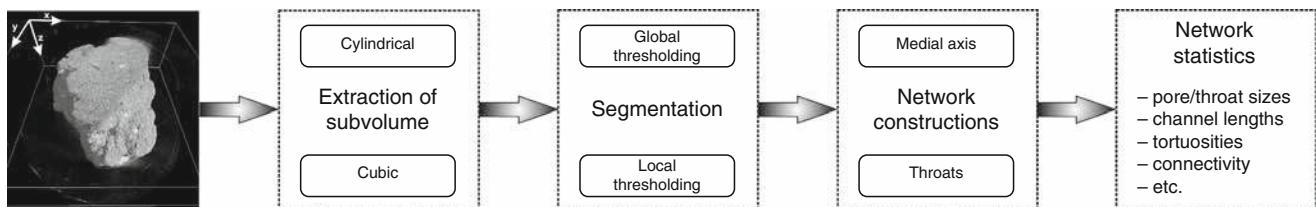

During a microtomography scan usually a couple of hundred (often $>1,000$) grayscale image slices are recorded and subsequently rendered into a 3D volume of the sample. Tools exist to visualize the 3D structure of the sample providing some qualitative information about the pore space architecture, e.g., the spatial arrangement and continuity of pores. However, in order to make objective comparisons between different samples, some kind of morphological and topological quantification is desired.

Morphological and topological features of pore networks may be quantified by means of 3D image analysis using algorithms that are based on the principles of mathematical morphology (e.g., Serra, 1982; Soille, 2003). Different sets of such morphometric algorithms that are suitable for analyzing soil pore spaces are available, e.g., *DXSoil* (Delerue and Perrier, 2002) and *3dma* (Lindquist

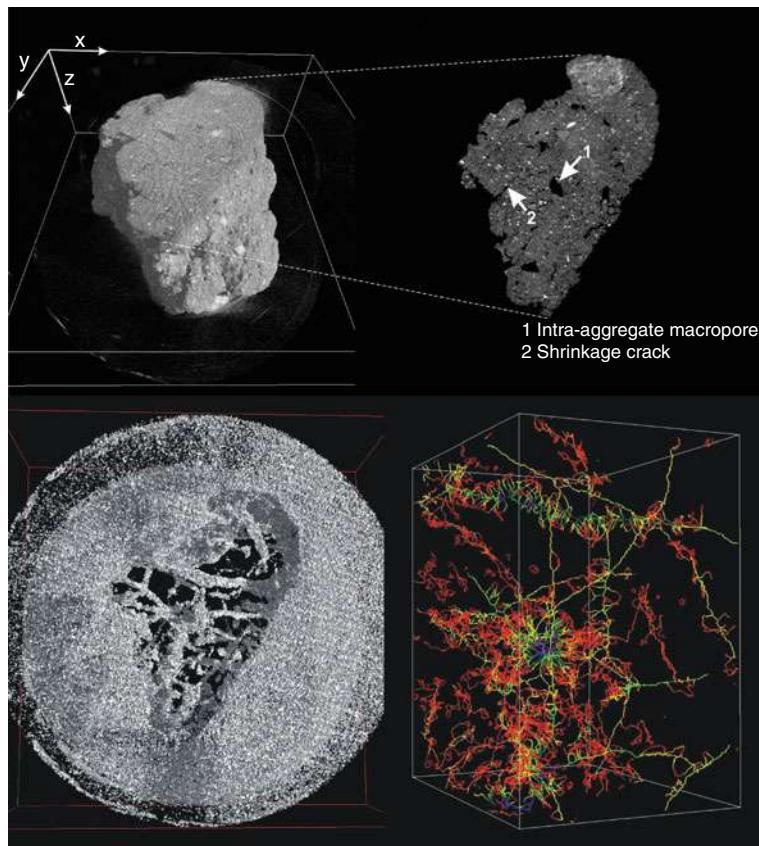

et al., 2005). Image analysis involves the stepwise transformation of the image data into sets (Horgan, 1998) from which a variety of geometrical features of the pore space structure can be calculated (e.g., size, shape, connectivity and tortuosity of pore channels; pore interface area; pore bottlenecks). Basic operations during image analysis with the software *3dma* are shown in Figure 2.

The application of *3dma* for analyzing the intra-aggregate pore space architecture of different soil aggregates was demonstrated by Peth et al. (2008a). Figure 3 shows

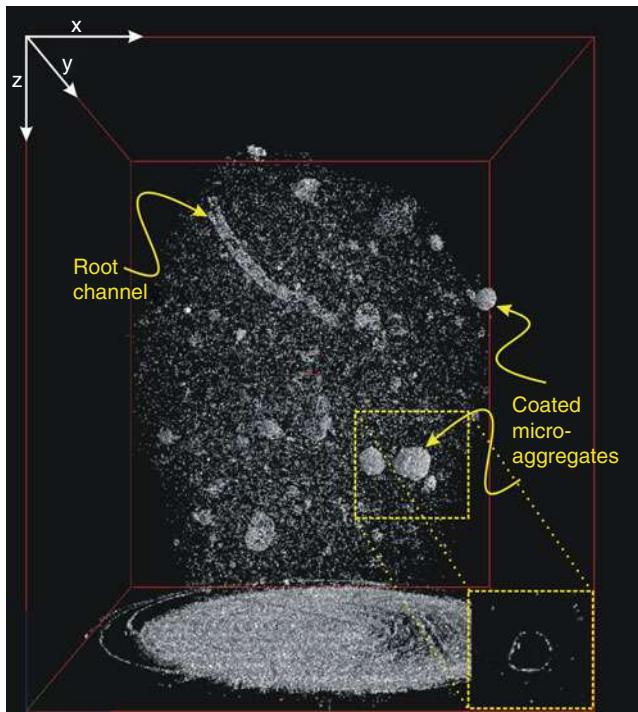

an example of the reconstructed 3D X-ray attenuation map of a small-scale soil aggregate (5-mm diameter) and the extracted shape of the internal macropore architecture. The calculation of the skeleton (medial axis) reveals the existence of numerous convoluted narrow pores and a few continuous pore channels. Pore channels become visible when the 3D representation is restricted to a short range of grayscale values corresponding to specific attenuation coefficients. Obviously, larger pore channels are plagued with highly absorbing material in this case.

Noninvasive Quantification of 3D Pore Space Structures in Soils, Figure 2 Basic image analysis steps in *3dma*. (Reprinted from Peth et al., 2008b with permission from SPIE.)

Noninvasive Quantification of 3D Pore Space Structures in Soils, Figure 3 Three-dimensional reconstruction (top, left) of a soil aggregate (Alfisol, Rotthalmünster/Germany) and an xy-image slice showing shrinkage cracks and intra-aggregate macropores (top, right). Reconstructed pore channels (bottom, left) and medial axis representation of the main pore network (bottom, right). (Reprinted from Peth et al., 2008b with permission from SPIE.)

Noninvasive Quantification of 3D Pore Space Structures in Soils, Figure 4 X-ray attenuation map of a specific grayscale range of a paddy rice field soil aggregate (*Stagnic Cambisol*, Yingtan/China) showing coatings around root channels and microaggregates.

This phenomenon is also often visible around root channels and microaggregates (Figure 4).

Summary

Functional traits of soil structure, irrespective of scale, rely on the connectivity, tortuosity, and the heterogeneity of pore spaces in 3D (Young et al., 2001). This is often neglected using conventional approaches of investigating soil structure morphologies. Data concerning 3D architectures of pore spaces are invaluable when studying structural genesis, gas and water transport, habitat functions, water uptake, etc. Visualizing and quantifying the complex geometry of the pore network and soil structure on various scales is promising to enhance our understanding of the multiple interacting physical, biological, and biogeochemical processes taking place in soil pore spaces.

ONLINE MEASUREMENT OF SELECTED SOIL PHYSICAL PROPERTIES

Abdul Mounem Mouazen
Natural Resources Department, Natural Soil Resources Institute, Cranfield University, Cranfield, Bedfordshire, UK

Synonyms

Soil physical properties measurement

Definition

Online measurement of soil properties. Installing a measurement system of soil properties on a tractor and driving across the field, while collecting data on soil.

Introduction

Online soil sensing requires advanced sensing technologies based on single or sensor fusion systems. Researchers have used a large variety of sensing technologies, while the majority of them did not consider the sensor fusion concept. Adamchuk et al. (2004) have listed six different categories of online sensing methods, namely, electrical and electromagnetic sensors, optical and radiometric sensors, mechanical sensors, electrochemical sensors,

acoustic sensors, and pneumatic sensors. Calibration of many of these technologies is a challenging task due to the interference of different soil physical properties that prevents extracting useful information about a given soil property.

Liu et al. (1996) reported the first sensor fusion system of soil physical properties. They combined draught sensor with a dielectric-based moisture content sensor, a radar gun to measure speed, a linear potentiometer to measure depth, and a Trimble global positioning system (GPS) unit. Based on this system they could perform online measurement of texture/compaction using an empirical model. Mouazen et al. (2003) stated that this model may have a narrow range of applicability due to relatively high soil heterogeneity and rather complex relationships among variables involved.

A more robotic type of soil sensor fusion system has been developed in Tokyo University of Agricultural Technology by Shibusawa et al. (2003). The most upgraded system consisted of several sensing units, including a penetration tine, whose tip was equipped with a resistance measurement cell, a fiber type visible (Vis), and near infrared (NIR) spectrophotometer from Zeiss (Carl Zeiss Ltd, Germany) with a measurement range of 400–1,700 nm, a micro CCD camera (Toshiba IK-UM42) to monitor the soil surface roughness, a micro NIR thermometer to monitor soil temperature, a line laser marker to monitor the flatness of soil surface, and an GPS (Trimble MS740) antenna and receiver to monitor the position of the system. An electrical conductivity device was attached to the system to acquire additional information about soil physical properties. The system proved applicable to acquire data on soil physical and chemical properties, namely, resistance, moisture content, organic matter, nitrate, and pH (Shibusawa et al., 2003).

A simplified sensor fusion system (Mouazen, 2006), as compared to that of Shibusawa et al. (2003) was later

reported by Mouazen and Ramon (2006). The system enabled indirect measurement of soil bulk density indicating soil compaction level. It was also used to measure soil gravimetric moisture content. A detailed description of the system is provided below.

Sun et al. (2006) developed a dual sensor consisting of a penetrometer equipped with strain-gage load cell to measure horizontal mechanical penetration resistance and a dielectric sensor to measure moisture content. Later, Zeng et al. (2008) have attached electrical conductivity (EC) sensor to measure soil texture to be accounted for during online measurement of soil resistance, since soil resistance is a function of moisture content, bulk density, and texture.

Among several versions of their sensing systems, Adamchuk and Christenson (2007) reported a sensor fusion system that consisted of an instrumented blade with strain gauges to measure the resistance of soil profile, a capacitance-based sensor to measure soil moisture constant, and an optical sensor to measure variability of soil organic matter. This paper describes on the online sensing system of soil physical properties of Mouazen and Ramon (2006).

Online sensor of soil properties

The online measurement system of soil properties developed by Mouazen and Ramon (2006) consists of three different sensing techniques, namely, a load cell to measure subsoiler draught, a wheel gauge to measure subsoiler depth, and an optical probe attached to a portable fiber type spectrophotometer (Zeiss Corona, Zeiss Ltd, Germany) to measure soil physical and chemical properties (Mouazen, 2006). With the last-mentioned sensor, the smooth soil surface prepared by the subsoiler and optical probe coming behind is illuminated and the diffuse light from the surface is captured and transferred back to the spectrophotometer by means of the illumination and detection fibers, respectively. The measurement system is equipped with a differential global positioning system (DGPS) to determine the position while moving over the field. This online measurement system was initially developed to measure soil physical properties, namely, bulk density and moisture content, but the implementation of the sensor was extended to the chemical properties of soil (Mouazen et al., 2007, 2009).

Online measurement of soil moisture content

Certainly, soil moisture content is the easiest property to be measured with Vis–NIR spectroscopy because of the important water absorption bands at 950, 1,450, and 1,950 nm (Mouazen et al., 2006; Plamer and Williams, 1974). However, the accuracy of measurement depends upon several factors including soil texture, color, and the scale of calibration model used (field, landscape, regional, continental, or global). Due to these variables a general calibration model developed for the measurement of moisture content for a large geographic area including Belgium

and northern France was less accurate ($R^2 = 0.91$ and root mean square error of prediction (RMSEP) = 0.015 kg kg⁻¹) than a model developed for one single field in Belgium with $R^2 = 0.97$ and RMSEP = 0.021 kg kg⁻¹ (Mouazen et al., 2006). This can be interpreted by the fact that the variation of these variables is much larger at large geographical area as compared to a single field scale. Although these results were under nonmobile laboratory measurement conditions, a similar tendency was reported for online field measurement conditions (Mouazen et al., 2005a, 2007).

Online measurement of bulk density indicating soil compaction

Reports on online measurement of soil compaction often consider penetration resistance and/or draught of soil cutting tools, measured by load cells or strain gauges as indicators of soil compaction. However, it is well known that draught and penetration resistance are functions of not only bulk density indicating soil compaction, but also moisture content and organic matter, in addition to soil texture type (Mouazen and Ramon, 2006). Therefore, a mathematical model is needed to account for these different influencing variables during the online measurement of soil compaction. Mouazen and Ramon (2002) have developed a hybrid numerical-statistical model to calculate bulk density indicating soil compaction as a function of draught, moisture content, and depth. In order to acquire data for all influencing factors considered in the model, a sensor fusion system has been developed as described above. The model and the measurement systems were successfully tested in a sandy loam field (Mouazen and Ramon, 2006), and later expanded to loamy sand, loam, silt loam, and silt soils (Mouazen and Ramon, 2009). They proved that the spatial pattern of bulk density maps produced using this mathematical model and the online measurement system were very realistic and similar to the measured bulk density maps by conventional core sampling method in sandy loam field ($R^2 = 0.56$) and in loamy sand, loam, silt loam, and silt field ($R^2 = 0.52$). A depth control system (Mouazen et al., 2005b) was developed, which resulted in improved accuracy of measurement of soil compaction. The authors suggested that online measurement of soil compaction has to consider bulk density instead of draught or penetration resistance, while a sensor fusion system and a mathematical model are essential for successful and accurate measurement.

Summary

Since agricultural soils are complex materials, online measurement of soil physical properties can be a difficult and sometimes misleading procedure if the approaches and techniques considered are not adequate. To arrive at realistic measurement methodologies, advanced measurement and modeling techniques might be worth considering. However, some soil physical properties might be possible

to be measured online with a single sensing technology; for example, soil moisture content can be measured successfully with Vis–NIR spectroscopy. Other properties such as soil compaction (bulk density) cannot be measured with simple techniques (e.g., penetration resistance), and a sensor fusion system is recommended.

ORGANIC DUSTS, ELECTROSTATIC PROPERTIES

Wiktor Pietrzyk, Marek Horyński

Department of Computer and Electrical Engineering,
Lublin University of Technology, Lublin, Poland

Synonyms

Dielectrics; Dust pollutants; Dusts

Definition

Organic dust. Fraction of solid body particles contained in air.

Dielectric. Material that does not conduct electric current.

Electric permeability. Physical quantity characterizing electric properties of the environment – dust.

Electric susceptibility. Dimensionless physical quantity determining the dielectric polarizability.

Dielectric loss tangent. Parameter describing the losses in a dielectric in a variable electric field.

Introduction

The loose and grainy materials commonly occurring in nature are used in many industrial processes and characterized with respect to their phenomenology or structure. As a result of the first approach, they are classified in the group

consisting of expandable elastoplastic materials, and in accordance with structural approach, they are defined as a two or three phases substance consisting of solid particles and pores between them filled with fluid and gas.

The dusts are defined as solid body particles contained in air. They are subdivided into the following classes in accordance with the size of dust grains:

- Dusts characterized by macroscopic size of grains, that is, between 1 and 1,000 μm .
- Dusts characterized by colloidal size of grains, that is, between 0.001 and 1 μm .

Depending on the original source of the dust or the form of its occurrence, the following subdivision has been established:

- Dispersing dusts, that is, those created as a result of mechanical disintegration of solids (e.g., coal dust in course of coal crushing and milling in power generation plants).
- Condensing dusts, that is, those created as a result of condensation and solidification of vapors of various chemical substances (e.g., soot). They are usually occurring in the category characterized by colloidal size of grains.

With respect to their behavior under gravity, the dusts are subdivided into the following categories:

- Falling dust, that is, dust being subject to sedimentation.
- Dust suspended in air, that is, dust not being subject to sedimentation.

With respect to origin of dispersed phase, the dusts are subdivided into the following categories:

- Inorganic dusts
- Mineral dusts (silica, asbestos, chalk, coal)
- Metal dusts (iron, lead, copper, chromium)
- Organic dusts
- Plant origin dusts (wood, cotton, flour, pollen, hay)
- Animal origin dusts (hair, feathers, skin cells, hoofs)
- Chemical origin dusts (plastic)
- Mixed dusts (organic and inorganic)
- Organized dusts (microorganisms, spores)
- Radioactive dusts

Organic dusts

The plant and animal origin dusts constitute a huge family of dusts containing various types of plant and animal particles as their basic components. They usually occur in the form of mixtures consisting of inorganic particles as well as many fractions of microflora and microfauna with substances produced by their representatives except of the basic fractions consisting of plant and animal particles. It is the specific feature characterizing this family of dusts. This relationship is best visible in the agricultural dusts with the composition determined by the diversity of working materials and materials constituting the source of dust emissions, also including the chemicals introduced into

production process, for example, pesticides and mineral fertilizers as well as superimposing pollutants originating mainly from industrial waste and exhaust gases produced by the transport sector.

These dusts are diversified in respect to dimensions of particles contained therein. The percentage of fractions expressed as the number of particles under $<5 \mu\text{m}$ is included between 40% and 98%, and their weight percentage up to 60%.

Furthermore the microorganisms and endotoxins can be found in almost all plant and animal origin dusts. Free silica is contained in a significant part of these dusts. The highest content of SiO_2 in inhalable dust, even up to 60%, depending on the type of soil, takes place in the plant raw material production and harvesting phase; this content is reduced in the next processing phases to the level lower than 10% and most frequently to 0 in the final production phase. The role of this fraction in the dusts occurring in animal breeding and in animal raw material processing is not significant.

Electrostatic properties

The description of the electrostatic properties of organic dusts encompasses the properties of solid phase in the two-phase system: solid body–air. The dimensions of the dust grains are irregular and included between 10 and 500 μm .

The electrostatic properties of organic dusts are not well known. They belong to an inflammable and explosive group of materials. Therefore mechanical methods, that is, textile filters and cyclones are used for their elimination. Only the knowledge of particle size distribution is required in order to apply these methods.

The knowledge of electrostatic properties of the dust was not required before LV electrostatic bifilar filter was developed. An organic dust with humidity of 0 up to 20% is used as a dielectric.

The basic dielectric properties of the dust are described by the electric permeability ϵ , which is a complex number, that is:

$$\epsilon = \epsilon' + j\epsilon'' \quad (1)$$

In Equation 1, ϵ' is the real component of electric permeability, and ϵ'' – the imaginary component of electric permeability.

Knowing both components, we can calculate the dielectric loss tangent δ :

$$\operatorname{tg} \delta = \frac{\epsilon''}{\epsilon'} \quad (2)$$

and the electric conductivity of the dielectric:

$$\sigma = \omega \epsilon'' \quad (3)$$

where

$$\omega = 2\pi f \quad (4)$$

and f is the frequency of voltage variations.

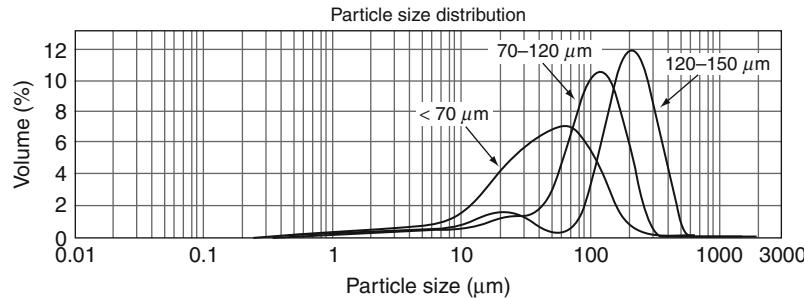

The facilities operating in food industry, particularly the corn mills, animal feed mixing, and manufacturing plants processing grains in course of various processes are the sources of organic dust emissions as a result of human activity. Wheat grains are most frequently used as the raw material. Therefore the dust obtained from the milling of "Zawisza" winter wheat by means of the laboratory disc mill has been examined as an example of organic dust.

The particle size distribution for three samples of dust obtained from wheat grains after passing through the sieves 150, 120, and 70 μm is illustrated in Figure 1.

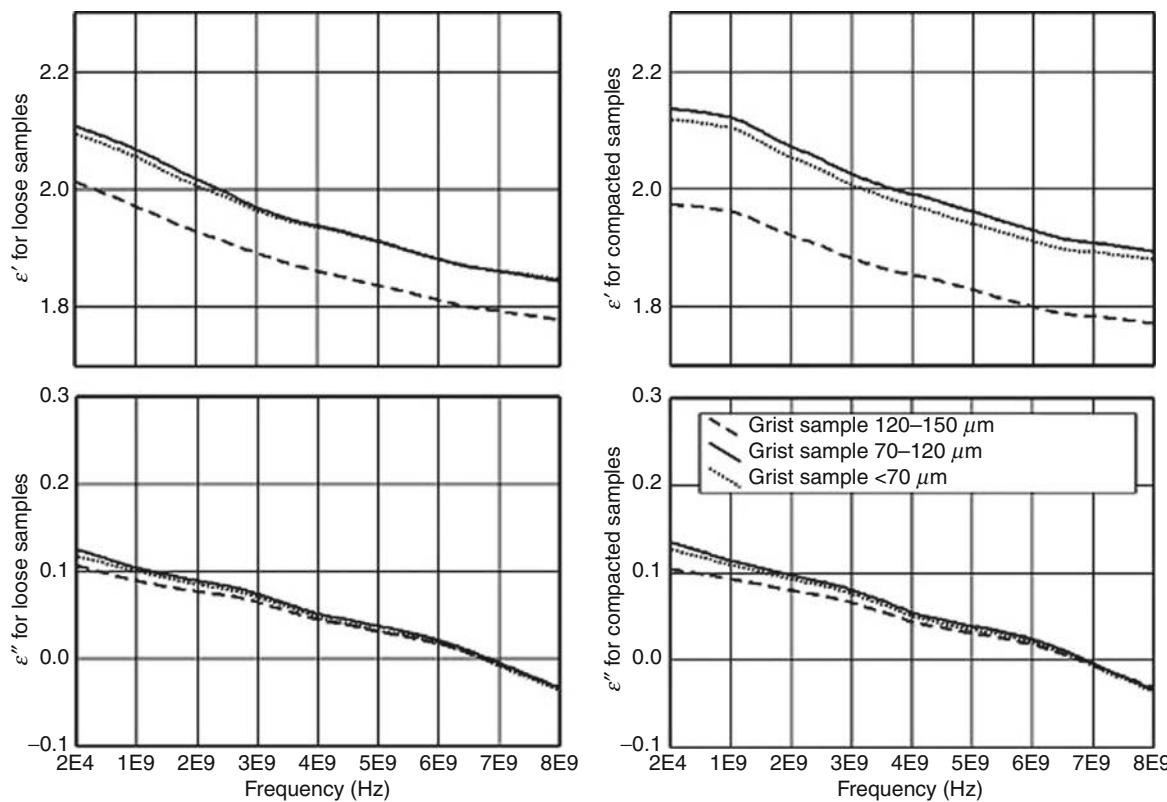

The values of electric permeability ϵ' and ϵ'' versus frequency have been illustrated in Figure 2 for loose samples. In course of examinations we have found that the impact of dust compression on frequency characteristics is insignificant in case of the real as well as imaginary component of electric permeability.

The value of component of electric permeability ϵ'' is small in comparison with the real component.

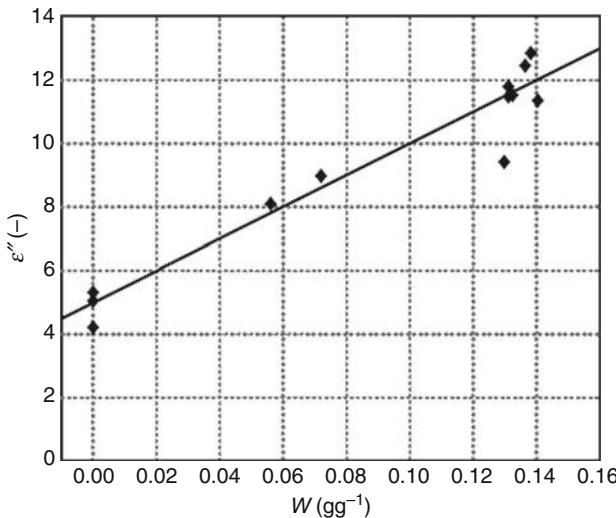

In case of wet samples (Figure 2), the values of the real ϵ' and imaginary component ϵ'' are insignificantly increased for compressed dust samples in comparison with the loose dust samples.

Organic Dusts, Electrostatic Properties, Figure 1 Particle size distribution for three samples of dust obtained from "Zawisza" wheat grains.

Organic Dusts, Electrostatic Properties, Figure 2 Frequency characteristics of the real ϵ' and imaginary component ϵ'' of complex electric permeability ϵ for the samples after moisture elimination, with diversified particle size distribution.

Organic Dusts, Electrostatic Properties, Figure 3 The value of imaginary electric permeability ϵ'' in dust solid phase versus moisture.

From the diagrams presented in the Figures 1 and 2 it appears that no relaxation phenomena are present because any significant increase of ϵ'' accompanied by reduction of ϵ' for the same frequency has been not found. Therefore it is possible to determine electric conductivity σ basing upon the measurements of the component ϵ'' (Equation 3).

The variability range σ for the dust under examination is included between 0.0 and $0.04 \text{ S} \cdot \text{m}^{-1}$, the higher value refers to wet samples.

The value of electric permeability for organic dusts is strongly influenced by their humidity and increases versus humidity in accordance with linear relationship.

An example of the curve of imaginary electric permeability measured by means of TDR method (Time Domain Reflectometry) has been illustrated in Figure 3.

The value of electric permeability in dust is reduced when its temperature is increased. The impact of the temperature is lower than that of moisture.

In case of increased density of the dust the value of its electric permeability is proportionally increased.

Summary

The organic dusts are produced in natural environments as well as in manufacturing processes carried out in the corn mills and in animal feed manufacturing plants. The plant dust particles are classified as dielectric materials characterized by low polarizability, diversified shapes, frequently nonuniform structures, and diversified particle sizes. The size of particles of dust occurring in agricultural and food industry and in nature is diversified, that is, large, medium, and small particles are contained. Therefore the classification of dust, that is, in coarse or fine category depends on the percentage of particles of a size, that is, particle size distribution of the dust.

ORGANIC FARMING, EFFECT ON THE SOIL PHYSICAL ENVIRONMENT

Apostolos Papadopoulos

Research and Development, Branston Ltd, Branston, UK

Definition

Organic farming is based on the concept of sustainability, in which the inherent fertility and biological activity of the soil is returned such that, with careful management, the soil can remain consistently productive over long periods of time (Lampkin, 1990). As such, it relies on the use of crop rotations, animal and green manures, and biological pest control, combined with abstention from using synthetic fertilizers and pesticides (USDA, 1980).

Introduction

Conventional agriculture relies heavily on the use of synthetic fertilizers, pesticides, and intensive tillage methods

to meet its objectives of high yields and low labor requirements (Gerhardt, 1997). Conventional farming systems have evolved with a primary emphasis on high yield and quality of crop production, and secondary considerations for the condition of the soil (Reganold, 1995).

It has been suggested that organic farming systems are “a valid alternative approach,” which deliver agronomic and environmental benefits (Stockdale et al., 2001) and offer potential for better soil physical conditions (Shepherd et al., 2002). The basic philosophy within which all organic certification bodies work, is one of building and maintaining inherent soil fertility, through the employment of natural biological processes, as opposed to importing short-term fertility in the form of soluble mineral fertilizers and pesticides, as occurs in conventional farming (Defra, 2002).

Organic farming vs. conventional farming

Pulleman et al. (2003) found that when compared with conventional arable, organic soil showed increased total soil organic matter (SOM), earthworm activity, water-stable macro-aggregation, and N mineralization, which are important indicators of soil quality. Although less sensitive to slaking than soil under conventional arable, organic arable soil has been shown to be susceptible to compaction due to tillage, traffic, and grazing under Dutch climatic conditions. Structural degradation due to slaking or compaction results in unfavorable conditions for crop production, mineralization, and workability of the soil (Jensen et al., 1996; Droogers et al., 1997).

Droogers and Bouma (1996) found that greater SOM content under organic arable resulted in increased soil strength compared with conventional arable. SOM content is an important indicator of soil physical quality. Soils under long-term intensive arable agriculture, in which SOM levels decline compared to the value under native vegetation, permanent pasture, or ley-arable rotations, could become increasingly sensitive to physical damage. However, Watts et al. (2001) stated in less well-structured soils, a small loss of SOM may result in a dynamic lowering in soil physical quality. One factor that may help to prevent a continuous decline in soil quality is the ability of damaged soils to reaggregate around organic matter. Reganold (1988) in another study found organic soils had a more granular structure, a less hard and more friable consistency, and a significantly greater A horizon and SOM than conventional soils. Defra (2002) stated on average, comparisons with nonorganic systems did not show organically farmed soils to be consistently better or worse in terms of structure. Shepherd et al. (2002) concluded that a few differences in organic matter content have been found between organic and conventionally managed pasture soils, and only small differences found between conventional and organically managed arable soils in the UK.

Siegrist et al. (1998) emphasized the importance of the ley phase, and its duration, in maintaining large earthworm populations in organic rotations and it has been

argued that clover is particularly beneficial to earthworms because of its high protein content (Edwards and Bohlen, 1996). These findings are consistent with other studies. Berry and Karlen (1993) found higher populations of earthworms in organic as compared with conventional stockless systems. In contrast, Yeates et al. (1997) found greater earthworm biomass in conventional rather than organic grassland soils. Anon (1998) also found that in most cases, the benefits of leys did not persist much beyond the first year of arable cropping.

Defra (2002) concluded that organic farming practices have a positive effect on soil microbial numbers, processes, and activities. Van Diepeningen et al. (2006) reported that changing from conventional to organic farming leads to a gradual increase in biodiversity. They also indicated that higher biodiversity in organic soil can be due to the lower plow depth and especially the use of organic amendments and absence of mineral fertilizers. Pest and root diseases are generally less severe in organically managed soils than in conventionally managed soils (Van Bruggen and Termoshuizen, 2003). Much of the cited literature has made direct comparisons between organic/biodynamic and non-organically managed soils (i.e., Pulleman et al., 2003; Droogers and Bouma, 1996) with the evidence generally supporting greater microbial population size, diversity and activity, and benefits to other soil organisms. Little is currently known about the influence of changes in biomass size/activity/diversity on soil processes and rates of processes. Neither is it possible to conclude that all organic farming practices have beneficial effects while nonorganic practices have negative effects.

Tillage operations modify soil structure and distribute energy-rich organic substrates into the soil. Pulleman et al. (2003) mentioned the effects of mechanical disturbance during tillage and harvest might also explain why long-term organic matter protection in stable aggregates is not increased under organic arable.

Conclusion

The conventional soil management practices, such as frequent soil mixing by tillage, and by leaving the soil bare during crucial times, are associated with an increased oxidation of organic matter and subsequent reduction of organic matter levels, increasing the risk of erosion. Management practices such as the organic matter input, no tillage cultivations, the use of less synthetic pesticides, and more of soil improvement products based on biological activity, which are associated with organic farming, promote a more active soil physical environment with positive effects to the environment and agriculture.

ORGANIC MATTER, EFFECTS ON SOIL PHYSICAL PROPERTIES AND PROCESSES

Rattan Lal

Carbon Management and Sequestration Center, SENR,
The Ohio State University, Columbus, OH, USA

Synonyms

Aeration and gaseous exchange between soil and the atmosphere; Anaerobiosis and poor aeration or lack of O₂ in soil; Densification and compaction; Greenhouse gases and radiatively-active gases; Soil organic matter and soil organic carbon; Soil structure and aggregation

Definition

Aggregation: Formation of secondary particles through flocculation and cementation of primary particles.

Densification: Increase in soil bulk density that restricts root growth and inhibits aeration.

Erodibility: Susceptibility of soil to erosion.

Erosivity: Energy of rainfall and wind to cause soil erosion.

Humification: Conversion of biomass (plant and animal residues) into humus.

Illuviation: Transfer of material from surface into subsoil layers.

Nutrient Use Efficiency: Nutrient use per unit agronomic production (mg kg⁻¹).

Pedological Processes: Soil-related processes.

Saline Soils: Soils containing high concentration of salts and high electrical conductivity.

Soil C Sequestration: Transfer of atmospheric CO₂ into soil C pool.

Water Use Efficiency: Water use per unit agronomic production (mm kg⁻¹).

Introduction

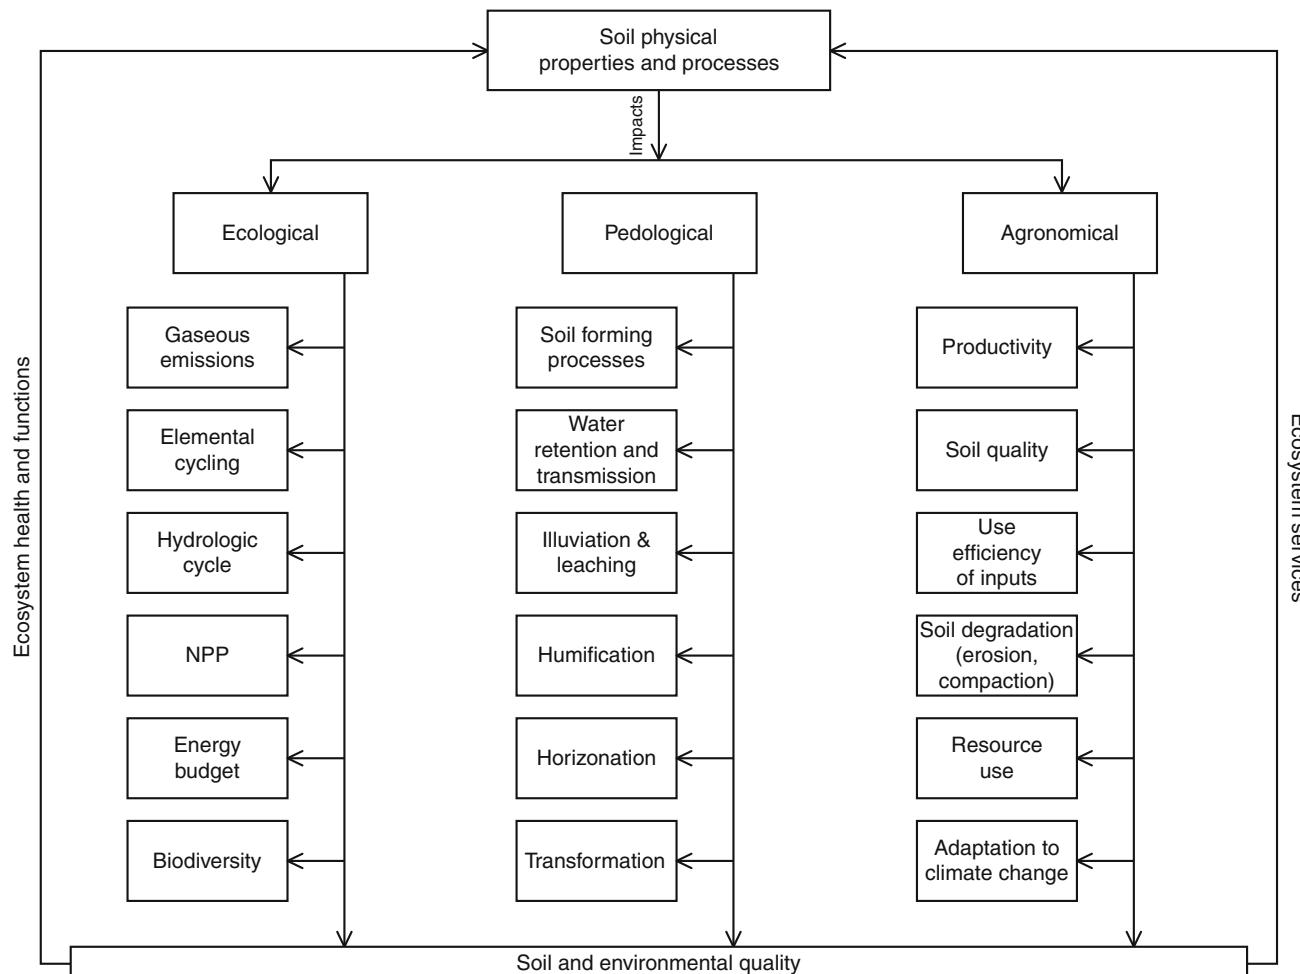

Soil physical properties include physical attributes related to: size distribution of particles (texture), arrangement of particles (structure), volume and continuity/stability of voids (porosity), amount of solids within a specified volume (density), movement of water into (infiltration) and through the soil (hydraulic conductivity), the amount of

water held in soil pores that plants (available water capacity) and microbes (residual water) can use, the amount of heat required to raise temperature of a unit mass of soil by 1°C (heat capacity), gaseous concentrations in soil atmosphere (soil air), and susceptibility of soil to erosion (erodibility). Principal processes mediated by key soil physical properties include: densification/compaction influenced by bulk density, crusting and infiltration by texture and structure, erosion by erodibility and texture, aeration by total/macropores and gaseous composition of soil air, soil warming by heat capacity, and runoff by infiltration rate and texture. These key properties strongly impact ecological, pedological, and agronomical processes with consequences to ecosystem services and ecological processes (Figure 1) at soilscape, landscape, and watershed scales and are affected by soil organic matter (SOM) and its dynamics (Janzen et al., 1997; Reynolds et al., 2002).

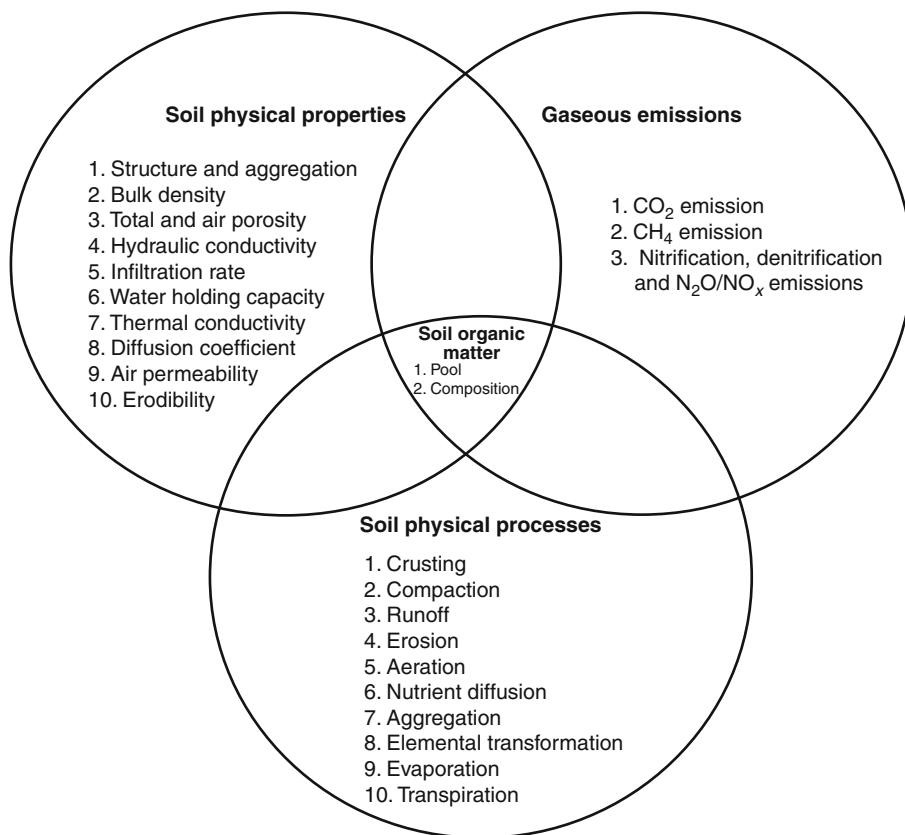

Soil physical properties mediate gaseous flux, elemental cycling, hydrological cycles, energy budgets,

biodiversity, and net primary productivity (NPP) among principal ecological processes. Similarly, rate of soil formation, humification, illuviation, horizonation and transformation, and leaching are examples of pedological processes affected by soil physical properties. Consequently, agronomic yield and productivity (use efficiency of input) is influenced by soil physical properties. Adaptation to climate, changes in seasonality and parameters affecting it, is mediated by soil physical properties and the related processes.

Changes in soil properties in turn affect soil organic matter (SOM) content and its turnover. For example, SOM affects soil properties (such as structure, porosity, density, hydraulic conductivity, water holding capacity, and thermal conductivity), which affect SOM pool and its dynamics. The latter also impacts principal processes such as crusting, compaction, water runoff, erosion, aeration, nutrient/elemental diffusion, and transformation. Furthermore, SOM is a key determinant of gaseous emissions including CO₂, CH₄, and N₂O. Strong connectivity

and feedbacks among these properties and processes are mediated by SOM content, dynamic, and turnover. The SOM content and its quality impact soil physical properties and processes (Figure 2).

This article describes the importance of SOM on some soil physical processes mediated by physical properties and SOM content. Key processes discussed are gaseous flux between soil and the atmosphere, soil aggregation, water availability to plants, soil erosion, and soil compaction and densification.

Gaseous flux between soil and the atmosphere

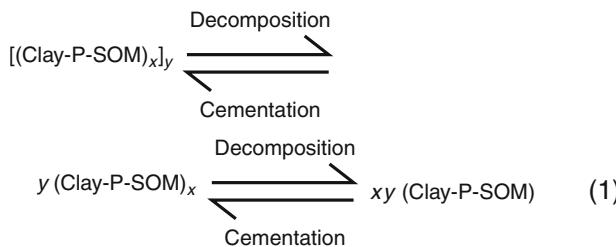

Soil can be a source or sink of greenhouse gases (GHGs) depending on land use, soil/vegetation management, and soil physical properties. Important soil physical properties affecting gaseous flux are bulk density, total and macro-porosity, and the degree of anaerobiosis or lack of oxygen in soil air. With good soil structure and adequate aeration, soil is a sink for CH₄ and vice versa. Similarly, soil aeration and structural properties moderate nitrification/denitrification process and the attendant emission of N₂O into the atmosphere. Annual flux of CO₂-C between soil and atmosphere, because of soil respiration, is about 60 Gt C year⁻¹ (Lal, 2004). With total soil organic carbon (SOC) pool of 2,500 Gt to 2 m depth (Batjes, 1999), the

mean residence time of C in world soils (pool/flux) is $2,500 \text{ Gt} \div (60 \text{ Gt C year}^{-1}) \cong 40 \text{ years}$. The site-specific residence time, however, varies among soil types and ecoregions depending on the SOC pool and CO₂-C flux. At soilscape scale, flux of CO₂-C from soil depends on both ambient and soil temperatures and moisture regimes, bulk density, and total and macro-porosity. Microbial activity increases with increase in soil temperature, leading to a strong variation in CO₂ flux among seasons, terrain aspect, landscape position, and management. The latter includes application of easily decomposable biomass (e.g., crop residues, compost, manure). The rate of soil respiration also depends on the presence of extracellular enzymes which degrade complex organic compounds and accentuate the rate of C turnover in soil (Allison and Jastrow, 2006). In contrast to C turnover that influences aggregation, turnover of aggregates can also influence the SOC pool and CO₂-C flux. Aggregate turnover directly controls the stabilization and physical protection of SOM (De Gryze et al., 2006). Soil microbial community dynamics is another important factor affecting CO₂ flux and C sequestration (Six et al., 2006). In view of the risks of projected global warming and the role of SOC in the global C cycle, understanding the magnitude and determinants of gaseous flux is important to mitigating

and adapting to climate change. Increasing aggregation, improving aeration, and creating positive C budgets are essential to making soil a net sink of CO₂ and CH₄ (Lal, 2004, 2010).

Soil aggregation

Soil structure and its formation are as important to biosphere as is photosynthesis but it is much less understood and is difficult to manage in intensive agroecosystems. Soil structure mediates many soil biological and physical processes and is influenced by SOM content, which acts as a cementing agent for binding clay particles into domains, domains into microaggregates (<250 µm), and microaggregates into macroaggregates (>250 µm). The SOM content is a key attribute of soil quality that strongly impacts formation and stabilization of soil aggregates (Franzluebbers, 2002). In general, bonds within microaggregates are stronger than those between microaggregates. Edwards and Bremner (1967) proposed the general model of aggregation as shown in **Equation 1**:

where P is a polyvalent cation, SOM is soil organic matter or humic substance, and x and y are number of units combined together to form microaggregates and macroaggregates. Tisdall and Oades (1982) indicated that microaggregates are formed in stages with different types of bonds at each stage. Soil aggregation is related to many biological processes in the root zone (Batten et al., 2005). Roots and external hyphae are also important to formation of macroaggregates (Jastrow et al., 1998). Macroaggregation is positively influenced by fungal activity (Bossuyt et al., 2001). Aggregation may also be affected by increase in atmospheric abundance of CO₂, especially to faster turnover of macroaggregates compared to microaggregates (Six et al., 2001).

There are numerous soil management practices which affect aggregation and SOM dynamics. Type and intensity of tillage, along with incorporation or maintenance of crop residues on the soil surface, strongly impacts aggregation and flux of soil C and N. Therefore, no-tillage (NT) and plow-based tillage affect soil structure differently (Six et al., 1998). Conversion of plow-based tillage to conservation tillage can enhance aggregation. Permanent raised bed systems, a form of conservation tillage, can also improve aggregation (Lichter et al., 2008). Use of NT farming enhances aggregation and improves soil structure (Six et al., 2002; Mahboubi and Lal, 1998). Aggregation is also strongly influenced by crop residue and its management. Removal of crop residues for other purposes

(e.g., biofuels) has adverse impact on soil physical properties, especially aggregation, crusting, infiltration rate, and hydraulic conductivity (Blanco-Canqui and Lal, 2007a, b, c, 2008). In general, aggregation increases linearly with increasing amounts of residue application (De Gryze et al., 2005; Duiker and Lal, 1999; Mulumba and Lal, 2008).

Plant available water capacity

The capacity of a soil to supply water to plant roots is an important attribute of soil physical quality especially in regions where rainfall is variable and soil-water storage is crucial to satisfying crop yields. Agronomic yield in arid and semiarid regions is sensitive to combination of small/variable rainfall and small available water capacity (AWC) of soils (Asseng et al., 2008). Soils with high AWC provide buffers to store water for use by plants between rainfall events (Wang et al., 2009). The AWC of soil (centimeter of water in the root zone), defined as the difference in field capacity and wilting point, differs among soils of different structural properties (Droogers et al., 1997). The AWC is defined by **Equation 2** as follows:

$$\text{AWC(cm)} = \sum_{i=1}^n (\theta_{fc} - \theta_{wp}) d_i \quad (2)$$

where θ_{fc} is the volumetric moisture content (cm³/cm³) retained in the soil after the free water (excess water) has been drained through the macropores by the force of gravity. In the laboratory, θ_{fc} is measured by subjecting a saturated undisturbed soil core (clod) to a pressure of 0.3 bar (30 kPa) for a fine-textured soil and 0.1 bar (10 kPa) for a coarse-textured soil. Soil moisture constant θ_{wp} is the volumetric soil moisture content when plants undergo permanent wilting and do not recover even when transferred to an atmosphere of 100% relative humidity. In the laboratory, θ_{wp} is measured when soil is subjected to a pressure of 15 bar (1,500 kPa). In coarse-textured soils, θ_{wp} may be attained at a low pressure of 1 bar (100 kPa). The term $(\theta_{fc} - \theta_{wp})$ is multiplied by the depth (d, in cm) and summed for the number of layers (n) comprising the effective/desired rooting depth (Dane and Hopmans, 2002; Topp et al., 1993). Management of θ_{fc} , determined by aggregation through interaction between texture and SOM content, is essential to enhancing AWC.

Increase in SOM concentration in soil increases θ_{fc} (Rakic et al., 2009) but has no or less impact on θ_{wp} . Thus, a soil with higher SOM content has more AWC than the same soil with lower SOM (Lowery et al., 1996; Lal, 1994). The beneficial impact of SOM on AWC is more on coarse-textured than fine-textured soils (Wesseling et al., 2009). Thus, AWC can be improved through adoption of those agricultural practices which enhance SOM content. Important among these are organic amendments (e.g., compost, farm yard manure) and use of crop residues (Becher, 1996; Bhogal et al., 2009). Incorporation of compost can increase AWC even in drastically disturbed soils (Curtis and Claassen, 2005) and in saline soils (Groenveld et al., 2004).

Soil compaction and densification

Increase in soil bulk density, more solids per unit volume, is a problem in intensively mechanized farm operations involving frequent traffic of heavy machinery. All other factors remaining the same (e.g., texture, vehicular traffic), soils with higher SOM content and stable aggregates are less susceptible to densification than those with lower SOM content and weak aggregates (Soane, 1988). In general, soil bulk density decreases linearly with increase in SOM content (Angers and Simard, 1986; Rawls, 1983; Zaytsev, 1967; Saini, 1966). Soil compaction adversely impacts agronomic production by decreasing crop growth (Nadian et al., 2005; Arvidsson, 1998; Gemtos and Lellis, 1997), reducing root penetration, and reducing AWC (Ohu et al., 1986). Therefore, addition of organic matter reduces risks of soil compaction (Mamman et al., 2007) by decreasing bulk density and increasing activity of earthworms and other soil biota (Jordan et al., 2000; Ruehlmann and Korschens, 2009). Reduction in compaction increases crop yields and the overall agronomic productivity (Ohu et al., 1986, 1987; Janssen and Vanderweert, 1977). Application of sphagnum peat can also decrease bulk density, improve AWC, and enhance potato (*Solanum tuberosum* L.) yield even in sandy soils (Li et al., 2004).

Soil erosion and organic matter content

Accelerated soil erosion (by water and wind) is among the serious global issues of the twenty-first century. Soil degradation by erosion affects agronomic productivity (Lal, 1998) and accentuates emissions of GHGs into the atmosphere (Lal, 2003). The potential hazard of soil erosion is determined by two factors: climatic erosivity and soil erodibility. The latter, susceptibility of a soil to erosional processes, depends on key soil physical properties including texture, structure, infiltration rate, permeability, and SOM content. In general, soil erodibility decreases with increase in structural stability, and the latter increases with increase in SOM content (Lal and Elliot, 1994). The SOM content can have a strong impact on detachment of particles, especially in soils of low activity clays (Kuhn, 2007). Therefore, management of SOM content is essential to an effective erosion control.

One of the co-benefits of soil C sequestration is erosion control and reduction of the nonpoint source pollution (Lal, 2004). Increase in SOM concentration reduces soil erosion risks by increasing aggregation, decreasing erodibility, reducing susceptibility to crusting and compaction, improving activity of earthworms and other soil fauna, increasing infiltration rate, and reducing runoff rate and amount, and decreasing dissolved and suspended loads in surface flow. Soils with high SOM content generate lower amounts of particles/sediments available for transport by soil and inter-soil processes.

Conclusions

The SOM content is important to enhancing and sustaining physical properties and processes. Soil physical

properties affected by SOM include bulk density, aggregation, water retention and movement, air composition, and heat capacity and transmission. Soil physical processes impacted by SOM content include crusting, compaction, water runoff, erosion, gaseous diffusion, and nutrient transformation and movement. These properties and processes are moderated by amount, quality, and dynamics (turnover) of SOM.

Thus, SOM content is an important property for improving and enhancing soil physical quality. Maintenance of SOM content above the critical threshold level is essential to formation and stabilization of soil aggregates, creation, and stabilization of transmission and retention pores and their continuity, buffering soils against compactive and erosive forces, and increasing plant available water capacity. Use efficiency of agronomic input is more for soils with high than low SOM content.

Therefore, strategy of sustainable soil management is to create positive C and elemental budgets (N, P, S, K). Soil and crop management practices which enhance SOM content include conservation tillage with use of crop residue mulch, cover cropping, use of organic amendments (e.g., manure, compost, biochar), and adoption of complex farming systems including agroforestry.

Through their strong impact on soil physical properties and processes, SOM content and dynamics affect ecosystem services such as moderation of atmospheric chemistry through rendering soil a source or sink of GHGs, catalysis of photosynthesis and increase in net primary production and food to ensure food/nutritional security, filtration and purification of natural waters with attendant impact on nonpoint source pollution and hypoxia of coastal ecosystems, and creation of habitat and energy source for soil microorganisms and other biota. Maintenance of SOM content above the threshold level is essential to the desirable/required level of soil's life support systems. Indeed, SOM pool is nation's precious resource. It must be improved, restored, and judiciously managed for the maintenance of the ecosystem services.

ORNAMENTAL PLANTS, PHYSICAL PROPERTIES

Paweł Szot

Institute of Ornamental Plants and Architecture of Landscape, University of Life Sciences, Lublin, Poland

Ornamental plants, similar to other crop plants, are characterized by considerable differentiation of physical traits, both within the species and cultivars grown and in the course of harvest, storage, and transport.

Ornamental plants, especially after their cutting (i.e., separation from the organs that supply water and mineral salts) rapidly lose their resistance to the effect of mechanical forces. In a highly simplified sense, the anatomy of plants comprises specialized tissues – collenchyma and sclerenchyma that form the mechanical structure. However, in the broader sense it relates to all cells, and thus the mechanical system of the plants should be considered on the level of a plant organ and not that of tissue. In the case of cut ornamental plants used for making floral compositions, the stem plays a highly important role. Among the fundamental mechanical properties that may represent stem strength are the bending force, stress, and strain (**Table 1**). Stem stress may occur under the effect of tensile or compressive forces, as a result of which reversible or irreversible strain takes place. In actual structures, deformation of a stem is always accompanied by shearing stress and strain, caused by forces that are parallel to the surface under consideration. In plant organs, shearing stress does not usually exceed the respective strength. When that is exceeded, there takes place a shift or split in the shear plane. In the case of stems of ornamental plants, what is significant is the bending strength and rigidity of the stem, and its resistance to buckling (i.e., deformation caused by compressive forces and resulting in bending of the compressed body). Every deformation is accompanied by an input of work.

Basically, a non-lignified cell wall has only tensile strength, like a sheet of paper. A cell in the state of turgor becomes resistant to compression, torsion, and bending, as in that state of the cell all the deforming forces become converted to forces applying tensile stress to the cell wall; hence, the special importance of the tensile strength of cell walls. The cell wall may be stiff and resistant to direct compression if it contains lignin. Also the presence of endogenous plant hormones has an effect on the

Ornamental Plants, Physical Properties, Table 1 Examples of mean values of selected mechanical properties of flower or inflorescence stems of some ornamental plants

<i>Tulipa</i> sp.	2.5	12.8	23.6

mechanical properties of plant stems. Auxins cause greater plasticity and elasticity of cell walls, and their effect depends on the content of pectins that may retain or release ions (Ca, Mg, or K).

The mechanical properties of stems and another part of ornamental plants can be enhanced through optimisation of cultivation of particular species, and application of suitable growth regulators and conditioners that also extend the ornamental values of the plants in time (Hetman et al., 1994; Szot and Rybczyński, 2008; Szot et al., 2009).

ORTSTEIN, PHYSICAL PROPERTIES

Jacek Chodorowski

Department of Soil Science, Maria Curie-Skłodowska University, Lublin, Poland

Definition

Ortstein (German: *ort*-place, *stein*-stone) is defined by Soil Survey Staff (1992) as all or part of the spodic horizon, when moist, it is at least weakly cemented into a massive horizon that is present in more than half of each pedon.

Origin: Ortstein is usually a hard, partly or entirely cemented illuvial horizon B of podzol or gley-podzol soils, formed as a result of illuviation of aluminum, iron, manganese, and humus compounds from the overlying horizons. In gley-podzol soils, some iron and manganese compounds may come from precipitation from groundwater (Chodorowski, 2009). A huge accumulation of the complexes leads to the formation of coherent aggregates,

and even of continuous, highly cemented layers referred to as ortstein.

Properties: Ortstein is 25 mm or more thick and 50% or more (by volume) cemented (Soil Survey Staff, 1999). As a rule, the horizon has sandy grain-size distribution. Compared to the adjacent non-cemented horizons, ortstein usually has a higher bulk density (Lambert and Hole, 1971; Wang et al., 1978). It is also stronger; the penetration resistance of cone of the ortstein horizon may amount to the value of approximately 8 MPa (Chodorowski, 2009). Water retention and capillary conductivity of ortstein are more influenced by moisture content or matric potential than those of the adjacent horizons (Lambert and Hole, 1971). Due to strong cementation and high concentration of toxic aluminum and manganese ions, ortstein is a mechanical and chemical barrier to the root growth of both forest and crop plants.

OVERBURDEN PRESSURE

A term used in soil science and storage of granular solids in silo denoting the pressure imposed by the weight of overlying layers of material.

OVERLAND FLOW

Elias Dimitriou
Institute of Inland Waters, Hellenic Centre for Marine Research, Anavissos, Attika, Greece

Synonyms

Hortonian overland flow; Infiltration excess overland flow; Saturation excess overland flow; Surface runoff

Definition

Overland flow is the movement of water over the land, downslope toward a surface water body.

Overland flow is a very important aspect of the water cycle and can be generated under two different physical mechanisms. The infiltration excess overland flow is formed (named also Hortonian overland flow after Horton E. R.), when the rainfall intensity exceeds the soil infiltration capacity in an area (Liu et al., 2004). Then water accumulates on the soil and starts moving downslope, due to gravity, towards the hydrographic network. The second mechanism occurs when the soil saturation exceeds its maximum level due to groundwater uplifting, baseflow, and lateral subsurface water discharges, resulting in the appearance of saturation excess overland flow (Beven, 2001).

Factors such as soil permeability, topographic slope, and type and density of vegetation affect the development and distribution of overland flow in both time and space. Bare soil areas will facilitate infiltration excess overland flow because the energy of raindrops can lead to the rearrangement of the surface soil particles which will then create a crust and reduce the infiltration capacity. On the other hand, vegetation protects the soil and creates pathways for water infiltration through its roots and thus can reduce overland flow in an area (Beven, 2001). Additionally, for the formulation of saturation excess overland flow, the initial conditions of the local aquifer (water level and hydraulic conductivity), and the soil storage deficit play an important role in achieving the necessary soil saturation. An aquifer with well developed fracture system and good connectivity with the unsaturated zone can

maintain subsurface and baseflows for long time periods facilitating soil saturation and overland flow.

OXIDATION-REDUCTION REACTIONS IN THE ENVIRONMENT

Zofia Stepniewska

Department of Biochemistry & Environmental Chemistry,
The John Paul II Catholic University of Lublin, Lublin,
Poland

Synonyms

Oxidation-reduction conditions; Redox processes; Redox reactions

Definition

Oxidation-reduction (redox) reactions – reactions that are connected with electrons transfer from the atom oxidized to the atom reduced.

Oxidation-reduction conditions are connected with changes, where an element's positive valence is increased (electron loss), accompanied by a simultaneous reduction of element's valence that is decreased (electron gain).

Redox processes – processes where electron transfer between donors and acceptors take place and in any redox transformations causing oxidation states of the two components.

Introduction

Numerous processes from the microenvironment to the macro environment scale dependent to their redox conditions where dynamics are connected with serious oxidation-reduction reactions and can be expressed by redox potential (E_h) or by free electron pressure (p_e) showing the tendency of an environment to receive or to supply electrons in water solution. In a water sample or in a soil solution, the redox potential is determined by the concentration of effective electron acceptors. In the case of heterogeneous nature of soil, presence of oxygen plays role as a first acceptor of electrons in the series of redox reactions and its consumption by organisms. In oxic environments where oxygen accepts electrons, high redox potential is observed. In environments rich in oxygen, heterotrophic organisms provide their living processes by the use of O_2 as a powerful electron acceptor. The metabolism of reduced organic compounds in the soil generates electrons, which transports to O_2 transform different forms of carbon to CO_2 (product of soil respiration).

Redox potential

Electron free energy scale for mole of electrons can be expressed in ΔG (joule) or in E_h (volts) as well as in pE (dimensionless). The energy gained in the transfer of 1 mole of electrons from oxidants to H_2 , expressed in volts, is the redox potential (E_h) (Stumm and Morgan, 1996). Redox potential measurement is made with the use of inert (e.g., platinum) and reference (saturated calomel or silver chloride) electrodes. Redox potential E_h for the redox reaction

is expressed by Nernst equation, as follows:

$$E_h = E^o - (0.0592/n) \bullet \log Q \quad (2)$$

where $Q = [(C)^c(D)^d]/[(A)^a(B)^b]$, n = number of electrons transferred in reaction, E^o is the standard electrode potential at $25^\circ C$ in which all substances are at 1.0 M concentrations at $pH = 7$ in equilibrium.

Standard redox potential (E^o) expresses a tendency of a reducing agent to donate electrons when $Q = 1$.

In soil heterogeneous conditions where not one but many parallel reactions take place connected with different electron acceptors formed redox potential, which is called mixed redox potential (Bohn, 1971).

Redox status of electrochemical systems is often expressed in terms of electron activity (pe), which is derived from the equilibrium constant of the oxidation-reduction reaction (James and Bartlett, 2000). For any reaction

the equilibrium constant, K, is determined by

$$\log K = \log [Red] - \log [Ox] - \log [e^-] - \log [H^+] \quad (4)$$

where Ox is the oxidized form of the substrate and Red is the reduced product of the reaction.

In the case when the concentrations of oxidized and reduced species are equal then

$$pe + pH = \log K. \quad (5)$$

As a consequence of this formula, every tenfold change in the activity ratio causes a unit change in pe.

Because the sum of pe and pH is constant, if one of them increases, the other must decline. When a given reaction occurs at lower pH, it means that it will occur at higher redox potential or pe.

The value of redox potential can be converted to pe according to the formula

$$pe = \frac{E_h}{2.303(RT/F)} \quad (6)$$

where R = universal gas constant ($8.31447 \text{ J mol}^{-1} \text{ K}^{-1}$), F is Faraday's constant ($96,500 \text{ C mol}^{-1}$), T is the temperature in Kelvin, and 2.303 is a constant.

Effects of pH

Between redox conditions and pH there exists a strong relationship. In natural waters or soil solutions, which are in a highly dynamic state with regard to oxidation-reduction reactions the values of E_h (or pE) and pH are rather far from the thermodynamic equilibrium (Ponnamperuma, 1972). In the absence of biochemical catalysts (enzymes), most oxidation-reduction reactions under these conditions have a tendency to be much slower than acid-base reactions (Sposito, 1989). For example at pH 5, when equilibrium between Fe^{2+} and Fe^{3+} is established, the redox potential is about +400 mV.

At higher pH, the reaction equilibrium will shift to the right so Fe^{3+} will prevail in neutral and alkaline conditions. At lower pH, such as the acid anoxic waters of peat bogs, Fe^{2+} will prevail.

The redox potential (E_h) for the reaction $O_{2(Aq)} + 4H^+ + 4e^- \rightarrow 2H_2O$, taking place in any water solution containing soluble oxygen (e.g., $8 \text{ mg dm}^{-3} O_2 = 10^{-3.6} \text{ M} = 32 \text{ g mol}^{-1}$) at pH values of 5, 6, 7, 8, and 9 would be as follows: $E_{h_s} = 0.921 \text{ V}$, $E_{h_6} = 0.862 \text{ V}$, $E_{h_7} = 0.802 \text{ V}$, and $E_{h_9} = 0.684 \text{ V}$.

Changes in temperature also influence E_h . A rise in temperature by $1^\circ C$ will decrease E_h by 0.0016 V (Gliński and Stepniewski, 1985).

Under natural conditions at pH from 3 to 9 values of pE range from -6 to +12, and those of E_h from -600 to +400 mV (Figure 1).

Redox transformations of elements

Some macroelements such as C, N, O, S, Mn, and Fe, and trace elements or contaminants such as As, Se, Cr, Hg, U, Mo, V, Cu, Ag, and Pb can exist (Cicerone and Oremland, 1988; Faulkner and Patrick, 1992; Khalil et al., 1998) in a number of oxidation states in near-surface geologic environments (Figure 2).

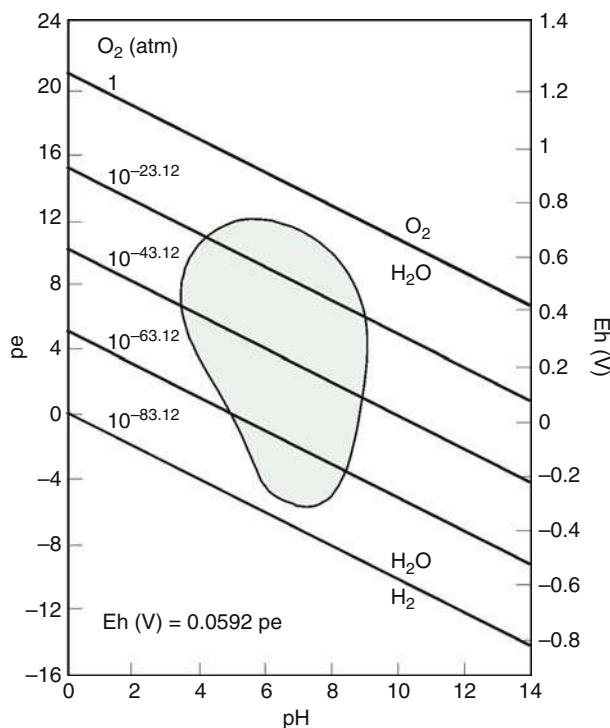

Redox processes in the environment

The values of redox potential in the environment according to oxygen availability are found as follows:

- (a) well-oxygenated water – $E_h \sim 0.802 \text{ V}$
- (b) oxygenated soils and surface waters – $E_h \sim 0.560 \text{ V}$
- (c) anaerobic waters or soils – $E_h \lesssim 0.300 \text{ V}$

As long as the system is exposed to the atmosphere, O_2 will maintain a high redox potential. In the absence of O_2 , a decline in redox potential and the reduction of oxidized forms (nitrate, Mn^{4+} , Fe^{3+} , and SO_4^{2-}) take place (Mosier, 1998).

The driving force causing a decrease in the redox potential is the consumption of oxygen by microbial respiration and the use of organic matter as a carbon source (Yu et al., 2006). All aerobic organisms must have O_2 to survive. Facultative anaerobes can tolerate periods of aerobic conditions (Brune et al., 2000).

Oxidation-Reduction Reactions in the Environment, Figure 1 The range of E_h found in natural environments (modified after Schlesinger (1997)).

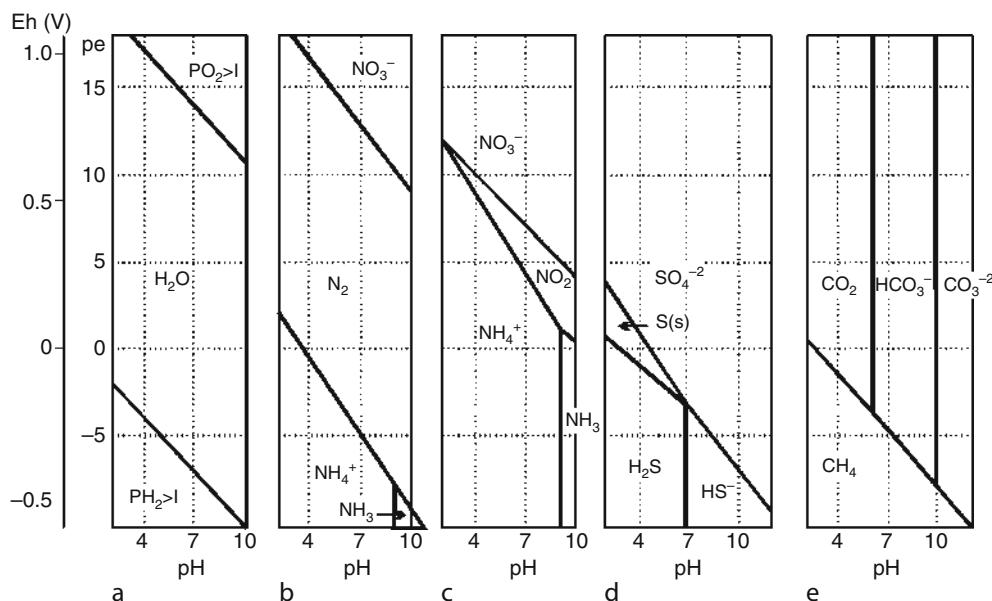

After O_2 is depleted by aerobic respiration, denitrification occurs within the redox potential interval from +750 to 300 mV, dependently on pH. Denitrifying bacteria use nitrate as an alternative electron acceptor during the oxidation of organic matter (Włodarczyk et al., 2004; Yu and Patrick, 2003). Below a redox potential of +500 mV, when nitrate is depleted, the reduction of Mn^{4+} begins. Reduction of manganese is performed also by facultative anaerobes (Stepniewska et al., 1997).

Obligate anaerobes at $E_h < -50$ mV perform the reduction of Fe^{3+} . Due to this, the appearance of reduced Fe^{+2} ions is used as the indicator of the transition from mildly reducing to strongly reducing conditions.

The oxidation processes proceed with some asymmetry versus redox potential (Figure 3). This is reflected by higher E_h (pe) values for the same reaction under oxidation conditions.

Seasonal fluctuations of water table or water level in surface waters may expose a previously flooded soil to the air, the boundary between oxidized and reduced conditions will shift downward in the profile, and the products of previous reduction reactions become substrates for oxidizing bacteria (Tiedje et al., 1984).

Denitrification is enhanced when seasonal periods of aerobic conditions stimulate the mineralization and nitrification of organic nitrogen (Smith et al., 1983), which makes nitrate more available for denitrifiers when the water level later rises (Stepniewska et al., 1996). Generally, pH and E_h (pe) are considered the master geochemical variables

Oxidation-Reduction Reactions in the Environment, Figure 2 The pe-pH diagrams for most biologically important elements (at 298K): (a) oxygen and hydrogen equilibrium with water; (b) and (c) nitrogen oxidation states with regard to N_2 ; (d) sulfur species stable for assumed conditions; (e) thermodynamically possible existence of C compounds (modified after Schlesinger (1997)).

controlling the geochemical reactions of elements in geo-logic and aquatic systems (Schlesinger, 1997).

Redox capacity – redox resistance

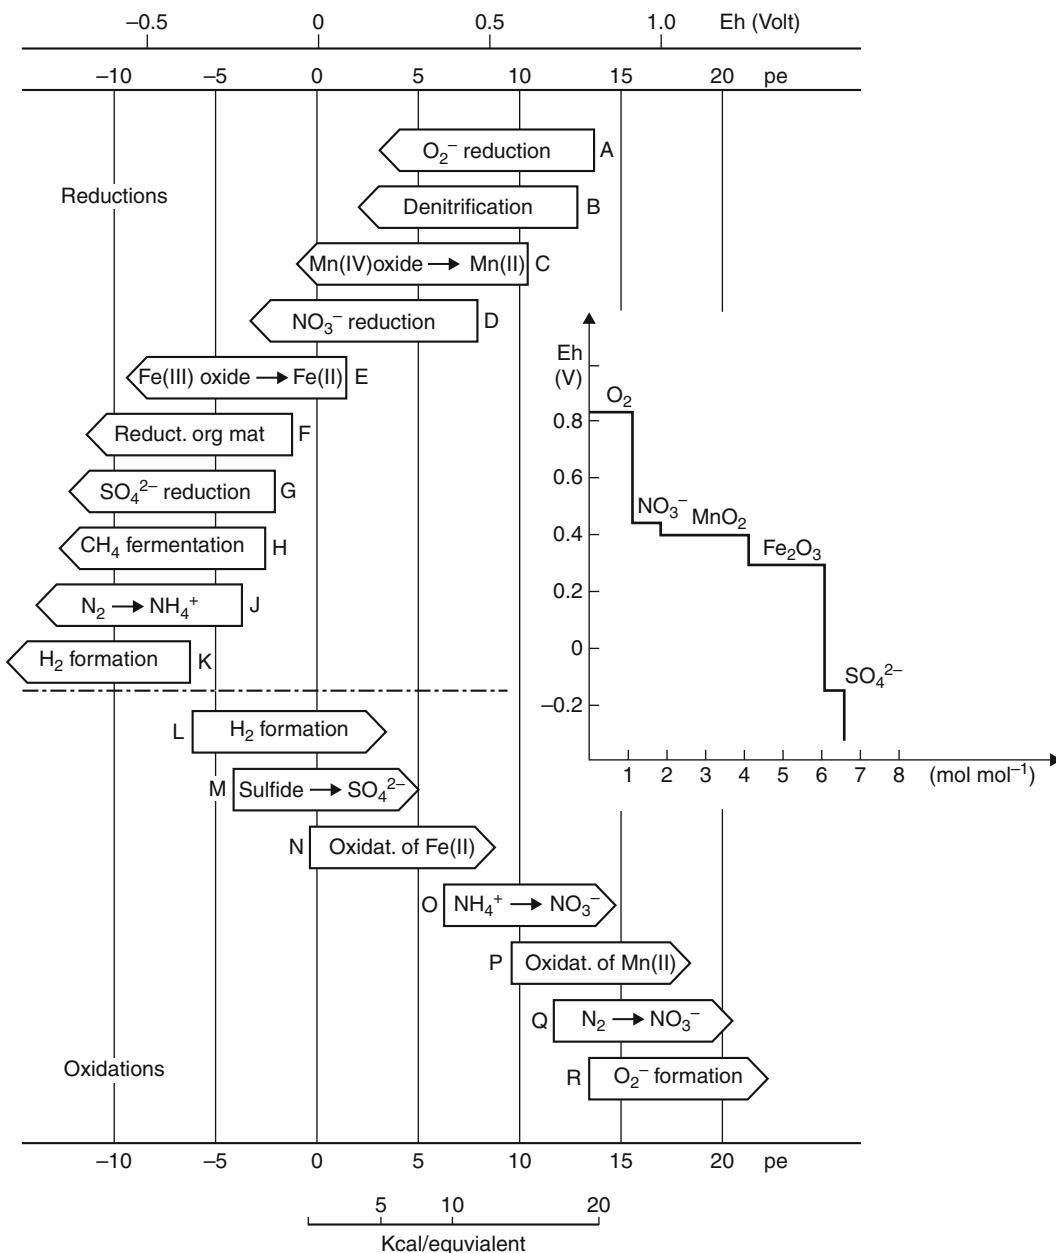

The stabilization of redox status of soils and sediments are express by resistance of changes in their redox potentials and is known as a redox resistance (Ponnamperuma, 1972). The term of buffering redox capacity r (eq/L) of the system express the ability of E_h stabilization and at

any E_h is defined as the quantity of strong reductant that must be added to reduce the E_h by 1 V,

$$r = dC/d(E_h) \quad (8)$$

or, as the time needed to decrease redox potential (E_h) to a given value to +400 mV corresponding to beginning of nitrate decomposition, or to +300 mV corresponding to the beginning of manganese and iron reduction.

Redox buffering capacity can help to interpret important reactions that control pH of natural waters and inform

Oxidation-Reduction Reactions in the Environment, Figure 3 Redox reactions that occur during wetting and rewetting of soils (modified after Schlesinger (1997)). The inset presents the E_h levels of particular compounds and their oxygen equivalents (width), that is, number of moles of a given compound substituting as electron acceptor 1 mole of oxygen (Stępniewski et al., 2005).

about stability of E_h in natural systems in connection with the mobilization and the accumulation of toxic substances (Yu et al., 2001; Stępniewska et al., 2003) as well the emission of greenhouse gases (Gorham, 1991; Chareonsilp et al., 2000; Le Mer and Roger, 2001; Mosier et al., 2002).

Summary

The application of redox transformation in recent years is connected with many different human activities. The first of all in agriculture for foreseen quality and quantity of food under controlling of water management as a irrigation of fields with water or waste water as well in respect to soil fertilization, nutrient availability, and cycling (Gliński and Stępniewski, 1985; Gorham, 1991; Faulkner and Patrick, 1992; Stępniewska et al., 1996; Włodarczyk et al., 2004). Transformations of Cr(III,VI) or As(III,V) in contaminated soils are controlled by oxidation states and response for pollution of ground and surface waters (Singh et al., 1999; James et al., 1997; Stępniewska and Bucior, 2001). Degradation of added to soil synthetic organic chemicals or pesticides by humans are resulted by oxidation-reduction (Vink et al., 1997). Quite fresh was found possibility for galvanic system, which generate electricity on the base of differentiation of redox potentials in the arid and saturated zone (Reimers et al., 2006; Rezaei et al., 2007; Kaku et al., 2008).

OXYGENOLOGY

Witold Stępniewski
Department of Land Surface Protection Engineering,
Lublin University of Technology, Lublin, Poland

Synonyms

Aeration (with respect to soils and plants only)

Definition

Oxygenology is defined as a scientific discipline comprising problems related to the presence and functions of oxygen in nature (Stępniewski and Stępniewska, 1998).

The term oxygenology, recently proposed by Stępniewski and Stępniewska (1998) is related to a scientific discipline, dealing with the presence and role of oxygen in the nature on Earth, which is an exceptional phenomenon on the cosmic scale. This discipline, constituting a branch of environmental sciences, covers issues of generation, storage, transport, absorption, turnover, functions, and measurement

of oxygen content in the environment. The name of oxygenology is analogous to that of hydrology.

Oxygen, as a dominant final acceptor of electrons, plays a unique role in the life of all macroorganisms and of most microorganisms, as well as in the chemical and biochemical processes occurring in the biosphere (Stępniewski et al., 2005). We can distinguish paleooxygenology related to the past geological époques and contemporary oxygenology focusing on the present-day processes and phenomena. In both cases, subbranches such as aquatic, lithospheric, atmospheric oxygenology can be distinguished. Moreover, we can talk about biooxygenology, that is, the oxygenology of biota.

Oxygenology of atmosphere is related to the presence of oxygen in its particular spheres. Thus, tropospheric, stratospheric, and mesospheric oxygenology as well as ozonology can be distinguished here. Aquatic oxygenology is divided into oceanic oxygenology, marine oxygenology, limnooxygenology (oxygenology of lakes), and potamic oxygenology (i.e., oxygenology of rivers). Oxygenology of lithosphere comprises such research areas as oxygenology of wetlands (natural, agricultural, and constructed), oxygenology of drylands (natural and agricultural), and oxygenology of anthropogenic systems (e.g., mines, buildings, and landfills). Biooxygenology is divided into microbial oxygenology, phytotoxic oxygenology, zoological oxygenology, and human oxygenology.

PARENT MATERIAL AND SOIL PHYSICAL PROPERTIES

Andrzej Mocek, Wojciech Owczarzak
Department of Soil Sciences and Land Protection,
University of Life Sciences, Poznań, Poland

Synonyms

Mantle rock; Soil parent rock

Definition

Parent material. The unconsolidated and more or less chemically weathered mineral or organic matter from which the solum of soils is developed by pedogenic processes (Glossary of Soil Science Terms, 1987; Resource Conservation Glossary, 1982; Soil Taxonomy, 1976).

Physical properties (of soils). Those characteristics, processes, or reactions of a soil that are caused by physical forces and that can be described by, or expressed in, physical terms or equations (Glossary of Soil Science Terms, 1987; Resource Conservation Glossary, 1982; Soil Taxonomy, 1976).

Introduction

Soil was formed as a result of long-term and complex transformations of its mineral matter called parent material. Primordial, abiotic factors such as properties of the parent material, relief, climate, and time played a key role during the first stage of these transformations. In the course of the second phase, the results of the primary factors became intertwined with the effects of biotic factors, namely with the impact of microorganisms as well as the plant and higher animal kingdoms either coming into existence or just developing. During the last, relatively short time of the Earth history, still one more, important factor appeared, namely man's activities in the broad sense of the word. However, the basis of contemporary soils is the diverse, primary mineral substrate, which developed under the influence of complex actions of a number of physical, chemical, and biological factors.

Genesis

It is known that solid rock underwent breakup as a result of fairly complex processes commonly referred to as weathering. The primary factor of this process was physical weathering (see [Physical \(Mechanical\) Weathering of Soil Parent Material](#)). Frequent, periodical temperature changes in surface rock layers caused uneven strains and stresses leading to the development of pulsations. The higher was the amplitude of temperature fluctuations, the faster were the flaking processes in rocks, development of crevices, splinters, etc. The process was supported by the heterogeneity of the rock structure and by the different coefficient of expansion of its components (minerals). Another important factor taking part in the process was water, especially in the case of the phase change from liquid to solid (frost processes).

Physical weathering processes overlapped with processes of chemical weathering. Also in this case, the main factor here was water in which soluble gases

occurred: carbon dioxide and oxygen. Such water solution caused a change of some minerals into other minerals, while poorly soluble ones turned into more soluble.

In the result of physical and chemical processes of weathering, solid rock was transferred into rock mantle of various degree of disintegration and, hence, of diverse physical properties. It is commonly assumed that this kind of weathered rock constitutes not more than 5% of the terrestrial globe lithosphere and, at the same time, it occupies 75% of the land area.

Geological classification of soil parent material

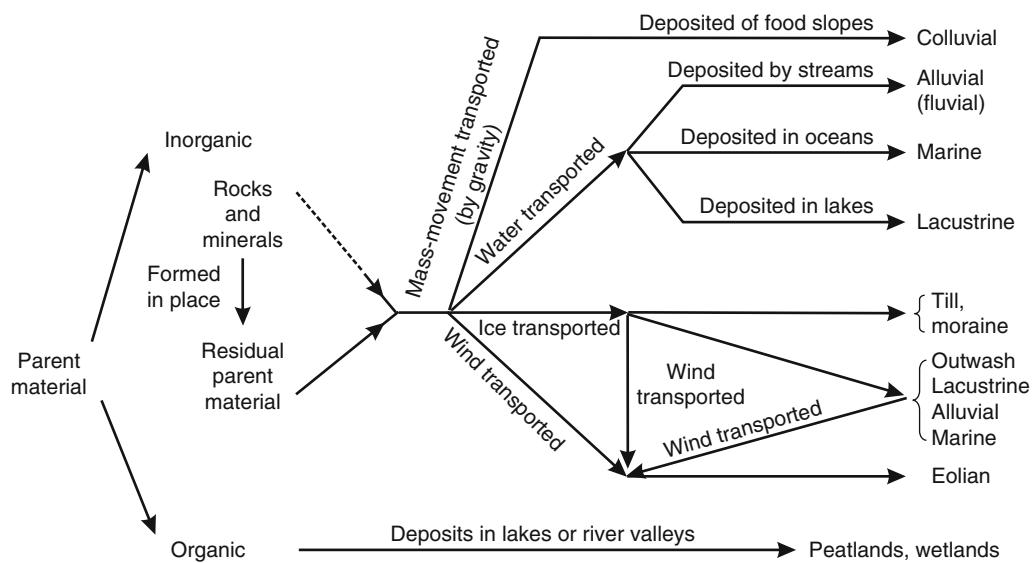

Bearing in mind the place of their development, mineral parent materials are divided into sedentary – formed in situ, and transported (Figure 1; Brady, 1990). Their characteristics are as follows:

Residual materials are usually formed from solid (compact) magmatic, sedimentary, and metamorphic rocks as a result of weathering processes. The developed mantle rock remains in place and is deposited on parent rocks (Buckman and Brady, 1969). It is partially impoverished by soluble components and, to a smaller extent, by particles floated by water currents and wind forces (slight translocation). The character of residual deposits depends on the intensity of weathering processes. Therefore, in warm and humid climates, regoliths undergo strong oxidation and fairly strong rinsing that explains their red, orange, or yellow color. In addition, they are characterized by low calcium content (Buckman and Brady, 1969). In colder conditions, which are also frequently drier, the weathering processes are less intensive. Oxidation processes and iron hydration in the regolith are less noticeable (colors are less intensive), while the content of calcium carbonate, as a rule, is higher. The discussed materials

can be found on all continents and their current characteristics depend on the diversification of intensity of individual soil-forming factors as well as on the degree of advancement of pedogenetic processes. Residual mantles most frequently exhibit the nature of clays or sand deposits.

Colluvial materials constitute heterogeneous rock raw material, which slides down from slopes as a result of gravitation forces (mass movements) from higher portions of slopes and which accumulates at their foot. Most frequently, they are unassorted deposits and are rarely found in poorly diversified geomorphological areas (Thompson and Troeh, 1973). Extensive colluvia can be found, primarily, in the mountains where steep slopes favor the formation of large slides and slips. One of the examples of colluvial formations includes the so-called scree, that is, loose rock debris consisting of pieces of rock broken away from the mountain face in the result of mechanical weathering as well as of slabbing rock blocks and stones covering slope sides (Pietkiewicz and Żmuda, 1973). They sometimes accumulate on slopes of these faces (mostly in gullies) but can be found mostly at the foot of mountains in the form of covers, heaps, or irregular steep cones.

Alluvial materials these are sediments deposited by waters of rivers and streams on the bottom of their beds, in flood lands (flood terraces), and in deltas at river mouths. The character of alluvial formations depends on the erosive-sedimentation activity of surface waters. Majority of stones and gravel are deposited in the river main current or in its upper course. Sandy formations accumulate along riverbanks, its arms, or on the flood plain neighboring the river. Fine particles float further on along the course of the river and are deposited further from

Parent Material and Soil Physical Properties, Figure 1 Classification of parent materials in relation to their kinds, development, transport, and deposition (Brady, 1990, modified).

the riverbed on the flood plain. Clays sediment along the lower course of the river where water velocity is minimal. Hence, three main groups of alluvial sediments are distinguished: flood terraces, alluvial cones, and delta sediments (Buckman and Brady, 1969; Brady, 1990). Flood terraces develop during river floodings (inundations). Sediments of a single flood exhibit similar particle-size distribution, which means that, in general, alluvial materials are characterized by stratified distribution; coarse sediments are deposited closer to the riverbed, while finer materials – further away from the river current. Alluvial cones constitute fan-like accumulation of alluvial sediments deposited by still or periodic waters in a place where a concave profile collapses and reduced inclination (distinct decrease in velocity) occurs on the way of these waters, for example, at the inlet of lateral valley (lateral river) to the main valley (main river). Alluvial cones are built, primarily, from sands and gravels. Coarser (gravel) material settles in the upper part of the developing cone, whereas finer particles are transferred toward its foot and toward the main river current. Sediments that form alluvial cones are sometimes referred to as proluvial sediments (Kowda, 1973). Materials forming them are badly graded, differently “turned” and, most frequently, improperly layered in an oblique manner. Silt sediments enriched in CaCO_3 can also occur along the periphery of proluvial cones. River delta deposits are formed at the mouth of rivers flowing into lakes or seas. The deposited finest material settles on an area whose shape is similar to a triangle. Deltas somewhat remind alluvial cones and their name derives from the Greek letter Δ (delta) (Thompson and Troeh, 1973). Sediments deposited in deltas are very fertile provided air-water conditions are controlled.

Marine materials are made up of sediments deposited in these reservoirs by surface waters and courses flowing in from inland areas. The above deposits were affected by various weathering-erosion factors and sorted first by flowing waters and then by sea waves. They form soil parent material when they emerge over the sea level. They can assume different shapes and forms of surface features such as delta bars, long river outwashes, sandbanks separated from the shore, which can give rise to lagoons, polders, bays, or swampy-saline areas (Kowda, 1973). In the majority of cases, delta bars and river outwashes are made of coarse-grained sandy material, while contemporary and old polders – from finer-grained clay material. In hot and dry climates, layers of chemical sediments in the form of soluble salts are formed at the bottom of lagoons and bays, whereas in the case of the occurrence of sandbanks – salines are developed ([Alkalinity, physical effects on soils](#)).

Limestones constitute an important group of sedimentary rocks, mainly of sea (less frequently of lake) chemical-organic origin. Their primary constituent is calcite or aragonite. Depending on various admixtures, limestone colors may vary from white, gray, yellow to brown, red, and bluish. As a rule, they are soft but sometimes they

can also be very hard and crystalline. This depends on the geological formation from which they derived. Mostly, they originate from residues of sea organisms (shell, coral and crinoid limestones, i.e., echinoids and crinoids). Some limestones contain glauconite (green), bituminous (black), or clay admixtures (Pietkiewicz and Źmuda, 1973). They constitute parent material of soils known as Rendzinas. Anhydrites (gypsum) belong to sediments of sea or lake origin. They develop as a result of drying of large water reservoirs (seas, less frequently lakes) forming extensive beds in tertiary deposits. They are also parent materials of soils known as anhydrite Rendzinas.

Lacustrine materials are formed from sediments deposited by rivers flowing into lakes from surrounding uplands. Coarser formations (gravel and sand) deposit along shores or in river deltas, whereas most of the silt and clay sediments are transferred further and settle in the central parts of lakes. Once lakes dry out, such sediments can constitute parent material for soil development. One of the examples of lake sediments can be varved clays consisting of numerous, alternative less than 5-mm thick light (aleurite) and dark (pearlite) layers occurring in stagnant lakes from ice period (Ryka and Maliszewska, 1991). Light layers derive from summer periods and dark ones from winter periods. Together with flowing waters, various chemical compounds in dissolved form are delivered into lake reservoirs and can undergo precipitation as chemical sediments (sediments of calcium carbonate). This is how limestones (oolitic limestones) – important soil parent materials – were formed.

Till (glacial) materials were formed as a result of glacier melting from deposits that were transported by them. They constitute a mixture of strongly diversified deposits, especially with regard to particle-size distribution. These deposits were deposited in the elements of postglacial landscape such as frontal and ground moraines, outwash zones, and marginal stream valleys (Prusinkiewicz, 1994). Frontal moraines, also known as terminal moraines, form a series of hills made up of variously grained rock material drifted and deposited by a glacier in a place in which the considerable speed of melting of the land-ice head made its further movement forward impossible. Frontal moraine ramparts are usually made of coarser rock material, that is, boulders, gravel, and sand and, therefore, constitute poor soil parent material. Ground moraines are made of deposits frozen to the base of the glacier or situated at its bottom. They consist of rock fragments broken away from the base by the carving action of the glacier. As a result of strong friction against the base and mutual wear of individual fragments, this material is scratched and rounded producing considerable quantities of boulder clay (glacial till) made up of fractions of clay, silt, sand, gravel, stones, and boulders mixed in different proportions. Ground moraines usually make flat or only fairly plicate forms and, hence, flat and corrugated ground moraines are distinguished. Top parts of ground moraines, sometimes called ablation moraines, contain more sand, whereas bottom parts exhibit more clayey

character (Prusinkiewicz, 1994). Boulder clays provide good soil parent material. The outwash zone consists of an extensive, flat cone slightly tilted in the distal direction situated directly in front of the frontal moraine. It is made up, mainly, from sands and gravels left by waters of the melting glacier. These deposits are frequently referred to as fluvioglacial sands containing significant quantities of skeletal deposits. Quartz (see *Estimation of Quartz Content in Mineral Soils*) is a dominant (60–90%) mineral in these sediments. Pradolinas (ice-marginal) valleys form wide valleys running latitudinally and are associated with extended periods of halts of the glacier during which they were furrowed by waters flowing along the melting front. They can be found in areas of all large quaternary glaciations. They are lined with variously grained deposits beginning with boulder clays through sands to more uniform alluvia of silt nature. Many old ice-marginal valleys were later covered by fluvioglacial deposits of later glaciations.

Eolian materials are developed as a result of relocation by wind of fine particles from all areas either deprived of all vegetation or poorly covered by plants, primarily from desert regions, seashore beaches, river flood terraces, and areas where fluvial deposits accumulate. Sand grains are transported not very far, while silt and clay fractions can be carried for considerable distances. Sand deposits are frequently referred to as sand dunes, whereas mainly silt and partly clay particles form loessic deposits. Dune sands most frequently form elevations called dunes built by wind. Seashore and inland as well as migrating and permanent dunes can be distinguished. They are of little value as soil parent material. Loesses constitute a classic sedimentary, porous, fine-grained, usually non-layered rock. They are straw yellow or dark yellow in color and their particle-size varies from 0.1 mm to 0.02 mm. They contain about 60–75% quartz silt, about 10–25% CaCO_3 , 4–6% clay minerals (see *Clay Minerals and Organo-Mineral Associates*) and dispersed iron hydroxides (Prusinkiewicz, 1994). Loesses belong to the best – albeit erosion-sensitive – soil parent materials and occupy approximately 4% of the earth's area. Loesses can be found, primarily, in China where their thickness reaches 200 m at places, although they also occur in Russia and America. In Western Europe, loesses are found in northern France, central Belgium, western and central Germany, southeastern Austria, in Moravia, southern Poland as well as in southern Slovakia, Hungary, and Romania (Pietkiewicz and Źmuda, 1973).

Parent materials of organic nature (most frequently of lake origin) occupy low, wet areas (see *Wetlands, Management, Degradation and Restoration*) where, at oxygen shortage, accumulation of organic matter known as peat takes place. This is an organic product of slow, structural, and chemical transformations of boggy plants undergo in conditions of high moisture and permanent anaerobiosis (Prusinkiewicz, 1994). Peat materials (see *Peats and Peatlands, Physical Properties*), apart from a certain amount of humus substances, also contain considerable

quantities of poorly decomposed plant residues and ash components. From the point of view of botanical composition, the following peats are usually distinguished: low-moor moss, sedge and rush peats as well as highmoor moss, heather peats, and boggy coniferous forest. Peats exhibit varying degrees of decomposition, hence, the following three groups are distinguished: poorly decomposed (*fabric*), medium-decomposed (*hemic*), and well-decomposed (*sapric*) peats (Soil Taxonomy, 1976). They constitute parent material of peat soils and, after advanced process of mineralization (drying), of muck soils. Also gyttia rocks, which make up the organic or mineral-organic sediment accumulating at the bottom of some eutrophic and well-aerated water reservoirs, constitute deposits of organic origin. The organic part of gyttia consists of decomposing plankton organisms including varying additions of clay particles. As a rule, gyttias constitute a thin, dark (jelly-like) layer of biomass in the bottom part of peats. Depending on the type and volume of co-components, the following gyttias are distinguished: calcareous (containing CaCO_3), clayey (presence of clay), and detritus (with plant detritus).

Soil physical properties

Soil physical properties are particularly important since they determine all its other properties, including chemical and biological ones. Soil is a porous, three-phase medium with its constituent elements found in solid, liquid, and gaseous phases (see *Soil Phases*). Soil solid phase is made up of mineral, organic, and organic-mineral particles of different degree of breakup. The liquid phase of the soil consists of water in which mineral and organic compounds are dissolved together making up soil solution. The gaseous phase is composed of a mixture of gases and water vapor and is also known as soil air. There is a continuous antagonism between liquid and gaseous phases since they can only occupy the same spatial volume (see *Spatial Variability of Soil Physical Properties*), which is not taken up by the solid phase, that is, soil pores (see *Pore Size Distribution*).

Primary and secondary soil physical properties are usually distinguished. Primary soil properties include those that constitute the quality of the soil material and its relation to the occupied space. They comprise texture (see *Soil Texture: Measurement Methods*), density (see *Bulk Density of Soils and Impact on Their Hydraulic Properties*), porosity, consistency, structure, viscosity, and compaction (see *Compaction of Soil*). Soil secondary properties are the function of primary properties and precondition soil properties as the environment and substrate for living organisms (plants and animals). They include water (see *Water Budget in Soil; Wetting and Drying, Effect on Soil Physical Properties*), air, and temperature (see *Temperature Effects in Soil*).

The basic and most important soil physical property is its texture, which describes the degree of size distribution of the mineral part of soil solid phase. This distribution

was developed during a long and complex geological process (weathering processes), in other words, in the course of the development of parent material and, at the present time, it is a constant property unchangeable even during a long period of time. The mineral part of the solid phase is both polydisperse, as it comprises particles of different sizes and heterodisperse because it exhibits diverse chemical-mineralogical composition.

Depending on the method of formation, transport, and sedimentation of the rock mantle deposition, it is possible to distinguish polyfraction materials – of different diameter span of mineral particles (till, moraine) and monofraction (alluvial, marine, outwash, eolian). Selective sedimentation and accumulation of more homogeneous material took place as a result of segregation processes. Soil colloids, that is, particle with the diameter smaller than 0.002 mm (clay minerals), constitute the most important fraction of the mineral part of the solid phase. Their extensive specific surface area (see *Specific Surface Area of Soils and Plants*) increases significantly water capacity (see *Field Water Capacity*) which, in the case of soil wetting, leads to soil swelling and during drying – to its shrinking, that is, to processes resulting in unfavorable soil volume changes – maximal soil loosening and compaction.

Apart from the size distribution of the soil material, its other important quality is the shape (sharp-edged, circular, elliptical, plate-like) and form (smoothness, roughness) of elemental particles. Both size distribution and the shape and form of elementary particles influence quantitative interrelationships of the three-phase soil medium affecting variations in the compactibility (see *Soil Compactibility and Compressibility*) of various soils.

Summary

Soil parent materials can be of mineral (magmatic, sedimentary, and metamorphic mantel rocks) or organic origin. According to geological classification of these deposits, the following mineral materials are distinguished: residual, colluvial, alluvial, marine, lacustrine, glacial, and eolian, whereas organic materials include peats and gyttias. The above-mentioned parent materials form three-phase systems (phases: solid, liquid, and gaseous). Mutual relationships between these phases are decisive with regard to both basic (texture, density, porosity, structure, compaction, etc.) and functional (air-water) soil properties.

PARTIAL PRESSURE

The pressure exerted by each gas in a mixture proportional to the amount of that gas in the mixture (e.g., proportion of oxygen in the soil atmosphere).

PARTICLE DENSITY

The density of the particles (e.g., soils and grains), the dry mass of the particles being divided by the solid (not bulk) volume of the particles, in contrast with bulk density.

PARTICLE FILM TECHNOLOGY

Michael Glenn
USDA-ARS Appalachian Fruit Research Station,
Kearneysville, WV, USA

Synonyms

Kaolin; Reflectant

Definition

Particle Film Technology involves establishing a mineral particle film on the surface of a plant or plant product that (1) is chemically inert, (2) has a mean particle diameter $<2\text{ }\mu\text{m}$, (3) is formulated to spread and create a uniform film, (4) does not physically disrupt gas exchange from the leaf, (5) transmits photosynthetically active radiation (PAR) to and partially reflects harmful ultraviolet (UV) and infrared (IR) radiation from the surface, (6) alters insect and/or pathogen behavior on the plant, and (7) can be removed from the plant or plant product. Particle Film Technology was developed using chemically inert kaolin mineral particles in aqueous formulations for application to crop plants to protect them from insect pests and environmental stresses. Field research demonstrated that this technology effectively provides a safe alternative to conventional insecticides for certain insect problems on a wide range of crops, including apple, pear, grape, blackberry, melons, tomato, onions, papaya, peach, nectarine, olive, pineapple, and citrus. Surround® Crop Protectant is the first particle film product to provide effective suppression of high heat damage and sunburn without the use of evaporative cooling. In organic agriculture, Particle Film Technology represents the first broad utility material that provides effective insect control and high produce quality in organic fruits and vegetables. Particle Film Technology represents a broadly based insect control system whose impact could be similar to the development of the first synthetic insecticides but without the adverse effects on ecosystems. Additionally, Particle Film Technology provides agriculture with the first sunburn and heat management tool that can manipulate ultraviolet, photosynthetically active infrared radiation. Surround is a registered trademark of Tessenderlo Kerley, Inc.

PARTICLE-SIZE DISTRIBUTION

The fractions of the various particle sizes (soils, powders) often expressed as mass percentages.

PARTICULATE ORGANIC MATTER

Material of plant or animal source suspended in water and usually capable of being removed by filtration.

²Institute of Soil Science and Environment Formation, University of Life Sciences, Lublin, Poland

Synonyms

Bogmoor; Moor; Peatland; Peat moor; Peat swamp

Definition

There are a number of various definitions of the word “peatland.” When defining peatlands, botanists will place emphasis on plant assemblages, geologists and soil scientists – on quality parameters and resources of peat deposits, whereas the ecologists prefer the habitat and ecosystem approach.

Peatland is:

1. One of the types of wetlands – strongly hydrogenic areas with the occurrence of specific vegetation and processes of accumulation of organic deposits. It is a habitat that is permanently waterlogged, developed on a hard-permeable substrate, covered with communities of mosses and moor-grassland vegetation (Keddy, 2004).
2. The biotope for moss–fruticose biocenosis, developing under conditions of strong hydration, with a peat layer with depth greater than 30 cm (Crum, 1992).
3. An ecosystem capable of permanent or periodical saturation or flooding with water, composed of hydric soils and hydrophytic vegetation (Committee on Characterization of Wetlands, 1995).
4. A plant community overgrowing a peat deposit created by itself (Weiner, 2000)
5. A deposit of peat – sedimentary rock formed as a result transformation, undergoing under specific conditions, of decayed plant residues, the youngest fossil coal. It contains less than 60% of carbon and is composed on non-decomposed plant residues and amorphous humus mass (Ilnicki, 2002).

6. Recently a new term is being introduced: suo (from the Finnish language), denoting areas of organic or mineral soils on which peat-forming vegetation is currently growing.

Occurrence and development

Peatlands occur primarily in the moderate humid and cool climate zone (in the northern part of Eurasia and North America, as well as in mountain regions).

Contemporary peatlands have been developing since the beginning of the oldest Dryas and Bölling, that is, from the time when the glaciations receded, i.e., for ca. 13,000 years. One of the oldest peatlands in Poland, probably also in the European Lowland, is the peatland Białe Ługi (Ilnicki, 2002).

In the moderate humid climate zone, the annual increment of a peatland is ca. 0.7–1.0 mm, on average.

Peatlands covering large areas (of the order of thousands of hectares) are referred to as peat complexes. The largest peat complex in Europe is Polesie.

Classification of peatlands

Classifications of peatlands take into account the trophy of habitats and the content of calcium compounds in the substrate that affect the composition of peatland vegetation assemblages. Another criterion is the water relations, resulting from the land relief. In Central Europe, the following are distinguished:

- Low moors – formed due to the flow or stagnation of eutrophic waters, most frequent in Europe; they develop within river valleys, fertile, and floristically rich: rush communities (reed, bulrush, horsetail) or turf communities (mosses, sedges)
- High moors – supplied with oligotrophic precipitation waters, morasses formed in depressions with no outlet, strongly acidic, poor in nutrients, and therefore also poor floristically (peat mosses, fruticose species from the genus *Ericaceae* such as *Ledum palustre*, *Vaccinium uliginosum*, *Oxycoccus palustris* and *Andromeda polifolia*, *Erica tetraix*, tawny cottongrass *Eriophorum vaginatum*, sedges, insectivorous plants); conditions suitable for bog forests develop here
- Transitional moors – encountered in intermediate habitat conditions. These moors are covered with morass-sedge communities composed of *Carex lasiocarpa*, *Carex limosa*, *Scheuchzeria palustris*, *Rhynchospora alba*, *Eriophorum angustifolium*, peat mosses (*Sphagnales*), and hypnaceous mosses (*Bryales*). Through natural succession, in those moors, there appear pine and birch, and in the northern part of Eurasia and in North America – also spruce.

Ecological significance

Peatlands fulfil significant functions in the natural environment: (1) they take part in water circulation and retention; (2) they are natural filters of environmental

pollutants; (3) they store organic matter and carbon, and thus affect global climate changes and carbon circulation; (4) they have a mollifying and stabilizing effect on the microclimate of the immediate environment; (5) they play an important role in the preservation of biodiversity; (6) they are an important characteristic element of landscape; (7) they constitute archaeological archives.

Ad. (1) Peatlands are considered to be important water reservoirs; they constitute some of the best retention reservoirs created by nature (Ilnicki, 2002; Mitsch and Gosselink, 1993). The retention capacity applies primarily to living peatlands, in which the peat-forming process continues. They can accept notably greater amounts of water and release it much more slowly than degraded peatlands do. Water is also stored in partially drained peat deposits. It is estimated that, e.g., the peatlands of Poland may hold ca. 34,000 million cubic meters of water, and the water retained in them would cover the whole territory of Poland with a layer of 1.10 cm (Tobolski, 2000). Valley peatlands play an important role in the shaping of the water level in the rivers and the adjacent valleys. River valleys with a high degree of conversion into peatlands have significantly increase water retention capacity and ensure more uniformly directed outflow of waters (Lipko, 2000).

Ad. (2) Through biogenic accumulation, peatlands play the role of efficient natural filters. The filtration properties of those ecosystems consist in the reduction of water solutions migrating vertically and horizontally, though their incorporation into solutions accumulated in peat. They can reduce the load of nutrients flowing to the rivers from the surrounding fields – limiting the flux of nitrogen, fixing phosphorus and sulphur compounds, and absorbing calcium and magnesium. Peatlands supplied with water from surface flooding participate in the process of purification of waters, and the efficiency of the process depends on the time of water retention and on the surface area of the peatland (Mitsch and Gosselink, 1993).

Ad. (3) Peatlands play also a significant role in the global balance of organic carbon and nitrogen. Depending on the way of their use, peatlands should be treated either as storage reservoirs for greenhouse gases or as a source of their emission. It is necessary to consider separately peatlands that are not drained and drained peatlands being used by agriculture, forestry, or the peat industry. Live peatlands, in which the peat-forming process continues, play an accumulative role and are natural reservoirs of carbon and nitrogen. Drained peatlands become emitters of greenhouse gases, releasing to the atmosphere compounds of carbon (carbon dioxide) and nitrogen (nitrous oxide). In the balance of greenhouse gases, another important element is the emission of methane which is high in non-drained peatlands, especially low moors, with a high level of ground water. It attains maximum values on flooded areas and also

increases on pastures fertilized with animal feces. No methane emission is observed in the case of extensively and intensively used grasslands and arable lands situated on peatlands (Klöve et al., 2009; Ilnicki, 2002).

Ad. (4) Peatlands, and especially their large complexes, significantly affect the climatic conditions in their surroundings. They are characterized by a specific microclimate – higher air humidity compared to mineral soils, greater frequency of occurrence of mists and dew, notably greater frequency of occurrence of ground frost, shorter periods without ground frost, lower air temperatures and lower topsoil temperatures in the summer period (Ilnicki, 2002).

Ad. (5) Peatlands are often treated as refuges of nature, enriching the biological diversity of neighboring areas, and especially of lowland regions. They are the habitats of numerous species of plants, animals, and fungi (Crum, 1992; Ilnicki, 2002), including species that are rare, covered with legal protection, and threatened. Valuable plant species occurring on transitional moors include, e.g., downy willow *Salix lapponum*, swamp willow *Salix myrtilloides*, bog orchid *Hammarbya paludosa*; on low moors, e.g., creeping marshwort *Apium repens*, marsh violet *Viola uliginosa*, dwarf marsh violet *Viola epipsila*. Peatlands are also considered to be major bird refuges in Central Europe, with the occurrence of such species as, e.g., Eurasian Bittern *Botaurus stellaris*, Jack Snipe *Lymnocryptes minimus*, Ruff *Philomachus pugnax*, Black Grouse *Tetrao tetrix*, Eurasian Curlew *Numenius arquata*, Aquatic Warbler *Acrocephalus paludicola*. Peatlands are also the sites of occurrence of numerous groups of relic species of plants and animals. Glacial (boreal) relicts include bush and fruticose species – dwarf birch *Betula humilis*, swamp willow *Salix myrtilloides*, downy willow *Salix lapponum*, marsh Labrador tea *Ledum palustre*, black crowberry *Empetrum nigrum*, herbaceous plants – yellow marsh saxifrage *Saxifraga hirculus*, royal loose-wort *Pedicularis sceptrum-carolinum*, creeping sedge *Carex chordorrhiza*, bryophytes – *Calliergon trifarium*, *Meesia triquetra*, *Scorpidium scorpioides*. The specific habitat conditions of peatlands cause that the flora of those ecosystems is characterized by a high share of species with a narrow ecological amplitude. Most plants occurring there are stenotopic species. In terms of water requirements, the largest group is hygrophytes, followed by hydrophytes. Dominant are photophilic species (heliophytes). As relates to the thermal requirements, oligothermic species dominate. The flora occurring on peatlands is varied in terms of tolerance to the level of nutrients in the soils (eutrophic, meso- and oligotrophic species) and to the soil reaction (acidophytes, species of weakly acid and alkaline habitats) (Ilnicki, 2002). One of the methods of adaptation of peatland plants to the habitat conditions (deficit of available nitrogen) is insectivorousness (carnivorousness), e.g., common butterwort *Pinguicula vulgaris*,

sundews *Drosera rotundifolia*, *Drosera intermedia*, *Drosera anglica*, and *Drosera × obovata*, as well as the waterwheel plant *Aldrovanda vesiculosa*, occurring in micro-reservoirs within transitional moors. Also important for the shaping of biodiversity are the large-area peatlands of river valleys and small midfield and mid-forest peat moors.

Ad. (6) Peatlands should be treated as a significant landscape-forming element. The role of peatlands in landscape, and especially their comprehensive effects in above-ecosystem systems, is more and more the object of analyses (Chmielewski, 2009; Succow and Joosten, 2001).

Ad. (7) Peatlands constitute archaeological archives created by the forces of nature. In the sequence of peat formations, there is a record of changes of climate and water relations, succession of plant assemblages, as well as of the conditions of human life (Crum, 1992; Ilnicki, 2002).

Threats to peatlands and problems of peatland conservation

Peatlands are highly susceptible to degradation and are among the fastest-disappearing ecosystems on Earth. The main reasons for the shrinkage of the area of peatland ecosystems are the following:

- Regulation of rivers, drainage of wetlands, and transformation of peatlands into grasslands and arable land
- Artificial afforestation of peatlands and processes of natural succession of trees and bushes onto drained peatland habitats
- Exploitation of peat deposits for use in agriculture, horticulture, balneology, and formerly also for fuel
- Climate warming and disappearance of species with cool climate preferences
- Eutrophisation of habitats and dwindling of species requiring habitats poor in biogens
- Fragmentation of landscape and of the spatial structure of peat complexes.

In view of the above, all peatlands that have still retained their natural character, or seminatural, require particular protection.

The fundamental international legal act concerning the protection of peatlands is the *Ramsar Convention on Wetlands* from 1971: <http://www.ramsar.org/cda/en/ramsar-home/main/ramsar/>. An important role in peatland protection in Europe is played also by the Council Directive 92/43/EEC on the Conservation of Natural Habitats and of Wild Fauna and Flora, from 1992 (*Habitats Directive*): http://ec.europa.eu/environment/nature/legislation/habitatsdirective/index_en.htm.

Since the 1980s, peatland restoration projects have been increasingly important in active conservation and restoration of the lost values of peatlands (Comin, 2010).

Conclusions

1. Peatlands belong to the most valuable and the most dangerous natural ecosystems in Eurasia and North America.
2. Peatlands fulfil significant functions in the natural environment: (1) they take part in water circulation and retention; (2) they are natural filters of environmental pollutants; (3) they store organic matter and carbon and thus affect global climate changes and carbon circulation; (4) they have a mollifying and stabilizing effect on the microclimate of the immediate environment; (5) they play an important role in the preservation of biodiversity; (6) they are an important characteristic element of landscape; (7) they constitute archaeological archives.
3. The fundamental international legal acts concerning the protection of peatlands are: *The Ramsar Convention on Wetlands* from 1971 and EU *Habitats Directive* from 1992.
4. Over the last 3 decades, increasing role in peatland conservation actions play wetland restoration projects.

Definition

Peat. Sedentarily accumulated material consisting of at least 30% (per dry mass) of dead organic material.

Peatland. An area with or without vegetation with a naturally accumulated peat layer at the surface.

Mire. A peatland where peat is currently being formed.

Introduction

Peat accumulation generally takes place as a result of limited decay (decomposition) of plant material. An important factor for peat accumulation is the chemical and structural composition of the organic material, which determines its “ability to decay.” However, water seems to be the most important external factor limiting decay. The ability to decay varies with species, plant part, and chemical and biochemical compounds. This means that some plant species, organs, and compounds are more inclined to accumulate peat than others. A large number of plant species occurring in mires can contribute to peat formation, such as sedges, grasses, *Sphagnum* and other mosses, and woody plants. Consequently, a wide variety of “botanical” peat types exists. Thus, botanical composition, relative amounts of the main plant species or species groups is the fundamental property for determining the nature of peat and the physical and chemical properties of the peat. Moreover, a classification of peat reflects the peat that is laid down beneath the dominant kinds of vegetation. Thus, three basic peat types are recognized – *Sphagnum*, sedge, reed, and woody peats – and various subtypes are recognized based on abundant species or species groups (Rydin and Jeglum, 2006). The great majority of present-day peatlands originated in the last 15,000 years. It is estimated that 4 million km² on Earth (some 3% of the land area) is covered with peatlands (Joosten and Clarke, 2002). Over 90% of peatlands are in the temperate and cold belt in the Northern Hemisphere (Western Siberia, Canada and Alaska, and Northern Europe). The remaining area is located in tropical and subtropical latitudes, much of it under forest (Southeast Asia, and parts of the Amazon basin) (Lappalainen, 1996).

Peatland and mire type

There are many different ways of classifying wetlands, peatlands, and mires depending on the purposes of the classification. Two major types are *bogs* (which are mainly rain-fed and nutrient-poor) and *fens* (which are mainly fed by surface or ground water and are more nutrients rich) (Joosten and Clarke, 2002). *Bogs* represent ombrotrophic peatlands with the surface above the surrounding terrain or otherwise isolated from laterally moving, mineral-rich soil waters. Although some bogs are convex in shape (raised bogs), bogs can also be quite flat or sloping, with slight rises at the margin that isolate them from incoming mineralogenous water. The peat is usually more than 40-cm deep. The main physiognomic groups are open bog and wooded bog (bog forest). There is large variation of wetness in bogs with a pattern of hummocks and hollows. *Fens* characterize minerotrophic peatlands with water table slightly below, at, or just above the surface. Usually there is slow internal drainage by seepage, but sometimes with over-surface flow. Peat depth is usually greater than 40 cm, but sometimes less (for instance adjacent to the mineral edges). Two broad types are *topogenous* (basin) fen and *soligenous* (sloping) fen. The main physiognomic groups of fen are open fen and wooded fen (with *tree cover*, or a sparse tall shrub cover, sometimes called *shrub carr*) (Rydin and Jeglum, 2006). Peat layer growth and the degree of decomposition (or humification) depend principally on its composition and on the degree of waterlogging. Peat formed in very wet conditions accumulates considerably faster, and is less decomposed, than that in drier places. The average annual growing of peat in the majority of mires amounts to scarcely more than 0.5 mm; only under extremely favorable conditions do thicknesses of over 1 mm per year occur (Joosten and Clarke, 2002).

Functions of peatlands

In peatlands, water, peat, and specific vegetation are strongly interconnected. If any one of these components is removed, the nature of the peatland is fundamentally changed. Peatlands may be naturally forested or naturally open and vegetated with mosses or sedges. Peatlands seem to be the most important carbon stores of the world, and contain about 90% water, thus acting as vast reservoirs. Peatlands are used for grazing and for growing crops, and are exploited for timber harvesting. In addition, some kinds of peat are commonly used for the preparation of organic fertilizers for agriculture, as well as for substrate and growing media for horticulture, and pomology. Peat reveals energetic features because it is extracted for fuel both for domestic and industrial use. Thus, peatlands contribute importantly to the economy of local communities. In addition, peatland ecosystems play an important function as archives, and provide suitable habitats for unique flora and fauna (Charman, 2002; Joosten and Clarke, 2002).

Decomposition degree

The solid phase of peat soils is made up of plant fibers and amorphous humus and inorganic matter such as particles of different sizes (from sand to clay), as well as amorphous substances primarily in the form of carbonates, phosphates, and hydroxides. The rate at which plant material in peatlands is decomposed (humified) depends on many factors such as acidity, temperature, moisture, oxygen supply, plant composition, and composition of peat organisms. The degree of decomposition or degree of humification of the peat is assessed by measuring its fiber or humus content. In practice, peat decomposition is determined by a field method, the von Post pressing method (von Post, 1922). The method identifies ten classes of decomposition, with H1 being undecomposed peat and H10 completely decomposed peat (Table 1). Low humification is associated with high fiber content, and vice versa. The classification system for peat commonly uses humification and fibrosity at a high level. For example, the USA uses three classes – fibric, hemic, and sapric peats. The American Society for Testing and Materials has adopted a laboratory classification of peat based on fiber content, ash content, acidity, absorbance, and botanical composition. Canada uses three similar classes designation although with differences in terminology – fibric, mesic, and humic peats. Both divisions correspond to the level of decomposition (Richardson and Brinson, 2001). The ten classes from the von Post pressing method correspond to the three Canadian classes (Table 1).

Ash content

Ash content seems to be a useful factor for characterizing peat soils. It is determined by igniting the dried peat samples in a muffle furnace at about 550°C until their weight is constant. The ash content is expressed in terms of percentage of the ignition residue with respect to the original dry matter. The amount of ash content for sedge and woody peats is considerably higher than that of *Sphagnum* peat (Table 2). However, raised bog peats are characterized by low ash content (1–5% on dry mass basis). In addition, the quantity of ash in fen peats is greater than in raised bog peat and ranges from 5% to 20%. The ash content of transitional peats may range from 3% to 15% (Szajdak, 2002).

Peat bulk and particle density

Bulk density (BD) seems to be the most frequently used index of the density of the soil formation. It is expressed in dry mass per unit volume (kg m^{-3}). It depends both on the soil mass in a unit of volume and on its specific density which, in turn, depends on the content of mineral particles in the soil. The bulk density of peat deposits varies according to the botanical composition of the plant remains and degree of decomposition of the peat. Bulk density ranges from 20 kg m^{-3} in the surface layers to $100\text{--}260 \text{ kg m}^{-3}$ in lower layers (Boelter, 1969).

Peats and Peatlands, Physical Properties, Table 1 The von Post system of humification H1–H10 (given in Agriculture Canada Expert Committee on Soil Survey, 1987). It reveals the three-part fiber content system used in Canada (Lemasters et al., 1983). It is similar, but with different terminology, used in the USA

Class of fiber content, Canada (USA)	von Post humification
Fibric = Fibric (USA) weakly decomposed, botanical readily identified, 40% or more of rubbed fiber (by volume)	H1 Undecomposed: plant structures unaltered; yields only clear, colorless water when squeezed H2 Mostly undecomposed: plant structures distinct, yields yellow-brown water, still almost clear H3 Very weakly decomposed: plant structures distinct; yields somewhat turbid, brown water; no peat substance passes between the fingers. Residue is not mushy (pasty) H4 Weakly decomposed: plant structures distinct; yields very muddy, dark, and turbid water; no peat substance passes between the fingers, and no distinct ridges after squeezing. Residue slightly mushy(pasty) H5 Moderately decomposed: plant structures clear but becoming indistinct; yields much turbid brown water, some peat (about one tenth) escapes between the fingers, and distinct ridges remain after squeezing. Residue very mushy (pasty) H6 Strongly decomposed: plant structures somewhat indistinct, but clear in the squeezed residue than in the undisturbed peat; about one third of the peat escapes between the fingers. Residue strongly mushy H7 Strongly decomposed: plant structures indistinct but recognizable; about one half of the peat escapes between the fingers H8 Almost completely decomposed: plant structures very indistinct almost unrecognizable; nearly all the peat escapes between the fingers H9 Completely decomposed: plant structures unrecognizable; all the peat escapes between the fingers
Mesic = (USA) medium decomposed, botanical origin indistinct but still recognizable, material partly altered both physically and chemically into amorphous humus, 10–40% rubbed fiber	
Humic = Sapric (USA) strongly decomposed, botanical original very indistinct, in advanced stage of decomposition, dominated by amorphous humus. Less than 10% of rubbed fiber	

Peats and Peatlands, Physical Properties, Table 2 Basic physical properties of peat soils. (Based on data from Päivänen (1973) and Szymanowski (1993))

Peat type	Degree of decomposition (von Post scale)	Ash content (% per dry mass)	Bulk density (kg m^{-3})	Porosity ($\text{m}^3 \text{m}^{-3}$)
Raised bog				
<i>Sphagnum</i>	H1–H3	2.6	61.0	0.958
<i>Sphagnum</i>	H4–H6	3.0	97.0	0.929
<i>Sphagnum</i>	H7–H10	4.2	134.0	0.898
Fen peat				
Moss	H1–H3	8.4	114.0	0.927
Moss	H4–H6	11.8	168.0	0.895
Sedge	H1–H3	10.2	115.0	0.928
Sedge	H4–H6	11.4	141.0	0.912
Sedge	H7–H10	13.7	165.0	0.898
Reed	H4–H6	11.0	126.0	0.920
Reed	H7–H10	14.3	164.0	0.900
Alder	H4–H6	14.3	145.0	0.911
Alder	H7–H10	15.1	175.0	0.893

Päivänen (1973) and Szymanowski (1993) presented some results of bulk density for peat (Table 2). In addition, Päivänen (1973) revealed a positive and approximately linear relationship with von Post humification. Moss peats are generally characterized by a smaller bulk density than fen peats, mainly due to a lower degree of decomposition and lower ash content. With increasing degree of decomposition, an increase in bulk density is often observed.

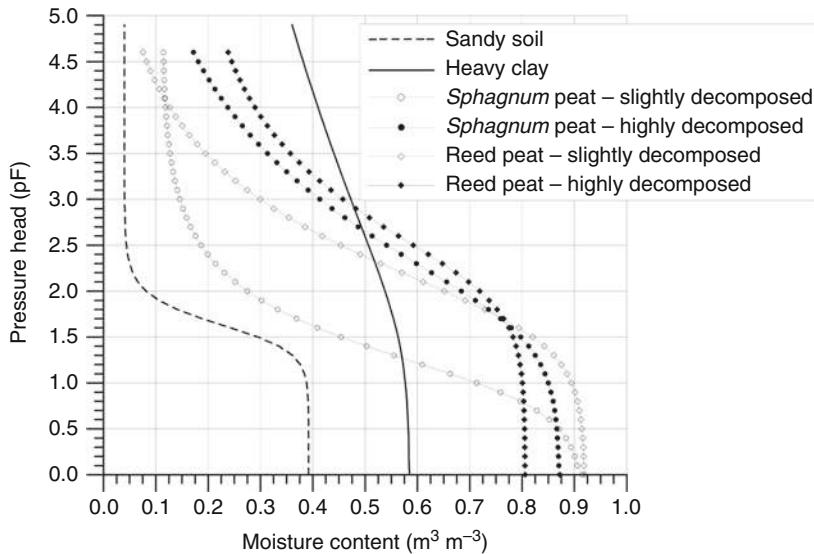

The particle density (density of solids), (SD) refers to the mass of dry solids divided by the volume of the solids. It is expressed in dry mass of solid packed matter (with no pore spaces) per unit volume. The average particle density of the organic soil mass is $1,450 \text{ kg m}^{-3}$ varying only slightly from $1,300 \text{ kg m}^{-3}$ to $1,600 \text{ kg m}^{-3}$ depending on the degree of decomposition (Okruszko, 1993). The particle density value for most mineral soils generally varies between $2,400 \text{ kg m}^{-3}$ and $2,650 \text{ kg m}^{-3}$.

Porosity

Peat is a porous material whose pores (macro- and micro-pore networks) differ in size and shape and are largely dependent on the plant residues and the degree of decomposition. Total pore space is often calculated as $\text{TP} = [1 - (\text{BD}/\text{SD})] \times 100\%$. The total porosity of peat is high, up to 96% for undecomposed, and about 90% for highly decomposed peats (Table 2). Porosity is high in fibric peats and decreases in mesic and humic peats. It seems that porosity decreases with increasing humification, bulk density, and the degree of compaction. With increasing humification and bulk density, the number of large pores decreases, but the number of small pores increases. In mineral soils, the total porosity is much lower, varying between 30% and 65%.

Moisture retention

The water retention curve of soil refers to the relationship between the soil water content and the soil water matric potential. The relationship between pressure (or matric

Peats and Peatlands, Physical Properties, Figure 1 Water retention curves for different peat and mineral soils. (Data for *Sphagnum* peat from Päivinen (1973).)

potential) and soil moisture in peat soils depends upon the degree of decomposition and the composition of the accumulated plant residues (Figure 1). The water retention capacity of peat soils is generally greater than that of mineral soils at low matric suction values. In the case of large matric suction values, too, coarse mineral soils usually retain less water than slightly decomposed *Sphagnum* peat, the water retention capacity of clay being of similar magnitude to that of moderately decomposed peat. Slightly decomposed peats contain a large quantity of water at saturation, but the water is released relatively easily with increasing matric suction.

Hydraulic conductivity

Darcy's law, an empirical relationship connecting the macroscopic velocity of water in a porous medium with the gradient of water potential down which the water flows, defines hydraulic conductivity. The hydraulic conductivity has various direct effects on the hydrology of peat and on the ecology of mire vegetation, and it varies with the degree of decomposition of the plant remains (Rycroft et al., 1975a, b). Undecomposed peats have a high hydraulic conductivity, which is of the order of 10^{-3} m s^{-1} to 10^{-5} m s^{-1} whereas highly decomposed peats have hydraulic conductivity around 10^{-8} m s^{-1} . Baden and Eggelmann (1963) found a negative hyperbolic relationship between the saturated hydraulic conductivity and the degree of decomposition of peats composed of *Sphagnum*, *Carex*, or *Phragmites* plant residues. The hydraulic conductivity of *Sphagnum* peat is usually considerably lower than that of fen peat.

Unsaturated hydraulic conductivity describes the ability of a porous medium to transmit water when the

whole cross section of the pores is not filled with water. The measured data for fen peat soils indicate the variation in unsaturated hydraulic conductivity, some of them are close to the data representing coarse soil while the others are close to the data representing very fine soil (Brandyk et al., 2003).

Peat shrinkage

The long-term intensive cultivation and agricultural use of peatlands is connected with drying. Drying of peat soils leads to soil volume decreases (Tuncer et al., 1986). Soil volume losses, usually between 53% and 70% compared with the initial peat volume (from saturation to oven-dry), vary with peat botanical composition and degree of decomposition. When peat shrinkage is larger, the greater is the degree of decomposition and the smaller is the ash content. An increased moss fraction decreases peat shrinkage. According to research performed by Ilnicki (1967), peats with a degree of decomposition over 45% show a clear tendency to cracking as a result of shrinkage induced by drying. The formation of cracks starts at volumetric moisture content of about 70% and becomes well visible at 50% volumetric water content. The intensity of cracking is proportional to an increase in the degree of the decomposition and is also dependent on peat type. Woody peats are most susceptible to cracking, followed by sedge, whereas moss peats are the least vulnerable to this process. In field soils, this shrinkage process results in the subsidence of the soil surface and in the occurrence of cracks. It is generally understood that the rate of subsidence varies strongly and depends on a number of factors, such as the type of peat, rate of decomposition, density and thickness of the peat layer, drainage depth and its duration,

climate, and land use (Ilnicki, 2003). Total subsidence due to drainage of peat soils can be subdivided into three following components:

1. "Wastage" of the peat resulting from loss of organic matter as a result of decomposition by biochemical processes
2. Shrinkage of the upper horizons as a result of water loss
3. Loss of buoyancy of the upper horizons by removal of water, which causes mechanical compression of permanently saturated peat layers below the groundwater level

Shrinkage of the upper horizons and loss of buoyancy are both a direct result of water removal from the upper horizons of the peat soil profile and depends on the amount of water stored in the profile. Subsidence rate of drained organic soils is typically found in the range of 0.3 cm year⁻¹ for grassland and 1.0–5.0 cm year⁻¹ for arable land (Ilnicki, 2003).

Summary

In peat soils, basic physical properties as well as water retention and hydraulic conductivity characteristics depend upon the degree of decomposition and the composition of the accumulated plant residues. Upon drying, most organic soils show a considerable shrinkage and hydrophobicity. The variability of peat physical properties is relatively large.

PEDON

A term used by pedology to describe structural elements block, column, granule, plate, or prism, formed by natural processes (in contrast with a clod, which is formed artificially in cultivated soils).

PEDON

A three-dimensional volume of soil with lateral dimensions large enough to permit the study of horizon shapes and relations. Its area ranges from 1 to 10 m².

PEDOTRANSFER FUNCTIONS

Definition

Pedotransfer functions. Equations or algorithms expressing relationships between soil properties different in difficulty of their measurement or their availability.

Introduction

Parameters governing the retention and movement of water and chemicals in soils are notorious for the difficulties and high labor costs involved in measuring them. Often, there is a need to resort to estimating these parameters from other, more readily available data. Following Briggs and Shantz (1912), who were the pioneers in the field, generations of researchers quantified and interpreted relationships between soil properties. Such terms as “prediction of” or “predicting” soil properties, “estimation of” or “estimating” soil properties, “correlation of” or “correlating” soil properties, were used interchangeably to name the contents, procedures, and results of these type of studies (Carter and Bentley, 1991; Rawls et al., 1991; van Genuchten and Leij, 1992; Timlin et al., 1996; McBratney et al., 2002). Relatively recently, equations expressing relationships between soil properties were proposed to be called “transfer functions” (Bouma and van Lanen, 1987) and later “pedotransfer functions” or PTFs (Bouma, 1989). Large international databases, such as UNSODA (Leij et al., 1996), HYPRES (Lilly, 1997; Wösten et al., 1999), WISE (Batjes, 1996), the NRCS pedon database (NRCS, 2007), as well as national databases such as the Soil Profiles Bank of Polish Mineral Soils (Gliński et al., 1991) were established and used for the purpose of PTF development. Recently the number of PTF applications increased significantly due to development of geographic information system based regional modeling.

Pedotransfer functions to predict soil hydraulic properties are most numerous. Such PTFs have many potential user groups in agrophysics. For example, soil water retention and hydraulic conductivity data are needed to partition precipitation into runoff and infiltration, to assess evapotranspiration, to schedule management practices, especially irrigation and chemical applications, to establish components of the heat balance, and to predict contaminant transport.

For soil water retention, one approach (using point PTFs) consists of estimating soil water contents at several soil water pressure heads using a separate predictive

equation for each pressure head. Another approach (using parametric PTFs) involves estimating coefficients in equations that express the dependence of the water content on the soil water potential. The equations that are most often used for this purpose are the Brooks–Corey equation (Brooks and Corey, 1964)

$$\frac{\theta - \theta_r}{\theta_s - \theta_r} = \left(\frac{h_b}{h} \right)^\lambda \quad (1)$$

and the van Genuchten equation (van Genuchten, 1980)

$$\frac{\theta - \theta_r}{\theta_s - \theta_r} = \frac{1}{(1 + |\alpha h|^n)^m} \quad (2)$$

where θ is the volumetric water content, θ_s is the saturated water content, θ_r is the residual water content, h is the soil water pressure head, h_b is the soil water pressure head corresponding to the soil bubbling pressure or air entry value. The parameters θ_r , h_b , and λ in Equation 1, and θ_r , α , m , and n in Equation 2 are empirical coefficients. Pedotransfer functions have been constructed to estimate these coefficients using many local and regional data sets.

For the saturated hydraulic conductivity, K_{sat} , one approach is to estimate this coefficient from basic soil parameters without employing soil water retention data (e.g., Bloemen, 1980). Another approach benefits from the use of soil pore space models to derive K_{sat} equations in which the coefficients must be estimated from basic soil properties (e.g., Han et al., 2006). Estimates of the unsaturated hydraulic conductivity are based predominantly on pore size distribution models that relate the unsaturated hydraulic conductivity to K_{sat} as well as several geometric parameters of the pore space inferred from water retention data. A general form of such a model was proposed by Alexander and Skaggs (1987):

$$k(h) = K_{sat}[S(\theta)]^\beta \left\{ \frac{\int_0^S [h(\theta)]^{-\gamma} d\theta}{\int_0^1 [h(\theta)]^{-\gamma} d\theta} \right\}^\delta \quad (3)$$

where S is effective saturation give by $S = (\theta - \theta_r)/(\theta_s - \theta_r)$, and β , γ , and δ are parameters. Pedotransfer functions must be used to estimate both K_{sat} and $h(\theta)$ in Equation 3 to evaluate the integral and calculate the unsaturated hydraulic conductivity (Pachepsky et al., 2000).

Soil erosion prediction models frequently rely upon a variety of soil pedotransfer functions that most often estimate soil erodibility and soil infiltration parameters (Flanagan, 2004). Existing long-term historical erosion plot data (e.g., the USLE database) provide sufficient information to create pedotransfer equations for soil erosion models.

Solute and gas retention and transport parameters can be predicted reasonably well also from basic soil properties, although caution should be exercised because of

possible scale effects (i.e., the effect of the scale of solute transport on solute dispersion and retardation). Unified diffusivity models can use existing PTFs to estimate solute and gas diffusivities as a function of soil water content (Minasny and Perfect, 2004). Based on current knowledge, the pore size distribution appears to be an acceptable dispersivity predictor, with water retention PTFs being helpful in developing PTFs for the dispersivity.

Soil water retention has been related to soil rheology by defining several characteristic points on the water retention curve that separate segments of the retention curve where the forces causing water retention have a distinctly different physical nature (Voronin, 1990; Shein et al., 2004). Water contents at the characteristic points in this approach are termed key water contents and are related to the soil pressure head. The key water contents can be estimated from the liquid limit, the plastic limit, and data on evaporation from soil. As soon as they are estimated, their relationships with the soil matric potential provide several points on the water retention curve.

PTF inputs

Soil water retention and the soil hydraulic conductivity are essential hydraulic properties that can be estimated using PTFs. The particle size distribution and its parameters are used in almost all pedotransfer functions. Differences in the particle size classes of various national and international classifications have to be factored in when PTFs are used. It is very important to use the correct boundaries of the sand and silt textural classes from the classification used during PTF development, rather than from a specific national classification.

Water retention PTFs generally become more accurate when some experimental information about water retention is used as the PTF input (Ahuja et al., 1985). Soil organic carbon content and composition both affect soil structure and the adsorption properties, which imply that soil bulk density, water retention, and hydraulic conductivity may be affected by soil organic carbon. The effect of soil organic carbon on the soil hydraulic properties exhibits a complex dependence on proportions of textural components and amount of organic carbon (Rawls et al., 2003).

Using soil morphological attributes and soil structure in pedotransfer functions is extremely important because of the dominant role of soil structure in soil hydrology. Unfortunately, effectively using soil morphological attributes is also very difficult because of the semiqualitative nature of soil morphology and related soil structure descriptors. It is possible to develop pedotransfer relationships to predict soil hydraulic properties and soil hydrological functioning from soil morphology data, including soil structure (Lin et al., 1999). These relationships can be expressed as either pedotransfer functions or semiqualitative pedotransfer rules. A considerable volume of soil morphological data residing in national and regional databases can be of great use in providing

information on soil hydrology. However, future progress may require the acceptance of standardized methodologies to describe and quantify soil morphological attributes, as well as to measure soil hydraulic properties in the field.

Soil aggregate composition is often assumed to be related to soil structure and as such has been expected to affect soil water retention. That has indeed been the case when the quantiles of soil aggregate size distributions have been used, instead of contents of individual aggregate fractions (Guber et al., 2003).

Soil mineralogical and chemical properties are conceptually important factors of the ability of a soil to retain and transmit water. This may be one of the reasons why a preliminary genetic grouping of soils appears to be a useful way to improve PTF performance (Pachepsky and Rawls, 1999). Much can be gained in understanding and estimating soil hydraulic properties when mineralogical and chemical data are coupled with soil physical information (Bruand, 2004). Such coupling is especially beneficial for regions where soil salinity and alkalinity constitute environmental and management problems.

PTFs in a spatial context

PTFs generally are constructed using data from small point samples, but then are most often applied to large spatial units. Results of applications will depend on basic soil data availability within those units, on soil variability within those units, on the capability of PTFs to reproduce this variability, and on our ability to modify PTFs according to the scale of the application. The spatial dependencies in PTF input may not necessarily translate correctly to spatial dependencies in the PTF output, in which case corrections of the existing PTFs are needed to reflect the spatial dependencies (Romano, 2004).

A relatively new promising direction in PTF development is the use of spatially dense physical information related to the soil cover. Soil properties are known to be related to landscape position. Since geomorphic information has long been routinely used in soil mapping, geomorphometry may be a valuable data source to predict basic soil properties. In particular, soil texture, organic matter content, and bulk density are known to reflect both landscape position and land surface shape. Because these soil properties are most often included in pedotransfer functions, one can hypothesize that soil hydraulic properties should have some relationship to landscape position and land surface shape. Overall, the reported studies and related discussions confirm the usefulness of topographic attributes as ancillary data to indirectly estimate soil hydraulic properties. Geophysical techniques, such as ground-penetrating radar, penetrometers, electric conductivity surveys, and remote sensing provide spatial coverage that shows great potential to be included in PTFs.

Methods to develop PTF

Statistical regression has been a popular tool for PTF development for many decades (e.g., Rawls et al., 1982).

An advantage of regression techniques is the possibility to obtain rigorous estimates of the statistics of the predicted values and the coefficients in the PTF equations. However, as shown by Vereecken and Herbst (2004), the blind use of statistical computer packages without a preliminary and *a posteriori* data analysis can have a deleterious effect on the regression results. Model misspecification, the presence of outliers, multicollinearity, and other drawbacks, have to be anticipated and overcome. As such, constructing PTFs using regression is an iterative procedure that may require many iteration steps.

Applying statistical regression to predict soil properties that are difficult to measure requires (a) deciding which properties are to be used as predictors and (b) which regression equation to use. Those decisions are not straightforward, especially when the databases involved contain many potential predictors and the relationships between soil properties may be different in different parts of the databases. For this reason, PTF development recently has employed data mining and exploration methods, as well as machine learning algorithms, which automate predictor and equation selections. Artificial neural networks have become a common tool for modeling complex “input–output” dependencies in pedotransfer functions because of their ability to mimic the behavior of complex systems (Pachepsky et al., 1996; Schaap and Bouten, 1996).

While being powerful approximators, artificial neural networks often lack a built-in methodology to remove the less or least important input variables. PTF development for this reason benefits from methods that do not assume a certain type of dependency, while still being able to eliminate some predictors. The most important predictors may also be different in different parts of the database. The database then has to be quite large to permit the use of artificial neural networks. A data exploratory technique aimed at uncovering some structure in the data can be useful in such cases. Regression tree modeling (e.g., Rawls and Pachepsky, 2002) is such a technique that gives transparent results and can be applied not only to numerical but also to categorical soil data. Another drawback of using neural networks may be the inability of finding the best approximation for the entire database. Using support vector machines in PTF development may provide a good solution (Lamorski et al., 2008).

PTF development presumes that similarity in input will result in similarity in output. For large enough databases, one can find soils with properties that are very close to the soil for which the pedotransfer prediction is needed. In such case, finding the closest neighbors and using their hydraulic properties as the required PTF predictions has been shown beneficial (Nemes et al., 2006).

PTFs have also been developed based on the additivity hypothesis that the property of interest (e.g., water retention) is known for certain soil components (e.g., certain particles size ranges), and that this property then can be estimated for the entire soil by adding component values with appropriate weights (Zeliguier et al., 2000).

PTF evaluation and selection

Evaluation of PTFs is an essential element of their development and use. Pachepsky et al. (1999) broadly defined the accuracy of a PTF as the degree of correspondence between measured and estimated data for the data set *from which the PTF was developed*. The reliability of a PTF was assessed in terms of the correspondence between measured and estimated data for the data set(s) *other than the one used to develop the PTF*. Finally, the utility of a PTF in modeling was viewed as the degree of correspondence between *measured and simulated environmental variables*.

The concept of PTF uncertainty (Schaap and Leij, 1998) encompasses the ambiguity in PTF predictions and parameters caused by input data variability and uneven representation of soils with different properties in the database. The uncertainty in PTF estimates may be evaluated using replicated PTF development with data resampling by either the bootstrap (Schaap et al., 1998) or jackknife (Pachepsky and Rawls, 1999) methods.

The reliability of a PTF is not directly related to its utility (Pachepsky et al., 1999). The latter is affected by the sensitivity of the model to PTF predictions, and also by the uncertainty in other model inputs (Leenhardt, 1995). The functional evaluation of PTFs considers the evaluation of PTFs on the base of their utility and uses criteria directly related to specific applications rather than statistics to characterize the accuracy. PTF accuracy may be not an issue since at least four factors affect the performance of a PTF in simulations. These are the accuracy of basic soil data used as inputs in the PTFs, the accuracy of the PTF itself, specific features of the simulation model, and the output used in the functional criteria (Wösten and van Genuchten, 1988).

Database size and measurement method are among the more important factors affecting PTF accuracy and reliability. The number of samples has to be large enough to develop PTFs that are both accurate and reliable. When the reliability of USA-wide PTFs was compared with the accuracy of those based on several smaller databases, and the PTFs were ranked by their reliability, the all-USA PTFs usually had one of the highest rankings (Tietje and Tapkenhinrichs, 1993; Kern, 1995). However, PTFs based on local information appear to be more accurate in the area where the data were collected.

There are indications that PTFs developed from regional databases give good results in regions with similar soil and landscape histories. For example, water retention PTFs developed in Belgium (Vereecken et al., 1989) were the most accurate as compared with 13 PTFs based on a database of Northern Germany (Tietje and Tapkenhinrichs, 1993). Water retention PTFs developed for the Hungarian Plain (Pachepsky et al., 1992) were applicable to the Caucasian Piedmont Plain (Nikolaeva et al., 1988). The development of PTF equations adapted for the conditions of Brazilian weathered soils allowed much better estimates of the parameters in [Equation 2](#), as

compared to the performance of PTFs derived for soils from temperate climates (Tomasella et al., 2000). It remains to be seen whether this observation holds for other cases, and which soil and landscape features have to be similar in two regions to assure the mutual reliability of the PTFs developed.

The use of models depends on the easiness to operate them, and PTFs are no exception. A PTF user has to be able to make an informed choice of the PTF, and to have a convenient tool to apply the PTF technology. One example of creating a multipurpose PTF tool is the soil inference system (McBratney et al., 2002). Also, software packages like Rosetta (Schaap et al., 2001) and k-Nearest (Nemes et al., 2008) provide graphic user interfaces that substantially simplify PTF use and the interpretation of results.

Since pedotransfer functions are empirical regression-type relationships, their accuracy outside of their development region is essentially unknown. Instead of attempting to find a single best PTF, Guber et al. (2009) proposed the use of multimodeling. The approach involves assigning weights to the simulation results obtained with different PTFs and then using the weighted average of these results. Improvements in the predictions have been attributed to the fact that multimodeling provides better coverage of possible variations in PTF inputs.

Limits of PTF accuracy

The accuracy and reliability of a PTF is sometimes limited by temporal variations in soil properties caused by changes in vegetation and soil management. Incorporation of organic matter, soil erosion, and tillage practices can cause variations in hydraulic properties that are comparable with variations within regional databases (Wösten et al., 2001). The PTFs may require a temporal component and vegetation parameters to improve their reliability (Sharma et al., 2006). Differences in measurement techniques for the samples in the same database will definitely affect PTF performance. Future PTF improvements will strongly depend on advances in characterization of fine-scale soil physical and chemical heterogeneities that controls flow and transport in soils at PTF application scales.

Conclusions

The history and the current status of PTF development demonstrate the need in and value of integrative studies. Systematic coupling measurements of various soil properties add value to all of those measurements as pedotransfer relationships can be derived for a variety of agrophysical applications. PTF development contributes to understanding of soil functioning and enhances the role of soil information in multiple applications. PTFs hence are essential tools to translate data that we have to date we need in agrophysical research and management applications.

PHYSICAL DEGRADATION OF SOILS, RISKS AND THREATS

Winfried E. H. Blum

Institute of Soil Research, University of Natural Resources and Applied Life Sciences (BOKU) Vienna, Vienna, Austria

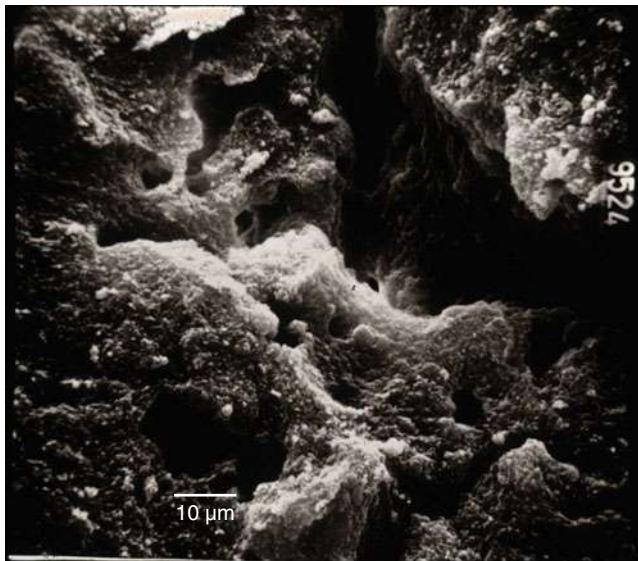

Definition

Physical soil degradation is one of the eight main risks and threats defined by the European Thematic Strategy for Soil Protection (COM(2002)179 final).

Physical degradation comprises very different processes and morphometric forms, mainly through the deformation of the inner soil structure by compaction, caused by tracking with heavy agricultural machinery, through vertical sheer stress caused by rotating parts of machines, e.g., wheels, as well as by chemical impacts such as salinization, especially alkalinization. Physical degradation also includes soil erosion by water and wind as well as the formation of crusts at the soil surface (soil crusting).

Physical degradation

The deformation of the inner soil structure, which comprises large ($>50 \mu\text{m}$ diameter) and small macropores ($50\text{--}10 \mu\text{m}$ diameter), medium pores ($10\text{--}0.2 \mu\text{m}$ diameter), and fine pores ($<0.2 \mu\text{m}$ diameter) (see Figure 1), occurs by heavy soil loading and results especially in the loss of soil macropores $>50 \mu\text{m}$ diameter or even smaller macropores $>10 \mu\text{m}$ diameter, under extreme conditions.

Physical Degradation of Soils, Risks and Threats,
Figure 1 Look into a soil by electronic microscopy (observe scale of $10 \mu\text{m}$), showing different types of pores, which are all interconnected (Blum, 2002).

Macropores are responsible for soil aeration and water conductivity and are also the living space of soil organisms, especially those which are not able to create own spaces in soil, like many earthworms. Therefore, the destruction of macropores, seldom medium pores ($10\text{--}0.2 \mu\text{m}$ diameter), means low water (rainwater) conductivity, causing stagnant water phases in soils, with anaerobic conditions changing soil chemistry as well as soil biology. Under specific topographical conditions, compaction also causes soil erosion by water surface flow. Sheer stress causes similar results, although less compacting, but smearing and closing or blinding pores, especially in the top soil, between 0 and 20 cm soil depth. A special form of sheer stress combined with loading and compaction is the formation of the so-called plough horizons, a compacted zone below the ploughed top soil with problems for root penetration and often changes in redox potential through decreased water infiltration, causing stagnant water conditions after intensive rainfall.

Compaction at soil depths $>50 \text{ cm}$ are nearly irreversible, because no technical measures are available to restore soil macroporosity, except biological processes, e.g., through earthworm activities, which is normally a very slow process and depends on further edafic conditions.

Moreover, physical soil degradation occurs also at the soil surface through the destruction of crumbly or blocky soil structures, mainly through the physical impact of rainwater, especially raindrops with high kinetic energy, called splash, destructing surface soil structures, causing smaller soil particles, which can be transported by water or wind (erosion) or may form crusts at the soil surface, especially under semiarid and arid climatic conditions. The physical degradation through splash by raindrops with high kinetic energy depends on the size of the raindrops, the wind velocity, and the type and stability of surface soil structures. Structure stability is highly influenced by soil organic matter. Through loss of soil organic matter in top soils, soil structures become unstable and therefore prone to erosion, especially crumbs or small blocks at the soil surface. Soils with a high silt content are most endangered by wind and water erosion. Soil erosion causes losses of the most fertile part of the soil, additionally decreasing soil fertility through a decrease of the rooting depth and consequently of the availability of water and nutrients for plant growth.

In climatic regions with long-lasting dry periods, fine soil particles produced by rain splash at the soil surface can form crusts, which are in most cases very resistant against deformation by water and wind, also because of fungal growth compacting these surfaces, additionally. Crusting occurs very often in soils under a mediterranean type of climate or in semiarid or semi-humid areas of the tropics and subtropics.

Conclusions

Physical soil degradation has negative impacts on nearly all soil characteristics and processes, e.g., space for plant

roots and soil biota, soil temperature, transport of water, air, and nutrients as well as natural attenuation of organic and inorganic contaminants.

 Lublin University of Technology, Lublin, Poland

Definition

A unit and a number are factors expressing the value of a physical quantity.

Dimensions of a physical quantity are the powers to which the base units of a measurement system are raised to get one unit of the physical quantity.

Introduction

Real world should be described in terms of its biophysical and qualitative attributes, which are physical quantities. Agricultural objects and processes are interdisciplinary

and they deal with nearly all physical, chemical, and biological aspects of real world. Therefore dimensions' and units' use in agriculture includes the respective physical quantities.

The majority of physical quantities that we actually deal with in science and also in our daily life can be expressed in terms of one or more base units.

International system of units (SI)

The most popular and scientifically recognized system of units is the International System of Units, known as the SI (from the French *Système International d'Unités*). Use of SI is recommended by most scientific journals and in many it is now mandatory. Multiples and submultiples of units should be chosen to minimize the repetition of zeros before or after the decimal point. Several units related to SI (e.g., tonne and hectare) are convenient in speech as well as in writing but should be avoided in analysis to minimize the risk of numerical errors.

The fundamental part of the units in the system is called a set of base units describing base quantities and the other units describing remaining quantities are called derived units.

There are seven base quantities used in the SI system: length, mass, time, electric current, temperature, amount of substance, and luminous intensity. The base quantities are independent by definition. The corresponding base units are: the meter, the kilogram, the second, the ampere, the kelvin, the mole, and the candela. The definition of each base unit (The International System of Units (SI), 2006) of the SI is carefully drawn up so that it is unique and provides a sound theoretical basis upon which the most accurate and reproducible measurements can be made. The realization of the definition of a unit is the procedure by which the definition may be used to establish the value and associated uncertainty of a quantity of the same kind as the unit.

All derived quantities may be written in terms of base quantities by the equations of physics.

Table 1 presents base quantities and their corresponding symbols, symbols for dimension, units, and symbols for the

Physical Dimensions and Units Use in Agriculture, Table 1
 Base quantities and dimensions used in the SI

Base quantity	Symbol for quantity	Symbol for dimension	Base unit	Symbol for base unit
Length	l, x, r	L	Meter	m
Mass	m	M	Kilogram	kg
Time, duration	t	T	Second	s
Electric current	I, i	I,	Ampere	A
Temperature	T	Θ	Kelvin	K
Amount of substance	n	N	Mole	M
Luminous intensity	I_v	J	Candela	cd

Aquametry	Soil				

units' dimension of any quantity, which is written using the SI system of units.

Traditional and popular units used in various parts of the world make some confusion and misunderstanding for others who are accustomed to other units. Conversion factors between most common units used in agrophysics is available in NIST Special Publication 1038 (Butcher et al., 2006).

Any derived physical quantity Q can then be dimensionally expressed as

$$[Q] = L^\alpha M^\beta T^\gamma I^\delta \Theta^\varepsilon N^\zeta J^\eta$$

where the exponents $\alpha, \beta, \gamma, \delta, \varepsilon, \zeta$, and η , which are generally small integers can be positive, negative, or zero, are called the dimensional exponents. The notation $[Q]$ means "the dimension of Q ."

The SI system adopted a series of prefix names and prefix symbols of the decimal multiples and submultiples of SI units ranging from 10^{12} to 10^{-12} . With the exception of da (deca), h (hecto), and k (kilo), all multiple prefix symbols are uppercase letters (e.g., 1 dag = 10 g, 1 hPa = 100 Pa, 1 km = 10^3 m, 1 Mg = 10^6 g, 1 GHz = 10^9 Hz), and all submultiple prefix symbols are lowercase letters (e.g., 1 mm = 10^{-3} m, 1 ps = 10^{-12} s). All prefix names are printed in lowercase letters, except at the beginning of a sentence. Compound prefix symbols as well as compound prefix names are not permitted, for example, nm (nanometer) is correct but not μm (millimicrometer).

Selected SI base and derived quantities, units, and dimensions used in agriculture

Agriculture, like other applied sciences, prefers specific quantities as well as corresponding units and dimensions, the selection of which is presented in Table 2 (American Society of Agronomy et al., 1988; Scott, 2000).

The examples for conversion of generally accepted units to SI base units are:

- Water potential: $J \cdot m^{-3} = (N \cdot m) \cdot m^{-3} = (kg \cdot m \cdot s^{-2} \cdot m) \cdot m^{-3} = kg \cdot m^{-1} \cdot s^{-2}$
- Thermal conductivity: $W \cdot m^{-1} \cdot K^{-1} = (J \cdot s^{-1}) \cdot m^{-1} \cdot K^{-1} = (N \cdot m \cdot s^{-1}) \cdot m^{-1} \cdot K^{-1} = (kg \cdot m \cdot s^{-2} \cdot m \cdot s^{-1}) \cdot m^{-1} \cdot K^{-1} = kg \cdot m \cdot s^{-3} \cdot K^{-1}$

Summary

The parallel use of traditional as well as formally acknowledged units is commonly applied by scientists representing agrophysics. As the interdisciplinary science agrophysics is particularly prone to the influences coming from other branches of science. To avoid ambiguity in presenting qualitative data it is advised to use International System of Units (SI).

PHYSICAL PHENOMENA AND PROPERTIES IMPORTANT FOR STORAGE OF AGRICULTURAL PRODUCTS

Marek Molenda, Józef Horabik

Institute of Agrophysics, Polish Academy of Sciences,
Lublin, Poland

Definition

Main tasks during the storage are to protect products against undesirable changes, to improve their *quality*, and to preserve their nutritional value. Physical phenomena that may be observed by instrumental methods serve as indices of state of material and parameters used in the design of equipment and in process control.

Introduction

Progress in science initiated in the beginning of the twentieth century resulted in a substantial development in communication and information technologies in the second part of that period. These were followed by harsh global competition in economy also in storage and processing of agricultural products.

A large group of materials may be regarded as agricultural products, which may include plant materials, animal materials, and materials used in the agricultural production such as chemicals or mineral fertilizers. In this article, only products of plant origin will be covered.

Physical phenomena occurring during the storage of agricultural products may be a direct cause of damage, but on the other hand create environment for chemical and biological processes and as such may intensify or moderate their pace. Optimization of storage of agricultural products involve large spectrum of actions. This includes elaboration of new methods of preservation and treatment in order to maintain structure, firmness, color, taste, and aroma, and elimination of diseases and pesticide

residues: all to meet the demands of increasingly sophisticated markets. Storage loss may be considered in terms of either quantity or *quality*. Quantitative loss is a physical loss of substance as shown by a reduction in weight or volume. It is the form of loss that can most readily be measured and valued. Qualitative loss is more difficult to assess and is perhaps best estimated through comparison with standards. Nutritional loss and loss of seed are both aspects of *quality* losses.

Physical phenomena having the strongest influence on conditions of storage of agricultural plant products or those that may be used in process control are mechanical, acoustic, electrical, optical, and thermal. Mechanical are those associated with equilibrium or motion of objects, deformation or damage of products. Acoustic phenomena are those involving propagation of mechanical waves such as sounds, infra sounds, or ultra sounds. Electrical phenomena that may be observed in macroscale are manifestations of interactions between electrical fields on the atomic scale. Optical phenomena are those involving light, manifest themselves as visual appearance of objects, important factor in consumer preference. Thermal phenomena are those associated with addition or removal of energy from materials or maintaining temperature at a given level. Physical phenomena are usually described using relationships between independent and dependent variables presented in the form of equations involving factors called physical properties or, in the case of engineering applications, material parameters. Design and process control require values of those properties that may be taken from catalogs or have to be determined for specific application in laboratory tests. In the last case, standard method of determination of the property should be applied to ensure obtaining close value of the results in various laboratories.

Thus, *physical properties* are factors necessary to describe physical phenomena as relationships between variables. In this article, physical properties will be covered that are currently most frequently used in technological operations that are performed during the storage and handling of plant agricultural materials. Majority of definitions will be given after Mohsenin (1970), whose work even after 40 years remain very frequently cited reference for physical properties of agro-food materials and methods of their determination.

Physical characteristics used for the description of visual appearance of agro-food products

Such characteristics as shape, size, volume, density, or surface area are widely used for the characterization of agricultural products for trade as well as material parameters for design and process control. Some of those characteristics determine visual appearance of the product, which is an important factor for consumer's purchasing decision. Shape and color are considered main *quality* indicators of fruits.

Shape and size

Seeds, grains, fruits, and vegetables are irregular in shape and the measurement of several mutually perpendicular axes is necessary to approximately describe their shape. It may be determined precisely using specific measurements and/or mathematical relationships. For verbal description of shape, it may be described subjectively and compared with charted standards. Extreme variations in shape that may influence purchasing decisions are usually discarded during harvest or packing.

Size of individual units of product may influence consumer appeal, handling practices, storage potential, market selection, and final use. Size may be determined by one of the three methods: dimension (length, width, diameter, or circumference), weight, or volume. The most desired shape and size depend on the product, on its application, and on the preferences of specific market. Probably, very large potatoes will be used for starch production rather than for fresh market sales.

Volume and density

Volume and density of agro-food products play an important role in applications such as design of silos, *drying*, mechanical compaction, stability of pellets and wafers, separation and grading, evaluation of maturity, or *quality* evaluation. The irregular shape of most of the agricultural products, the small size of numerous materials (such as grains or seeds), and the porous nature of others (such as straw or grain in bulk) pose some difficulties in volume and density measurement. Because of the irregular shape of the product, volume is usually determined by liquid displacement and most frequently water is used.

Porosity

For applications involving flow of gases through porous material such as *aeration*, *drying*, cooling, or fumigation, the percent of voids in the material is crucial factor. For porous materials of high moisture content gas pycnometer method may be used as proposed by Sereno et al. (2007). The volume is obtained by measuring the change in pressure experienced by an amount of compressed gas filling a constant volume reference chamber when it expands into a second chamber containing a sample of the material to be tested. From such pressure change and the knowledge of the volumes of the two chambers, the volume of the sample solid matrix is determined. The gas pycnometer proposed by those authors offers reliable results of particle volume for any type of solids, specifically foods and other materials with high moisture content.

Surface area

Surface area is an important technological parameter considering both plant material parts (as leaf or fruit) and porous substances. Leaf area is an indicator of photosynthetic capacity and growth rate of a plant. Surface area of fruits is important in the determination of spray coverage,

respiration rate, light reflectance, color evaluation, or heat transfer in cooling or heating.

The surface area determines numerous processes in porous media such as dissolution of powders, moisture transport, or intensity of fumigation. The true surface area of porous material, including surface irregularities and pore interiors, may be determined at the atomic level by the adsorption of an unreactive or inert gas. The amount adsorbed is a function not only of the total amount of exposed surface, but also of (1) temperature, (2) gas pressure, and (3) the strength of interaction between gas and solid.

Mechanical properties

Strength, hardness, toughness, elasticity, plasticity, brittleness, and ductility are the mechanical properties used to measure the behavior of material under a load. These properties are described in terms of the types of load (force or stress) that the material must withstand without damage or loss of *quality*. Common types of stress are compression, tension, shear, torsion, impact, or a combination of these.

Compression stresses develop within a material when forces compress or crush the material. Grain column in a silo that acts on layers close to floor generate compression, and the internal stresses that develop within the lower layers are compression.

Tension (or tensile) stresses develop when a material is subject to a pulling load; for example, when using a rope to lift a load or a chain to transfer movement. Tensile strength is defined as resistance to longitudinal stress or pull and can be measured in Newtons per square meter of cross-section. Shearing stresses occur within a material when external forces are applied along parallel lines in opposite directions. Shearing forces can separate material by sliding part of it in one direction and the rest in the opposite direction.

Some materials are equally strong in compression, tension, and shear. Strength of biomaterials differs not only dependently on the type of load, but also on the load direction – this feature is called *anisotropy*. Describing of maximum strength, the type of loading and load direction should be always stated.

Strength

Strength is the property that enables a material to resist deformation under a load. The ultimate strength is the maximum strain a material can withstand. Tensile strength is a measurement of the resistance to being pulled apart when placed in a tension load.

Impact strength is the ability of a material to resist suddenly applied loads and is measured in kJ m^{-2} .

Hardness

Hardness is the property of a material to resist permanent indentation. Because there are several methods of

measuring hardness, the hardness of a material is always specified in terms of the particular test that was used to measure this property. Rockwell, Vickers, and Brinell are some of the methods of testing. Of these tests, Rockwell is the one most frequently used. The basic principle used in the Rockwell test is that a hard material can penetrate a softer one. We then measure the amount of penetration and compare it to a scale. For ferrous metals, which are usually harder than nonferrous metals, a diamond tip is used and the hardness is indicated by a Rockwell "C" number. On nonferrous metals, that are softer, a metal ball is used and the hardness is indicated by a Rockwell "B" number. To get an idea of the property of hardness, compare lead and steel. Lead can be scratched with a pointed wooden stick but steel cannot because it is harder than lead. For elastomers and rubbers, Shore method is used that better suits relatively soft biomaterials. Shore in 1920s developed a measurement device called durometer and currently 12 scales are used depending on the characterized material.

Toughness

Toughness is the property that enables a material to withstand shock and to be deformed without rupturing. Toughness may be considered as a combination of strength and plasticity and may be measured as the work done in making a unit surface of crack within it. In the case of biological materials, devices are used with scissors or with a wedge.

Elasticity

When a material has a load applied to it, the load causes the material to deform. Elasticity is the ability of a material to return to its original shape after the load is removed. Theoretically, the elastic limit of a material is the limit to which a material can be loaded and still recover its original shape after the load is removed. Since the modulus of elasticity is determined from the ratio of stress to corresponding strain in an elastic range of deformation knowing the upper limit of elastic range is essential. The interpretation of force–deformation curve must follow recommendation of one of established standards.

Plasticity

Plasticity is the ability of a material to deform permanently without breaking or rupturing. This property is the opposite of elasticity. In processing of agricultural materials, irreversible deformation is used to give shape feasible for transport and storage of products such as butter, cheese, or bakery doughs. To characterize plasticity yield, stress is used that may be measured by penetrometer or extrusion tests.

Brittleness

Brittleness is the opposite of the property of plasticity. A brittle material is one that breaks or shatters at relatively

low deformation. In the case of metals, temperature acts as a factor changing its properties from elastic solid, through plastic solid to viscous liquid in melted material. Some biological materials, particularly those containing high amount of starch similarly react to water content. Dry grain is brittle, while wet grain reveals plastic behavior.

The state of the art in predicting the mechanical and rheological properties is not developed to the same degree as it is in the case of thermal properties due to the much greater influence of the structure of the product on its mechanical properties.

Information of mechanical properties of agricultural materials is necessary for the design of optimum processes and equipment. Search of such information for the design of hemp conditioner and harvester was reported by Chen et al. (2004). Field operation for hemp harvesting includes swathing with a traditional windrower or a haybine harvester, and baling the windrows. The bales are stored for later processing for fibers. The authors conducted experiments to estimate mechanical properties of hemp by cutting stems using a sickle knife section and a countershear. The shear strength and resistance to penetration were found significantly affected by the interactions of stem moisture content and blade type. When cutting low moisture hemp, a serrated blade should be used, while a smooth blade edge may be chosen to cut higher moisture hemp.

Acoustic, ultrasound, and vibration

Acoustics is an interdisciplinary science that deals with the study of sound, ultrasound, and infrasound – all mechanical waves in solids, liquids, and gases. One of longtime used acoustic methods is ultrasonic inspection. This nondestructive test method employs high-frequency mechanical vibration energy to detect and locate structural discontinuities or differences and to measure the thickness of materials. Radiation frequency is of the order 0.1–25 MHz. The beam travels unimpeded through large objects, may be angled for testing layered stocks, and can impact materials immersed in liquids. Access is required to only one side of the material being tested. This nondestructive testing (NDT) method can detect microstructural alterations, such as microcracks, foreign particles, precipitates, grain boundaries, or interphase boundaries.

In recent decades, acoustic methods became extensively used to determine mechanical properties of agro-food materials. Ultrasonic velocity was used to evaluate textural properties of meat products, as well as to examine liquids and starch-based materials. Measurement of ultrasonic wave velocity and attenuation was used to monitor internal changes during ripening of avocado fruit, to determine firmness of muskmelons, or to investigate density and porosity of plant granular materials. Acoustics was employed to monitor development of fissures in rice, to

detect pistachio nuts with closed shells, or to determine hardness of wheat kernels.

Ultrasound pulse echo method has been used for the inspection of integrity of food packages. The technique was able to spot defects less than 10 µm and might distinguish what is in the channel of a defect – air, water, or strands of a protein. For certain applications, ultrasound process outperforms other nondestructive imaging techniques, such as machine vision, X-ray, infrared, or magnetic resonance.

Electric properties

Electric properties in practical use are essentially the dielectric permittivity and loss of the material (Nesvadba et al., 2004). Permittivity is related to material ability to transmit electrical field. In SI units, it is measured in farads per meter. It is not constant, but depends on location in the material, frequency of applied electrical field, moisture content of the material, and other parameters. Permittivity of considered material is usually related to the permittivity of vacuum and termed relative permittivity. Response of the vacuum does not depend on the frequency of the field, while response of regular materials does. Material polarization involved in response does not take place instantaneously to an applied field, but with certain delay that may be characterized through phase difference. Thus, permittivity is frequently treated as complex function since complex numbers allow for specification of magnitude and phase. Complex permittivity is naturally separated into real and imaginary parts:

$$\epsilon(\omega) = \epsilon'(\omega) + i\epsilon''(\omega) \quad (1)$$

where ω is angular frequency. Often the loss tangent, $\tan \delta = \epsilon''/\epsilon'$, or dissipation factor, as a descriptive dielectric parameter. Usually (as, e.g., Nelson, 1999) ϵ'' is interpreted to include energy losses in the dielectric due to all operating dielectric relaxation mechanisms and ionic conduction. The principal needs for information on the *dielectric properties of agricultural products* have been their use in explaining the behavior of the materials when exposed to dielectric or microwave heating and their use for rapid sensing.

Some other electrical properties, such as electrical resistance, resistivity, impedance, and conductivity of fruits and vegetables also have been investigated. Usually, the objective of these investigations was to establish relationships between electrical property and some *quality* factor of the product.

Measurement of dielectric properties may be used for the determination of moisture content of seeds, grain kernels, nuts, etc. Kraszewski and Nelson (1992) used microwave resonant cavities for making size independent moisture determination individual seeds, grain kernels of arbitrary shape and for simultaneous determination of both mass and moisture content in kernels of uniform shape. Resonant cavity is a dielectric region completely

surrounded by a conducting surface. In a proper configuration of hollow resonant cavity, standing wave pattern may be formed and may persist if energy is supplied to offset losses in the cavity. When a small dielectric sample object is placed in the cavity, the change in the resonant angular frequency takes place. Because the permittivity of practical materials is complex, the resonant angular frequency should be considered complex as well. The authors measured simultaneously the change in complex characteristic of the cavity reflected in two factors: frequency shift ΔF and the cavity transmission factor ΔT . In the case of spherically shaped seeds, the ratio $\Delta F/\Delta T$ was found to provide accurate moisture determination independent of seed size. Moisture content of objects of varying shape and size could also be determined accurately, but measurements of ΔF and ΔT at two perpendicular orientations were required. Both moisture content and mass of objects of uniform shape, such as peanut kernel, could be determined by a single measurement of ΔF and ΔT when the kernels were presented in uniform orientation with respect to the electric field vector in the cavity.

Optical properties

Some optical properties discernible by human sight are used since long time to distinguish between varieties or commercial types of products. For *quality* evaluation by consumer color, gloss and translucency are the most important engineering properties (Barbosa-Canovas et al., 2004).

Color is a general term applied to the reaction of human sight to visible range of electromagnetic radiation of frequency from 3.45×10^{14} to 7.5×10^{14} Hz, and is related to visual appearance of agro-food products (such as shape, size, surface, and flesh structure, and defects). It is essentially a beam of light composed of irregularly distributed energy emitted at different wavelengths. Depending on the type of illumination, the same materials can show different appearance.

Gloss is the name given to light reflected from a plain smooth surface. It can be characterized by a goniophotometric curve, which represents intensity of light reflected at the surface at different angles of incidence and viewing.

Translucency of agro-food products is defined using an opaque-to-translucent scale. This sensation reflects a degree of scatter of light inside the material. Many products (such as cloudy fruit juices) are neither fully opaque nor fully transparent, but are translucent. Measurements of color are very important for food manufacturer in order to achieve uniformity and consistency of color of the product. Several device independent systems of color analysis have been created but nearly universally accepted is CIE standard published in 1931, the first system for scientifically defining light colors. This standard uses a tristimulus model CIE XYZ in which each perceivable color is specified as a triplet of numbers. The CIE X, Y, and Z values

correspond to reactions of three types of color-sensing human retina cells, and are normally defined between 0% and 100%. The human eye photoreceptors have three sensitivity peaks in short (420–440 nm), medium (530–540 nm), and long (560–580 nm) wavelengths. Thus, three parameters describe color sensation. The tristimulus values of a color are amounts of three primary colors in the three-component additive color model needed to match the test color. The CIE has defined a set of three color matching functions, called $x(\lambda)$, $y(\lambda)$, and $z(\lambda)$. The tabulated numerical values of these functions are known collectively as the CIE standard observer.

Physicists search for objective and instrumental methods of description of human eye sensations or engineering properties through physical properties of materials. Optical properties can be represented by absorption or reflection spectra. For instrumental evaluation, not only visible but also infrared and ultraviolet ranges of electromagnetic radiation are used for measuring *quality* of products (Nesvadba et al., 2004). Instruments called spectrophotometers are used to measure light intensity as a function of wavelength (corresponding to color). Probably the most popular application of spectrophotometers is measurement of light absorption, but they may be used to measure light reflectance as well.

One of popular applications of optical techniques is estimation of state of maturation of fruits. Bodria et al. (2004) used optical techniques to assess the chlorophyll content in red-pigmented apples and peaches to estimate ripeness and to optimize harvesting and postharvest management. Application of dual-band reflectance probe was found promising, particularly because this system was simple, handheld, and relatively low cost. The R/IR index, defined as the ratio of the signals measured at 675–800 nm, was found to be accurate in estimating the chlorophyll content of apple and peach fruit. Moreover, the R/IR index monitored the postharvest ripening of fresh peaches, showing different evolution patterns for fruits harvested at different dates.

Thermal properties

Temperature and availability of light, water, and oxygen decide about the rate of respiration (enzymatic processes) in plant material. Moisture content of the product itself, as well as the humidity of surrounding air are very important for safe storage. Fruits during storage mature and age and these processes are dependent on the ambient temperature. Increase or decrease in the temperature may be used for the control of the rate of respiration, that is, enzymatic processes. The rate of chemical reactions in fruits generally doubles for every 10°C increase in the temperature. Changes in fruits during ripening include intensification of color and aroma, softening and manifestations of activity of harmful microorganisms.

Very common technique to prolong the shelf life of the product is storage under refrigeration or freezing, in which

case a decrease in the temperature of the product is brought about. There are three modes of heat transfer (Rha, 1975): conduction, convection, and radiation, each of which requires its own set of parameters to be described. Conduction is the prevalent mechanism of heat transfer, when product is placed in direct contact with a solid heating or cooling medium. Convection is macroscopic movement of fluid. Radiation is heat transmission between phases, and it depends on the temperature of radiating body.

In conduction, heat transfer is summarized in *thermal conductivity K* that is defined by Fourier equation:

$$q = -KA \frac{\partial T}{\partial x} \quad (2)$$

where q is conductive rate of heat transfer, A is the area for heat transfer, T is temperature, and x is the length.

In convection, heat transfer is accomplished by actual physical movement of heating medium, which is usually fluid. The equation that expresses the convective heat transfer is as follows:

$$q = h_c A (T_s - T_\infty) \quad (3)$$

where q is convective rate of heat transfer, h_c is coefficient of convective heat transfer, A is area for heat transfer, T_s is surface temperature, and T_∞ is temperature of heating medium.

In radiation, heat transfer electromagnetic waves travel along straight-line path at the speed of light. When radiation energy strikes a body it is partially absorbed, partially reflected. The heat transferred by radiation from body 1 to body 2 is the difference between the energy emitted by body 1 and body 2:

$$q_{1-2} = A\sigma f(e_1 T_1^4 - e_2 T_2^4) \quad (4)$$

where q_1 and q_2 are heat fluxes, T is absolute temperature, e_1 and e_2 are emissivities, A is area for heat transfer, and σ is Stefan–Boltzmann constant $= 5.670400 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$.

Heat transfer by the three described modes depend on physical properties of the heating medium such as thermal conductivity, heat capacity, density, viscosity, coefficient of thermal expansion, emissivity, and absorptivity. Once the heat is transferred to the material, the change of its temperature depends on the properties of the material, specific heat and density, viscosity and thermal expansion, as well as on its thermal conductivity and enthalpy of phase change. Thermal properties are important for modeling processes (drying, heating, freezing, etc.), design of storage and processing equipment, calculating energy demand, etc. Important thermal properties are specific heat C_p , thermal conductivity K , and thermal diffusivity D .

Specific heat ($\text{J kg}^{-1} \text{ K}^{-1}$) determines the quantity of heat to be supplied or removed in order to bring the food material to the desired temperature.

Thermal conductivity ($\text{Wm}^{-1} \text{ K}^{-1}$) is the property of a material that indicates ability to conduct heat. Most of

fresh plant products contain a large percent of water and thermal conductivity of water may be used as a very rough approximation of the thermal conductivity of the material.

Thermal diffusivity ($\text{mm}^2 \text{ s}^{-1}$) defines a rate at which heat diffuses by conduction through a material. It is represented by the rate at which temperature changes in a certain volume of material, while transient heat is conducted through it in a certain direction in or out of the material.

In determining the thermal properties, usually the known quantity of heat is supplied to the system and change in the temperatures of the system is measured. In experimental determination of the thermal properties of plant agricultural material, it is necessary to select representative and homogeneous samples, as in other experiment with biological materials.

Temperature-dependant moisture migration is a very common process in the storage of grain in silos (Loewer et al., 1994). *Thermal conductivity* of grain is relatively low and when grain is placed in a silo in the fall, the center tends to remain near the initial temperature. The grain near the wall tends to cool to reach average ambient temperature. With a further decrease in ambient temperature, air currents develop where colder and denser air near the wall moves down forcing the warmer air up through the center of grain mass. As it reaches the top center surface of the grain, it cools to a point at which it cannot hold the moisture it had absorbed. The excess moisture condenses on the surface of the grain creating the environment that enhances molds and insects growth. The reverse situation occurs during the summer months. To minimize the problem of moisture migration temperatures near the silo wall and in the center should be kept relatively close, within 10°C range. This may be accomplished by using aeration fans that pull air down through the grain until the temperature of grain reach prescribed value.

Summary

To control physical phenomena occurring during the storage of agricultural products, knowledge of physical properties of the materials is necessary that are material parameters included in equations modeling processes. Methods of instrumental characterization of agricultural materials during storage still remain on the stage of development and standardization of methods is far from completing. Inherent feature of structure of biological material is its complexity and unhomogeneity. Material properties may vary depending on the location of the area of measurement (unhomogeneity). Even at the same area, properties may vary with direction (*anisotropy*). In general, biological materials do not follow single classical model, but usually their behavior combines a number of these classic effects. Design of efficient technologies of storage of agricultural materials require further work in advancing research, development, and implementation.

PHYSICAL PROPERTIES AS INDICATORS OF FOOD QUALITY

Martin G. Scanlon

Department of Food Science, University of Manitoba, Winnipeg, Canada

Synonyms

Physical properties: constitutive properties; Quality: merit, grade or value; Quality: property or characteristic

Definition

Physical Properties: Essential attributes shared by all members of a class of material.

Introduction

Quality is defined by the *Encyclopedia Britannica* in two ways: as a synonym for “property” or “characteristic,” and in situations where merit, grade, or value is appraised. Inevitably, physical properties are assessed when either definition is applied to foods. For example, when evaluating its acceptability to a consumer, a quality of a fruit is that it is “pleasant to the eyes,” or the uniformity in characteristics of individual food items is such that, when adjudged by the appropriate standards, this particular batch of food commands a higher price. The latter definition, where a physical property is the basis for a trading specification, may be because it is directly relevant to consumer acceptability, such as the USDA quality standards for mechanical toughness in frozen carrots (USDA, 2010), or because the physical property is a predictor of quality in a derived food product, e.g., the battery of physical property tests on wheat flour doughs that are conducted by the Canadian Grain Commission to assure offshore millers and bakers of the quality of Canadian wheat (CGC, 2010). Measurement of physical properties as the basis for quality assurance in the trading of commodities or partly manufactured foods between different food manufacturers is a pervasive activity in food science. Notwithstanding this actuality, subsequent discussion of physical properties as indicators of food quality is restricted to physical properties as determinants of food acceptability to consumers, because the ultimate objective of trading specifications between food manufacturers is to ensure the delivery of high-quality products to their customers.

Creating quality in foods

Quality in foods can be defined in a multitude of ways, but at its most basic it is comprised of:

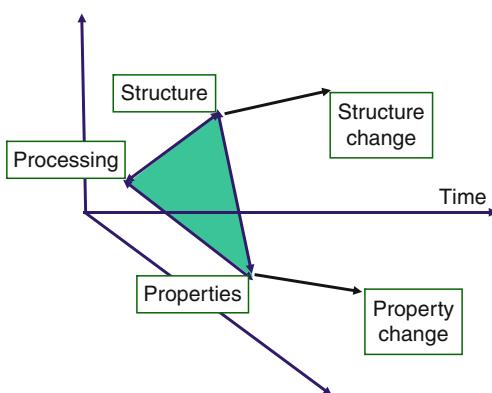

1. The maintenance of the as-harvested or as-processed condition of the food, i.e., prolongation of shelf-life
2. The sensory acceptability of the food – its appearance, flavor/aroma, and texture

3. Two quality criteria of ever-increasing allure – the food's nutritional quality and its quality of convenience

The physical properties that govern these quality definitions are in turn dependent on the structure of the food. Food is structurally complex (Donald, 2004; Ubbink et al., 2008), and so the effects of structure on physical properties can originate from a number of length scales. For example, differences in fatty acid substitution in the triacylglycerols that are expressed from olives exert a molecular-scale effect on the pouring properties of the olive oil, while the hierarchy of various structural levels, from subcellular to cellular to tissue, profoundly affects the flavor and texture of an apple. For processed foods, and foods that are manufactured in the kitchen, the manipulation of structure by process operations is the key to delivering convenience to consumers, to creating new taste sensations, and even to eliciting desirable satiety and digestive physiology responses. The relation between structure creation through manipulation of process and the structural governance of the physical properties that are the determinants of food quality is illustrated schematically (Figure 1). In addition to this triad of interrelated factors, there are also temporal changes in structure and properties that are ongoing from the time of manufacture of the food to the time of its consumption. An example of a time-dependent change in food structure that affects consumer perception of quality is the syneresis of yoghurt, a quality-degradation phenomenon that arises from structural rearrangements in the yoghurt's casein particle network (Tamime et al., 2007).

Determining physical properties

A cursory glance at DIN, ISO, or ASTM standards (DIN, 2010; ISO, 2010; ASTM, 2010) informs that many standardized tests exist for measuring the physical properties of food so that food quality can be determined. The numerous tests in these catalogs of conformity are

Physical Properties as Indicators of Food Quality,

Figure 1 Schematic illustrating the interdependence of physical properties on food structure and how that structure is manipulated by processing and the dynamic changes in properties and structure that can occur with time.

augmented by rigorously defined tests of physical properties for in-house use by food companies seeking to optimize the quality of their food products by controlling each of their unit process operations. Testing methods for physical properties can be grouped into four categories:

1. Methods to measure fundamental physical properties
2. Methods to measure fundamental physical properties when results are analyzed with an appropriate model
3. Methods to measure physical properties under conditions dictated by an appropriate model in order that measurements relate to sensory properties
4. Methods to measure physical properties of practical use in food quality assessments

An example associated with food quality will be used to illustrate each of these measurement categories. Crispness is an essential quality parameter for foods such as crackers (Luyten et al., 2004), and in evaluations of crispness, a three-point bending test may be employed. If the dimensions of the cracker are such that they conform to recommendations in ASTM D790, a valid measurement of the elastic modulus of the cracker can also be obtained from the quality assessment test. In indentation (penetrometer) testing of solid triacylglycerol samples, a consistency parameter derived from the measured force-displacement curve is commonly used for routine quality assurance (Wright et al., 2001). However, it is also possible to derive a fundamental mechanical characterization of the triacylglycerol sample's constitutive properties from its force-displacement curve if an appropriate constitutive model is utilized. In measuring the color quality of a frozen dessert, it is imperative that the dessert's optical properties are measured under standardized conditions. But, if the composition of the diffusively reflected light is spectrally weighted to match the spectral sensitivity of the human eye, then the measured optical properties of the dessert directly relate to human perception of the dessert's color (Hunter and Harold, 1991). Finally, in a multitude of empirical or imitative tests of food quality, physical properties strongly influence the measured quality parameter. However, the relation between physical properties and the measured quality parameter may not be readily apparent. Shearing of meat samples in the Warner–Bratzler test affords a force reading that correlates to meat textural quality (Bourne, 2002), while, on the basis of the intensity of light passing through red, yellow, and blue glasses, a Lovibond tintometer defines the color quality of beer (Hunter and Harold, 1991). In some tests, the causal relation between physical property and quality parameter is rather difficult to discern, e.g., measurement of flour color grade to predict whether the flour will produce an attractive loaf of bread.

Physical properties of foods

Specific physical properties can play a crucial role in many definitions of quality for a wide array of food products. Included here, necessarily brief, is a cursory

overview of significant physical properties in the context of food quality; comprehensive treatments of physical properties and food quality are given in the classic texts of Mohsenin (1970, 1986), and in the more current texts of Sahin and Sumnu (2006) and Figura and Teixeira (2007), emphasizing the enduring interest in evaluating the physical properties of foods and understanding the mechanisms that govern them.

Most texts on the physical properties of foods devote a chapter to definitions and assessments of physical characteristics. Although these extensively defined physical properties, such as product size and shape, are not true physical properties, they are frequently used as food quality indices. For example, in New Zealand, five size categories are used in partial definition of the quality of eggs (EPF, 2010). Similarly, shape standards are applied to quality definitions of some commodities, with misshapen eggs eliminated from the USDA's two top quality standards (USDA, 2010), and shape uniformity being a prerequisite for the higher official US quality grades of many food products (USDA, 2010). In addition, because of the multiphase nature of many foods, the size and shape of individual particles within the food product substantially influence perceived quality. For example, during frozen storage of ice cream, the rate of disproportionation of ice crystals may be such that ice crystals will grow to a size that the resulting perception of grittiness imparts a negative impression of product quality to the consumer (Marshall et al., 2003).

Density

Density is perhaps the single most important physical property for understanding the quality attributes of food products. Density governs instability in many multiphase food systems, e.g., the tendency of components to undesirably cream or sediment (Friberg et al., 2004); it is a critical factor in understanding the stability and textural quality of aerated food systems (Scanlon, 2004); and, it is an excellent predictor of overall end-product quality for a number of agricultural commodities, e.g., potatoes and tomatoes (Dauthy, 1995). In addition, very precise measurements of the density of solutions using vibrating tube technologies permit quantification of solution components that define product quality. An example is the routine quality assurance role for density meters in accurate assessment of ethanol concentration by brewers and vintners (Jacobson, 2006).

Optical and dielectric properties

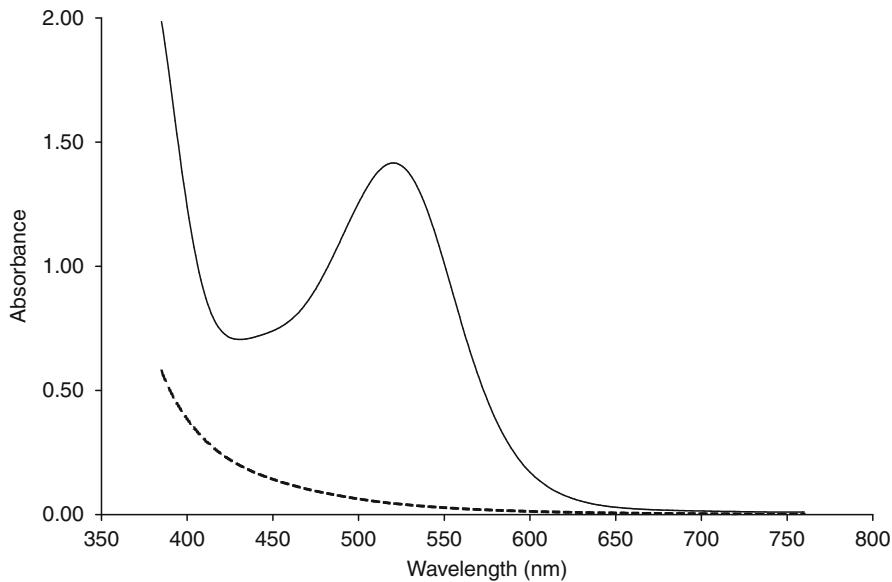

In an initial appraisal of food quality, appearance is undoubtedly the primary quality attribute (Clydesdale, 1993). Thus, optical properties are a highly relevant set of physical properties because the manner in which petahertz electromagnetic radiation interacts with food materials and structures ordains the appearance of the food. In addition, because the quality of convenience is an indispensable element of modern food product quality,

foods should heat up rapidly and evenly when exposed to an electromagnetic field of microwave wavelengths without undergoing physical and/or chemical changes that will undermine the gustatory attributes of the food. Therefore, the manner in which food components and food structures respond to low-frequency electromagnetic radiation is relevant to food manufacturers and to consumer evaluations of food quality.

When electromagnetic radiation of a given frequency strikes a food surface, it is either reflected or it is transmitted into the body of the food. Within the food, the radiation's propagation characteristics differ from those in air due to a difference in the velocity of propagation or in the absorptivity of the radiation, or both. In the absence of absorption, the refractive index (n), the ratio of the velocity of propagation of the radiation of a given frequency in vacuo to that in the food, is a useful physical property for characterizing food quality. The refractive index depends on how charged particles in the food materials respond to the electromagnetic radiation, electrons predominant in the visible region and dipolar molecules in the microwave region. Variation in the polarization of different molecules can serve as a signature for quality variation that can be determined by refractive index measurements. For example, the greater polarization of sucrose molecules compared to that of water molecules allows the refractive index to be a useful determinant of the amount of sucrose in syrups and the amount of water in honey (Figura and Teixeira, 2007).

The refractive index also determines how much energy of the electromagnetic field is reflected or transmitted at the surface of the food (although absorptivity is also a factor). The higher the refractive index, the higher the proportion of light reflected back, e.g., if absorptivity is ignored, ice with $n = 1.31$ reflects about 12% less light at 589 nm as water does with $n = 1.333$. If the food surface is smooth, such as the surface of a glazed donut, the specularly reflected light imparts a gloss or luster to the food, a distinctive food quality parameter for some foods, e.g., in a fruit packing house, the glossiness of apples is enhanced through wax applications in a series of polishing operations. More commonly, food surfaces are not smooth, and the structural organization of polarizable molecules is such that diffuse reflection occurs: the reflected light is reradiated over a wide range of angles, thereby lightening the overall appearance of the food.

Radiation transmitted into the food is very rarely unaffected by absorption. Accordingly, the intensity of the electromagnetic field is progressively reduced the further the radiation propagates into the food. For example, even in a transparent material such as pure water, optical absorption attenuates light transmission, with light intensity (at 550 nm) reaching the end of a meter-long column of water being only 85% of the intensity entering the column. Absorption mechanisms vary depending on the components in the food, but absorption is invariably frequency dependent (Figure 2). Thus, in the multiple-structured multi-materials that constitute food products, the process

Physical Properties as Indicators of Food Quality, Figure 2 Absorption spectra (relative to water) for a path length of 1 cm of apple juice (dashed line) and cranberry juice (solid line) in the visible region of the electromagnetic spectrum. (Data courtesy of Alison Ser.)

of multiple reflections and transmissions that takes place as the light encounters structural features within the food leads to its selective absorption, so that the diffusely re-reflected radiation gives rise to differences in food color; an example is β -carotene and lycopene, both conjugated alkene molecules of nutritional import (Miller et al., 1935). Although the features of their absorption spectra are fairly similar, the absorption maxima for lycopene occur at wavelengths that are approximately 20 nm longer than those of β -carotene. Thus, in the lycopene-rich structures of a tomato, there is greater loss of energy from the green region of the electromagnetic spectrum at each scattering event, and this establishes a red hue in tomatoes in contrast to the orange hue manifest in β -carotene-rich carrots. The greater the red hue of juiced tomatoes, the higher their quality grade. At microwave frequencies, higher absorptivity has both good and bad quality connotations. If the food materials effectively absorb microwave radiation, the food heats up quickly. However, too strong an absorptivity and microwave transmissivity into the interior of the food is hampered; an ensuing disparity between hot exterior and cold interior in a TV dinner or ready meal is not perceived as a desirable quality trait.

Mechanical properties

The evaluation of the mechanical properties of foods is central to definitions of food quality because food texture depends on mechanical behavior (Bourne, 2002). Mechanical properties also affect food quality by virtue of their maintenance of the integrity of solid foods, e.g., is the packet of cookies that one opens a friable mass of

crumbs or does it contain the same number of items that was packaged by the food manufacturer? Similarly, the mechanical and flow properties of liquid foods are important for mouthfeel and for factors associated with quality of convenience, e.g., does the tomato ketchup flow evenly or is it dispensed in a series of messy stick-slip events?

Kamyab et al. (1998) assumed that the textural characteristics of solid foods could be described by four mechanical properties – the Young's modulus, the yield stress, the coefficient of friction, and the fracture toughness. The importance of each of these mechanical properties to food quality can be illustrated with a specific textural attribute. In assessing the freshness of bread, a consumer squeeze test of crumb softness interrogates the elastic character of the crumb as defined by its Young's modulus (Scanlon and Zghal, 2001), albeit mediated by the customer's application of stress through the stiffer crust material. After an elastic response at small strains, a number of foods exhibit a yield stress, which may be defined as the minimum stress required to initiate flow in the food. A physical property defined in this manner is evidently a quality parameter for a number of spreadable foods, e.g., cream cheese (Steffe, 1996). There is increasing recognition of the relevance of the coefficient of friction between the surfaces of food materials and those of teeth, tongue, and palate in the oral appreciation of a number of foods. This appears to be more evident in foods with a creamy quality character (Dresselhuis et al., 2008), so that attaining the right coefficient of friction through food structure manipulation allows textural quality matching of fat-reduced foods with their full-fat counterparts. Although it is not easy to discount geometric effects and the mechanics of mastication

from the effect of mechanical properties, for those food products where crispiness and crunchiness are important quality criteria, fracture toughness is the relevant mechanical property in attaining desirable sensory characteristics (Luyten et al., 2004).

In beverages and in some solid-like foods, flow (rheological) properties govern mouthfeel quality (Bourne, 2002). Some relatively simple beverages display Newtonian behavior, so that regardless of the rate of testing, a single parameter, the viscosity, suffices to define the beverage's flow behavior; examples are fruit juices (Steffe, 1996). However, the vast majority of liquid foods are not this well behaved (Figure 3), and a statement on flow characteristics must also stipulate shear rate, with shear rates pertinent to those operative during mastication of special interest in relating the measured mechanical parameter to consumer oral quality assessments. A further hindrance to an exact characterization of mechanical performance by rheological methods is the fact that the properties of the vast majority of food materials are sensitive to their deformation history. To obviate ambiguity and to comprehensively evaluate the mechanical properties of food systems that are sensitive to temperature as well as time of testing, empirical evaluation of flow characteristics is conducted with rigorously controlled time-temperature treatments in instruments of well-defined geometry. An example is the evaluation of the pasting characteristics of starches or flours in the amylograph or rapid viscoanalyser.

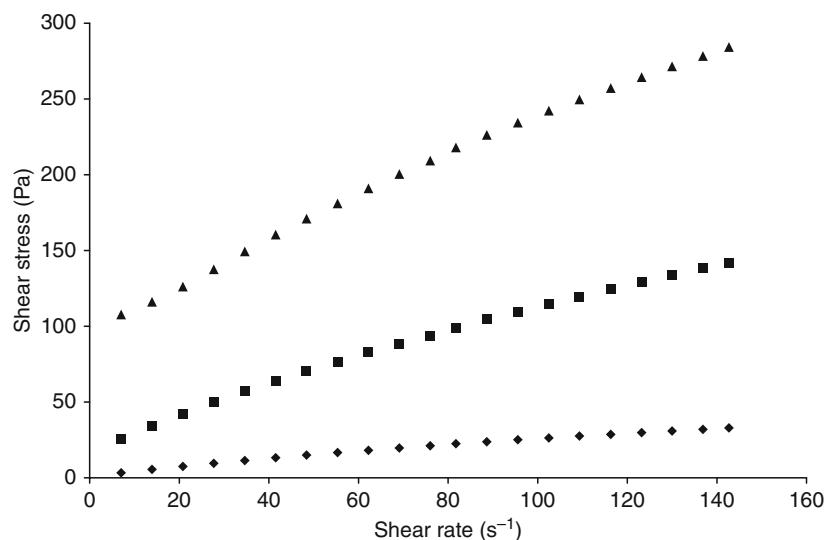

Thermal properties

The thermal properties of foods are unquestionably relevant to the attainment of good quality in most processed foods, e.g., see Lewis (1990) or Nesvadba et al. (2004).

An example from thermal process operations is thermal conductivity, a physical property that governs the degree of overprocessing, and thus the extent of quality degradation, that occurs in retorted foods as a consequence of ensuring that the coldest point in the food has an extremely low safety risk. However, as indicators of food quality per se, thermal properties are of lesser utility than other physical properties. Perhaps the most frequently used quality assurance assessment of thermal properties is obtained from differential scanning calorimetry, a technique that monitors specific enthalpy and melting points associated with phase transitions of food materials such as starch. Melting point determination is an informative quality criterion of shortening functionality for both domestic and industrial bakery applications, and so a simple test of this thermal property is measurement by drop point. A sample of shortening is heated in a glass tube and the temperature at which the sample slips defines its melting point (AOCS, 2009).

Other physical properties

The importance of water to so many facets of food quality means that many texts examining the physical properties of foods will devote a chapter or more to an examination of the adsorption of water to food materials (Rahman, 1995). Measurement of the shift in the vapor pressure of water molecules arising from the colligative properties of food molecules via water activity measurements is probably the most widely used technique for evaluating the effect of water content on product shelf life. In a similar vein, the change in electrical properties of a food resulting from moisture content changes can provide insights into the longevity of foods in storage facilities; for this purpose, the capacitance of grain samples is a relatively

Physical Properties as Indicators of Food Quality, Figure 3 Change in shear stress with increasing shear rate for a meringue mix (egg-whites and sucrose) with different volume fractions (ϕ) of bubbles entrained by mixing (\blacklozenge , $\phi = 0.46$; \blacksquare , $\phi = 0.65$; \blacktriangle , $\phi = 0.80$). (Data from Spencer and Scanlon [unpublished].)

simple means of evaluating moisture content and thus determining whether the grain should be dried in order that the quality of products derived from the grain is assured.

Temperature dependence of physical properties

All physical properties are affected by temperature, some more than others, e.g., cf. the temperature dependence of viscosity and density of food oils. The extent to which the quality of the food is changed depends on the food itself, but temperature-dependent effects are pronounced when a component in the food undergoes a phase transition as a result of the temperature change. Examples, with a resulting disastrous effect on food quality, are the melting of ice crystals in ice cream, and the melting of fat crystals in chocolate.

Conclusions

The structural and dynamic complexity of foods confounds a simplistic examination of the relationship between physical properties and food quality. Nevertheless, three driving forces impel food scientists to gain a better understanding of the causal relation between a given physical property and food quality: rapid advances in online detection technologies will permit physical property measurements by acoustic and electromagnetic fields to be related to online quality assurance provided the relation between the physical property and food quality is understood; the need for continuous innovation in the food industry, as well as in the culinary arts (Barham, 2001), demands a better understanding of how quality and physical properties are related if novel food products are to be created; the ongoing understanding from the nutritional sciences about relations between diet and health is driving product innovation to a focus on developing products that deliver greater health benefits without impairing food quality. These driving forces will undoubtedly shape the research that must be undertaken to better understand the relations between food materials, food structures, and quality changes as a function of time.

Physical properties of fresh and proceed agricultural crops

Definition

Physical property of agricultural material. A measurable property which describes a physical state of agricultural material at any given condition and time.

Agricultural raw materials. Biomaterials originating from farming or any agricultural production that are used as components for products processed by industries or human labor as a building material to create a new product or a new structure. Agrophysics focuses mostly on plant materials that are essential in creating agricultural products in food industry.

Agricultural products. Any goods created through farming or food processing based on usage of agricultural crops.

Introduction

The wide knowledge of physical properties of agricultural products is being used in the farming, planting, harvesting, drying, freezing, processing and storage of raw materials. Accurate design of machines and processes to harvest and handle raw materials and agricultural products and to change these crops into food requires an understanding of their physical properties. These properties include size,

shape, and density; deformation in response to applied forces; moisture content, adsorption and desorption of water, and hydrodynamic properties; and other characteristics describing physical state of agricultural material.

The physical properties of agricultural products are important in the design and processing of food (see also *Agriculture and Food Machinery, Application of Physics for Improving*). They can be classified as thermal, optical, electrical, mechanical, or structural properties. Most of these primary and secondary properties indicate changes in the chemical composition and structural organization of plant material consisting final product. The measurement techniques allow computation of these properties, which can provide information about the effects of processing conditions in fresh and proceeded foods. Some of characteristics, such as color, mechanical and rheological properties, thermal and electrical resistance, water content, and other physical quantities give excellent description of product quality.

This topic has been comprehensively covered by many researchers (Abbott and Harker, 2003; Barbosa-Cánovas et al., 2004; Dobrzański et al., 2006). When physical properties of agricultural products, such as grains, seeds, fruits and vegetables, dairy, meat and fish, oil crops, sugar crops, and fibers, are studied by considering either bulk or individual units of the material, it is important to have an accurate estimate of shape, size, volume, density, specific gravity, surface area, and other mechanical characteristics, which may be considered as designing parameters for food production.

Role of raw material in quality of agricultural products

The primary role of agriculture is, and should remain the production of agricultural raw materials for food and feed (CIAA, 2008). Agricultural raw materials are essential components for products processed by industries. The cost of agricultural raw materials represents between 30% and 80% of a food and drink manufacturer's operating costs.

Industry needs raw material supply that corresponds to specific quality criteria. According to the CIAA (2008) report, 70% of the European agricultural production is processed by the EU food and drink companies. Access to local supplies of raw materials remains a priority in certain food industries. The sustainable supply of agricultural materials represents an essential element in the long-term health and prosperity of the food and drink industry. Modern agriculture already provides the industry with products that respect a high and increasing level of requirement, notably in the area of environment and food safety. The coherence between farmers and the industrial sector in relation to consumers and market demand needs the researcher's access in study of physical properties of raw materials and is essential for ensuring competitive agricultural product. Measures and instruments developed under policies such as agricultural production, environment protection, biofuels promotion, food safety requirements, the

use of GMOs, and trade should be taken into consideration in study of physical properties of raw material and agricultural products. According to global production of top crops and raw materials ([Table 1](#)), the problem consists on the estimation of quality and sorting over 7,800 million tons of agricultural products.

Quality evaluation of raw materials and agricultural products has been a subject of interest to many researchers for many years (see [Quality of Agricultural Products in Relation to Physical Conditions](#)). Quality of agricultural products is an important factor to both the producers and the consumers. In this context the consumer is the person or organization receiving the product at every point in the production chain. This is important because quality will be perceived differently depending on the needs of the particular consumer: a packing shed operator will have a very different idea of quality to the ultimate eater of the fruit (Studman, [1994](#)). Quality factors for fresh fruits and vegetables listed by Kader ([1983](#)) are: hygiene and quarantine factors (parasites larvae, pupae, natural toxicants, contaminants, spray residues, heavy metals, etc.), cosmetic appearance (size, weight, volume, dimensions, shape, regularity, surface texture, smoothness, waxiness, gloss, color, uniformity, intensity, spectrum, physical defects, splits, cuts, dents, bruises), texture and flavor factors (firmness, hardness/softness, crispness, mealiness/grittiness, fibrousness, toughness), flavor (sweetness, sourness, astringency, bitterness, aroma, off-flavors, off-odors), and nutritional factors (dietary fiber, cancer inhibitors, carbohydrates proteins, lipids, vitamins, minerals).

Firstly, quality standards are affected by international and cultural preferences (Amos et al., [1994](#)). Secondly, standards can be affected by cultural changes or by strong marketing in the media. Quality standards may involve appearance, feel, taste, consistency, handling characteristics, ability to retain properties for long periods of time, or the absence of undesirable impurities (Kader, [1983](#)). There is no clear definition of quality, equal for all agricultural products. However, for each product and property interest, some objective means of measurement technique is required. Several methods are available for quality detection in horticultural commodities according to external and internal properties. The challenges are to make these techniques affordable in the market place and especially to relate the measurement parameters to the very subjective, sensory evaluation of quality by consumers.

Physical property of agricultural materials

In a Newtonian sense, the physical properties of an object may include many varietal properties; some of them are listed below alphabetically: absorption, area, boiling point, brittleness, capacitance, color, concentration, conductivity, density, dielectric (see [Dielectric Properties of Agricultural Products](#)), distribution, ductility, efficacy, electric charge, electric field, electric potential, emission, flow rate, fluidity, frequency, impedance, inductance, length, location, luminance, magnetic field, magnetic flux, malleability, mass, melting point, moment, permeability, permittivity, pressure, radiance, reflectivity, resistance, solubility, specific heat, spin, strength, temperature, tension, thermal transfer, velocity, viscosity, volume. These are frequently determined during the study of raw materials and agricultural products (see also [Databases on Physical Properties of Plants and Agricultural Products](#)).

Barbosa-Cánovas et al. ([2004](#)) divided physical properties into the following groups:

- Thermal properties such as specific heat, conductivity, diffusivity, and boiling point rise, freezing point depression (see also [Drying of Agricultural Products; Thermal Technologies in Food Processing](#))
- Optical properties, primarily color, but also gloss and translucency
- Electrical properties, primarily conductivity and permittivity (see also [Electrical Properties of Agricultural Products](#))
- Structural and geometrical properties such as density, particle size, shape, porosity, surface roughness, and cellularity
- Mechanical properties such as textural (including strength, compressibility, and deformability) and rheological properties (such as viscosity) (see also [Rheology in Agricultural Products and Foods](#))
- Others, including mass transfer related properties (diffusivity, permeability), surface tension, cloud stability, gelling ability, and radiation absorbance

Agricultural products and raw materials in general can display large compositional variations, inhomogeneities, and anisotropic structures. Composition can change due to seasonal variations and environmental conditions, or in the case of processed foods, properties can be affected by process conditions and material history.

Early physical property analyses of food and agricultural products required constant uniform values and were often oversimplified and inaccurate. Nowadays, computational engineering techniques, such as the finite element method, are much more sophisticated and can be used to evaluate nonuniform properties (e.g., thermal properties) that change with time, temperature, and location in food products that are heated or cooled. Improvements measuring the compositions of crop and food are now allowing predictions of physical properties that are more accurate than previously.

Physical methods for quality evaluation of agricultural products

Chen (1996) presents an overview of various quality evaluation techniques that are based on one of the following physical properties: density, firmness, vibration characteristics, x-ray and gamma-ray transmission, optical reflectance and transmission, electrical properties, aromatic volatile emission, and nuclear magnetic resonance (NMR) (see also *Physical Properties as Indicators of Food Quality*).

Zachriah (1976) reported that a number of researchers have investigated the electrical properties of fruits and vegetables, however, the results were not conclusive enough to permit development of a practical method for quality sorting of fruits and vegetables.

It was found that radiation in the near-infrared region of the spectrum can provide information related to many quality factors of agricultural products. Bellon and Sevilla (1993) developed an NIR system, which combined a CCD spectrophotometric camera and bifurcated fiber optics, for determining soluble solids in apples.

Short-wave radiations such as x-rays and gamma rays can penetrate through most agricultural products. The level of transmission of these rays depends mainly on the mass density and mass absorption coefficient of the material.

Nuclear magnetic resonance (NMR) is a technique that detects the concentration of hydrogen nuclei (protons) and is sensitive to variations in the concentration of liquid in the material. Although NMR imaging (MRI) has been used frequently in the medical field, however quality factors in raw materials and agricultural products has not been fully explored. Wang et al. (1988) used MRI methods to obtain images of water core and its distribution in Red Delicious apples. Chen et al. (1989) used MRI to evaluate various quality factors of crops.

One of the most practical and successful techniques for nondestructive quality evaluation and sorting of agricultural products is the electro-optical technique, based on

the optical properties of the product. Thus, determining such optical characteristics of an agricultural product can provide information related to quality factors of the product.

Texture and mechanical properties of tissue

Texture is a quality attribute that is critical in determining the acceptability of agricultural products. A few of the many terms used to describe sensory texture of crops are hard, firm, soft, crisp, limp, mealy, tough, leathery, melting, gritty, woolly, stringy, dry, and juicy. There are no accepted instrumental methods for measuring each of these attributes.

Abbott and Harker (2003) indicate that most important to understand the texture of a product is to identify the main elements of tissue strength and to determine which elements are responsible for the textural attributes of interest (see *Microstructure of Plant Tissue*). For example, it may be necessary to avoid tough strands of vascular material when measuring texture of soft tissues because the small amount of fiber produces an artificially high reading that does not agree with the sensory assessment of softness. On the other hand, it is important to measure the strength of fibers when determining toughness, such as in asparagus spears or broccoli stalks.

The arrangement and packing of parenchyma cells within the tissue is another factor that influences mechanical strength of raw material and products (Abbott and Harker, 2003). In carrots, the cells are small (approximately 50 µm in diameter), irregular in shape, and closely packed with a high degree of contact between neighboring cells and a small volume of intercellular gas-filled spaces. The cells can be arranged either as columns or as a staggered array where each cell overlays the junction of the two lower cells. These differences in cell packing may, in part, explain genotypic differences in susceptibility to harvest splitting in carrots. In the apple cortical tissue, the cells are large (up to 300 µm in diameter), elongated along the direction of the fruit radius, and organized into distinct columns (Vincent, 1989). As a result of this orientation of apple cells, the elastic modulus of tissue is higher and the strain at failure is lower when tissue plugs are compressed in a radial rather than a vertical or tangential orientation (Abbott and Lu, 1996; Vincent, 1989). Additionally, up to 25% of the volume of apple tissue may be gas-filled intercellular spaces, which indicates relatively inefficient cell packing and a low elasticity of tissue (Vincent, 1989).

Plant cells tend to maintain a small positive pressure, known as turgor pressure. This pressure develops when the concentration of solutes inside the cell is higher than outside the cell (Abbott and Harker, 2003). The extracellular solution fills the pores of the cell wall, sometimes infiltrates into gas-filled spaces, and usually is continuous with vascular (water conducting) pathways of the plant. Differences in solute concentration at the inner and outer surface of the plasma membrane cause water to flow into the cell

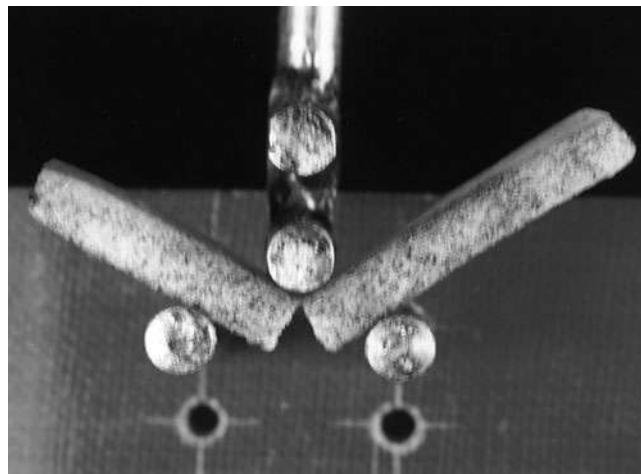

by the process of osmosis. This net movement of water is halted by the physical constraint of the rigid cell wall and, as a result of this, turgor develops inside the cell. At equilibrium, $\Psi = \Psi_p + \Psi_\pi$, where Ψ is the turgor (generally a positive value), Ψ_p is the water potential (water activity, generally a negative value) of the tissue, and Ψ_π is the osmotic pressure (generally a positive value) of the cell. Turgor has the effect of stressing the cell wall (see [Water in Forming Agricultural Products](#)). The consequences of this stressing depend on whether compressive or tensile loads are applied. When tissues are subjected to compressive loads, higher turgor tends to make the cell more brittle, that is, makes it fail at a lower force. When tissues are subjected to tensile measurements, turgor tends to harden the cell wall and a greater force is needed before cells fail (De Belie et al., 2000a). Also, turgor is thought to play a central role in softening and development of mealiness during storage of apples.

The strength of the cell wall relative to the adhesion between neighboring cells will determine whether cell rupture or cell-to-cell de-bonding is the mechanism of tissue failure. Cell rupture is generally associated with crisp and often juicy produce, as well as with unripe fruit and raw vegetables (Abbott and Harker, 2003). Cell-to-cell de-bonding is frequently associated with dry, unpleasant texture such as in mealy apples, chilling injured stone fruit and tomato, and juice loss in citrus (Harker et al., 1997). However, a dry texture is not always unacceptable to consumers, for example, banana.

Many crops contain a number of tissue zones – periderm, pericycle, and phloem parenchyma in carrot; skin, outer pericarp, inner pericarp, and core in kiwifruit; and outer pericarp, locular gel, seeds, and columella in tomato. These tissues differ in strength and biological properties and often need to be considered individually when measuring texture. For example, a very precise test for study the elasticity of apple was proposed and successfully used by Dobrzański et al. (2006). In this test, only a superficial layer of apple tissue with the skin over was loaded ([Figure 1](#)). It shows that fruit firmness was most influenced by elasticity of apple tissue and strength of apple skin and proves that strength of superficial layer of apple tissue more accurately indicates the mechanical properties of apple flesh in bending test (Rybczyński and Dobrzański, 2000) (see [Bending Properties of Plants](#)).

Instrumental measurement of texture

Szczesniak (1963) proposed a texture profile, a systematic approach to sensory texture analysis based on mechanical, geometrical, and other characteristics. Mechanical characteristics included basic parameters (hardness, cohesiveness, viscosity, elasticity, and adhesiveness) and secondary parameters (brittleness or fracturability, chewiness, and gumminess). Geometrical properties related to size, shape, and orientation of particles. The other characteristics comprised moisture and fat content. Moisture content is one of the most influential factor affected the mechanical

Physical Properties of Raw Materials and Agricultural Products, Figure 1 The failure of two layer tissue of apple beam (flesh with the skin) loaded in three-point support bending test.

resistance of raw material and agricultural products (see [Water Effects on Physical Properties of Raw Materials and Foods](#)). On the other hand, the change of moisture involves significant decrease or increase in volume of product observed as shrinkage or swelling (see also [Shrinkage and Swelling Phenomena in Agricultural Products](#)).

There are many types of mechanical loading: puncture, compression, shearing, twisting, extrusion, crushing, tension, bending, vibration, and impact. And there are four basic values that can be obtained from mechanical property tests: force (load), deformation (distance, displacement, penetration), slope (ratio of force to deformation), and area under the force/deformation curve (energy). The engineering terms based on these measurements are stress, strain, modulus, and energy, respectively. Stress is force per unit area, either of contact or cross-section, depending on the test. Strain is deformation as a percentage of initial height or length of the portion of sample subject to loading. Modulus of elasticity (tangent, secant, chord, or initial tangent) is a measure of stiffness based on the stress/strain ratio (see [Stress–Strain Relations](#)). Force and deformation values are more commonly used in food applications than stress and strain values and are sufficient, provided that the contact area and the distance the probe travels are constant and sample dimensions are similar from sample to sample. (Sample here means the portion of tissue tested, not necessarily the size of the fruit or vegetable.) In many horticultural texture tests, deformation is kept constant and the force value is reported. A typical force/deformation characteristic for a cylindrical piece of apple tissue compressed at constant speed gives F/D curve for puncture tests that look similar to compression curves. The portion of the initial slope up to point represents nondestructive elastic deformation; point is the inflection point where the curve begins to have a concave-downward shape and is called the elastic limit. The region before this point is where slope or elastic

modulus should be measured. Beyond the elastic limit, permanent tissue damage begins. There may be a biyield point where cells start to rupture or to move with respect to their neighbors, causing a noticeable decrease in slope (Abbott and Harker, 2003).

Mechanical properties of agricultural products and fruit firmness

Firmness is a property that is often used for evaluating the quality of fruits and vegetables. Firmness is not a physical quantity, however, is strongly related to numerous mechanical properties. In many agricultural products firmness is related to maturity. In general firmness of fruits decreases gradually as they become more mature and decreases rapidly as they ripen (Dobrzański and Rybczyński, 2000). Overripe and damaged fruits and vegetables become relatively soft. Several methods for measuring fruit firmness have been developed. Fekete and Felföldi (2000) reckoned firmness as a principal characteristic of fruits, importance for the quality, the optimum harvest date, and the evaluation of the maturity for storage and for shelf life (see *Physical Phenomena and Properties Important for Storage of Agricultural Products*). They divided the methods of fruit firmness measure on direct (contact: compression, shear, impact, rebound) and indirect (noncontact: vibration, sonic) techniques.

Firmness is related to maturity and it is well known; overripe and damaged fruits become relatively soft. Thus firmness can be used as a criterion for sorting of agricultural products into different maturity groups or for separating overripe and damaged fruits from good ones. Firmness is related to the quality factors, however, through use of simple penetrometers, only the maximum squeezing force has been frequently correlated with numerous quality factors. It is also well known, that the firmness should depends to the shape and size of fruit; size and contact area of plunger; rate of deformation; the way of fruit fixing, and other procedures influenced a final accuracy. Generally, determination of mechanical properties based on the high-precision measurement with expensive equipment requires a complete force/deformation curve. From the force/deformation curve, stiffness; modulus of elasticity; modulus of deformability; toughness; force and deformation to point of inflection, to biyield, and rupture; and maximum normal contact stress or stress index at low levels of deformation can be obtained. The force/deformation curve was frequently used in the study of physical properties of agricultural products; however, this measurement is not widely utilized in practice because of expensive and complicated procedures.

The most common texture tests of fruits and vegetables, the Magness-Taylor puncture and the Kramer Shear report only the maximum force attained, regardless of the deformation at which it occurs. Puncture testers (Magness and Taylor, 1925), are used to measure firmness of numerous fruits and vegetables to estimate harvest maturity or for postharvest evaluation of firmness (Abbott and Harker,

2003). Based on this procedure, Mizrach et al. (1992) used a 3-mm diameter pin as a mechanical thumb to sense firmness of oranges and tomatoes. Fekete and Felföldi (2000) have been reported four rapid penetration methods, where the values of force or deformation were measured. Bellon and Sevila (1993), reported the method, where the deformation was measured at constant force. Fekete and Felföldi (2000) designed device equipped with force sensor, an amplifier and A/D converter, connected to a hand-held microcomputer for data recording. Dobrzański and Rybczyński (2000) made the bases to develop a new device; nondestructive strain meter, where strain was measured at low constant force that allows estimating the modulus as firmness characteristic.

The Kramer Shear device is used extensively in the food processing industry and is used by some fresh-cut processors for quality control. Shearing in engineering terms does not mean cutting with a knife or scissors, but instead sliding adjacent parallel planes of cells past one another (Abbott and Harker, 2003). It does not measure true shear, however, the force measured by the test involves compression, shear, extrusion, and friction between the tissue and blades. As with the MT probe, comparisons should not be made between results from cells of different geometries.

Compression tests are also widely used in research on agricultural products (Abbott and Harker, 2003). Although raw materials and agricultural products are viscoelastic, they are often treated as elastic, so the force required to attain a specified deformation or to rupture (bruise or burst) the product is generally measured. Modulus of elasticity, stiffness, forces and deformation to biyield and to rupture, and contact stress can be calculated from elastic measurements, dimensions of the specimen, and Poisson's ratio. The elastic modulus or Young's modulus is often used by engineers. As the ratio of stress to strain or calculated from the slope of the force/deformation curve before the elastic limit, the modulus is the most accurate parameter of firmness.

Tensile measurement has not been as popular as puncture or compression testing because it is not intuitively as related to crushing or chewing as are puncture or compression and because it requires gripping or otherwise holding the ends of the sample so they can be pulled apart without crushing the tissues where they are held. Schoorl and Holt (1983) used clamps to hold apple tissue; however, only satisfactory results were obtained by Rybczyński and Dobrzański (1994).

Firmness of agricultural products can be measured at different force or deformation. Generally, these methods were based on the high precision measurement. F/D characteristics beyond the elastic limit may be more important than those before it because they simulate the destruction that occurs in bruising or eating (Bourne, 1980; Szczesniak, 1963).

Most force/deformation measurements are destructive. In these tests rupture forces usually provide the best correlation with sensory texture evaluations of foods.

Unfortunately destructive tests cannot be used in sorting of fruits and vegetables for subsequent sale, so a great deal of research has gone into developing nondestructive methods to estimate the mechanical properties and the textural quality of raw materials and agricultural products (Abbott and Harker, 2003; Chen and Sun, 1991).

Nondestructive techniques: frequency and product response

None of these nondestructive methods has attained wide commercial acceptance to date (see also *Nondestructive Measurements in Fruits*). After the relationship between an instrumental measurement and a quality attribute or acceptability is well established, the instrumental measurement is usually used to replace human evaluations (Peleg, 1994; Ruiz-Altisent et al., 1994; Wang et al., 1988). A nondestructive, noncontact firmness detector was elaborated and a laser to measure deflection caused by a short puff of high-pressure air was used. Under fixed air pressure, firmer products deflect less than softer ones. Laser-puff readings correlate well with destructive Magness-Taylor firmness values for apple, cantaloupe, kiwifruit, nectarine, orange, pear, peach, plum, and strawberry (McGlone and Jordan, 2000).

Impact, bounce, and vibration

Numerous studies have been conducted on the bounce responses of horticultural products and a number of impact parameters have been proposed to measure firmness, including peak force, coefficient of restitution, contact time, and the impact frequency spectrum (see *Mechanical Impacts at Harvest and After Harvest Technologies*). When one object collides with another object, its response is related to its mechanical properties, its mass, and the contact geometry (Abbott and Harker, 2003). The coefficient of restitution is the ratio of the velocities of the product just before and after impact and reflects the energy absorbed in the product during impact. Most impact tests involve dropping the agricultural product onto a sensor (McGlone and Schaare, 1993; Patel et al., 1993; Zapp et al., 1990) or striking the product with the sensor (Chen, 1996). Delwiche et al. (1991) developed a single-lane firmness sorting system for pear and peach. Impact measurements frequently do not correlate with the Magness-Taylor puncture measurement.

The force response of an elastic sphere impacting a rigid surface is governed by the impacting velocity, mass, radius of curvature, elastic modulus, and Poisson's ratio of the sphere. A problem inherent to the technique of dropping the fruit on a force sensor is that the impact force is also a function of the mass and radius of curvature of the fruit (Chen, 1996). Therefore, a large variation in these two parameters will affect the accuracy in firmness measurement.

A different approach is to impact the fruit with a small spherical impactor of known mass and shape and measuring the acceleration of the impactor. The advantage of this

method is that the impact-force response is independent of the fruit mass and is less sensitive to the variation of the fruit dimension. This technique was first described by Chen et al. (1985). A low-mass high-speed impact sensor was designed and tested with good results, however, only on kiwifruits and peaches.

The vibration characteristics of fruits are governed by their elasticity, mass, and size. Therefore, it is possible to evaluate firmness of fruits on the basis of their vibration characteristics. An extensive study of vibration characteristics of apples was conducted by Abbott et al. (1968). In general, the researchers detected a series of resonant frequencies. However, in the cases where the fruit was excited by a vibrator and the vibration was detected by an accelerometer. The lower resonant frequencies may not be those of the free vibration of the fruit, but may be resonant frequencies that were caused by the interaction between the fruit mass or accelerometer mass and the force developed by local deformation of the fruit.

Acoustic (sonic) and ultrasonic waves

Acoustic vibrations (sonic) are those within the human audibility range of frequency to 20,000 Hz. Sonic measurements provide a means of measuring fruit and vegetable firmness (Abbott and Harker, 2003). The traditional watermelon ripeness test is based on the acoustic principle, where one thumps the melon and listens to the pitch of the response. A number of sonic instruments and laboratory prototype sorting machines have been developed and tested (Abbott et al., 1968, 1992; Armstrong et al., 1990; Muramatsu et al., 2000; Peleg et al., 1990; Schotte et al., 1999; Stone et al., 1998; Zhang et al., 1994). When an object is caused to vibrate, amplitude varies with frequency of the vibration and will be at a maximum at some particular frequency determined by a combination of the shape, size, and density of the object; such a condition is referred to as resonance. Resonance measurement can be achieved by applying an impulse or thump that contains a range of frequencies. Kawano et al. (1994) reported a commercial sorting machine for detecting internal voids in Japanese watermelon. Shmulevich et al. (1995) developed a sonic instrument using a lightweight flexible piezoelectric film sensor to follow changes in fruit during storage. Muramatsu et al. (2000) examined the relationship of both phase shifts and resonant frequencies to firmness. Peleg et al. (1990) examined the sonic energy transmitted by the specimen rather than the resonant frequencies. Despite considerable research, sonic vibration has not yet become a viable option for the horticultural industry. However, there are several advanced commercial prototypes currently being evaluated.

Ultrasonic techniques have been used quite successfully for evaluating subcutaneous fat, total fat, lean, and other internal properties of live animals. However, researchers have not been so successful in using ultrasonic measurements to evaluate internal quality of fruits and vegetables.

On the other hand, ultrasonic wave range frequencies over >20,000 Hz are widely used in the medical field and for analyzing meat. Ultrasonic has been used with limited success for measuring physical properties of crops because of the high energy absorption of plant tissues. The commonly measured ultrasonic parameters are velocity, attenuation, and frequency spectrum composition. Bruises in apples (Upchurch et al., 1987) and hollow heart of potatoes (Cheng and Haugh, 1994) could be detected in the laboratory using ultrasonic wave. Mizrach et al. (1999) have followed the softening process in avocados, melons, and mangoes, respectively.

Visible light and color measurements

In physics, visible light is said to be composed of electromagnetic rays. The electromagnetic rays of visible light are different only in their frequency from the other rays such as: gamma rays, x-rays, ultraviolet, infrared, microwaves and rays carrying radio and television (Dobrzański et al., 2006). The frequency range reflected is influenced by the physical and chemical properties of the object and by the frequency ranges which are absorbed. However, the color of an object is unknown, because electromagnetic rays are colorless. An illuminated object reflects light, which is perceived and interpreted by persons. The human eye converts the electromagnetic rays and then brain interprets this information as sensation of color. The eye is able to convert varying frequencies of electromagnetic rays into information which the brain perceives as different colors. The eye is also able to convert the intensity of rays into information which the brain interprets as a sensation of lightness. Based on the fact that the retina of the human eye contains three different types of cone cells which are sensitive to the primary colors of red, green, and blue respectively.

Because humans are able to distinguish between several hundred thousand shades of color (approx. 350,000), it is necessary to introduce mathematical color models which enable each shade to be described exactly in terms of a numbered value. To enable colors to be described as geometrical interpretation, there are various 3-D models for color description. Some of these, e.g., the RGB color model are derived directly from the additive or CMY from the subtractive color mixing system. Therefore, each color in this cube is identified by its coordinates. Compared with the RGB and CMY color models, the HSV (hue, saturation, and value) color model, hexagon pyramid, has the advantage that the colors correspond closely to our perception of color. Consequently, this color space is often preferred for practical implementation of color measurement.

Most new colorimeters allow measurements of absolute color to be displayed in any of five color systems: Yxy, L*a*b*, L*C*H_o, Hunter Lab, or tristimulus values XYZ. Measurements of color difference can be displayed in any of four systems: $\Delta(L^*a^*b^*)/\Delta E^*ab$, $\Delta(L^*C^*H_o)/\Delta E^*ab$, $\Delta(Yxy)$, and Hunter $\Delta(\text{Lab})/\Delta E$ (Good, 2002).

Two of these systems is frequently applied in any quality estimation of raw materials and agricultural products.

The L*a*b* color system is one of the uniform color spaces recommended by CIE in 1976 as a way of more closely representing perceived color and color difference. In this system, L* is the lightness factor; a* and b* are the chromaticity coordinates.

The colorimeter measuring system is designed to provide accurate readings and uniform response. The light received by the meter is divided three ways and passed through special filters whose light absorbing characteristics combine with the spectral response of the photo cells. Upon reaching the silicon photocells, light energy is converted into electrical signals and sent to the microprocessor, where it is adjusted for the illuminating condition desired and then converted into co-ordinates according to the chosen color space. Readings are displayed on the LCD panel and can be transferred to a separate computer or processor through the data output terminal. For color readings, these values are translated into Yxy coordinates or in color L*a*b* standard. The device allows for different settings for illumination and CIE 2° – Standard Observer or CIE 10° – Supplementary Observer. All results were determined at daylight D65 of color temperature 6,500 K.

Crops and agricultural products behavior in visible light

With the increasing diversity of plant varieties, crop quality recognition is becoming more and more important. Along with quality estimation, color is one of the major factors in creating a consumer acceptance of crop and agricultural products (Alchanatis and Searcy, 1995; Dobrzański and Rybczyński, 2002; Kader, 1983; Kameoka et al., 1994; Lancaster, 1992; Molto et al., 1996; Motonaga et al., 1997; Studman, 1994). Therefore the appearance of products has a major influence on perceived quality. However, color as one of the most important quality parameter is influenced by cultural and consumer preferences (see *Color in Food Evaluation*).

The preferences of color depend on: uniformity of external color, repeatability of fruit color in crop, differences between high and ground color, intensity of blush and base color (saturation of red), size of blush, lightness-darkness, whiteness, physical defects, dents, browning, bruising, and stage of maturity (ripeness). After harvest, cosmetic appearance of apples seems to be the most important quality factor. However, the storage has substantial influence on final quality of fruits, as it affects the appearance and induces color changes (Dobrzański and Rybczyński, 2002; Dobrzański et al., 2006; Kader, 1999; Kameoka et al., 1994; Saks et al., 1999). Firstly, some of fruits are more influenced by storage conditions than others. Secondly, shelf-life is a period of storage, with unsuitable conditions, i.e., high temperature and low humidity, for keeping apple in good quality. At this

time, darkening of the skin observed by consumers, decreases perceptions of color, which influences the estimation of fruit quality. Impacts on fruits cause damages, and bruising leads to enzymatic browning of the tissue. Frequently, internal browning is visible externally.

One of the basic conditions for improvement of quality is proper sorting and handling of the fruit for market (Dobrzański et al., 2006). Hence, sorting for separating the fruit with the same blush or having the same base color should be the most important factor for improving quality and influence price. Separating ripe from over ripe or damaged would allow the “good” food (having adequate shelf life) to be shipped to fresh market while the less desirable, the green and the over ripe and bruised fraction, could be sent to a processing plant where quality could be enhanced by appropriate bioprocessing techniques (McClure, 1995).

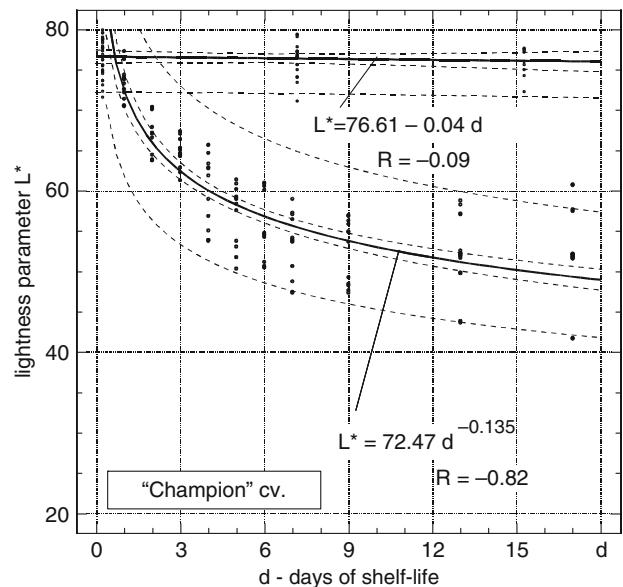

The change of fruit color as a result of storage, shelf-life, and bruising

The ground color of blush dependent on sun rays during growing. In this case, the low value of L^* parameter indicates dark skin of fruit. After five months of storage the color of apples was stable, however, some changes of color components at shelf-life were observed. The increases of the L^* coordinate in this case indicates, that the apples seem to become brighter during the shelf-life.

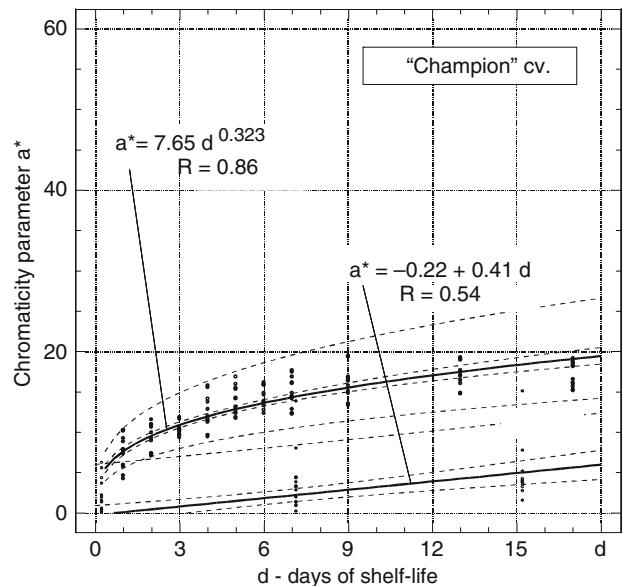

Some differences in color in 3-D Figures on the cube of color coordinates, where the lightness L^* and chromaticity coordinates of a^* and b^* of storage apple were presented by Dobrzański and Rybczyński (2002). For most apples, chromaticity a^* ranges negative values representing light green of the base color. The most sensitive parameter a^* , indicates blush reaching the values over 40. Further, the storage of apples for two additional months does not change the color of fruits, however, slight differences for all quality classes are observed.

Dobrzański et al. (2006), analyzed the $L^*a^*b^*$ color coordinates of bruised apples during the shelf-life (see also *Fruits, Mechanical Properties and Bruise Susceptibility*). More distinct differences are visible on the base color of fruit. The lightness coordinate L^* is stable during the shelf-life; however, darkening of apple increases each day and L^* parameter rapidly decrease indicating bruising after 5 days (Figure 2).

The blush color consists of more intensive components, which is frequently the reason why bruising is invisible on this surface. Only the component of red color presented by a^* decrease after bruising, while slightly increases at shelf-life (Figure 3). The red less skin of Champion apples indicates a^* value near zero. However, the bruising caused browning of tissue, which appearing intensity of red color component on the skin and increase of the index a^* . The red color of bruising is close to the blush color, being invisible on this area, while, the bruising appears on the base color of the opposite side of fruit.

Physical Properties of Raw Materials and Agricultural Products, Figure 2 The lightness coordinate L^* of ground color at shelf-life of Champion apples and the change of color after bruising.

Physical Properties of Raw Materials and Agricultural Products, Figure 3 The chromaticity coordinate a^* of ground color at shelf-life of Champion apples and the change of color after bruising.

The value of the chromaticity parameter a^* indicates the blush affecting the cosmetic's appearance. However, after 2 days of shelf-life the bruising on this area of base color looks not acceptable for the consumer.

Light scatter imaging

As light passes through tissue, cellular contents such as starch granules, cell walls, and intercellular spaces cause scatter. The extent of scatter of collimated light such as a laser beam may change during ripening due to changes in cell-to-cell contact and compositional changes. Measurement of the scatter using computer vision may thus provide an indirect indication of textural changes. Significant correlations between mechanical properties and image size have been shown in apples (De Belie et al., 2000b) and tomatoes (Tu et al., 2000). Interest is increasing in the development of machine vision systems to replace human visual inspection. One of the major requirements in developing machine vision systems for sorting fruits and vegetables is the ability to analyze an image accurately and quickly (Abbott and Harker, 2003).

Summary

Agricultural raw materials are essential components for products processed by industries. The top characteristics of raw materials and agricultural products, definitions, and methods for determination of the physical properties of agricultural materials are presented.

A measurable property which describes physical state of raw agricultural material at any given condition and time can be defined as a physical property of product. The physical properties of raw materials and agricultural products are wide knowledge being used in the farming, planting, harvesting, drying, freezing, processing and storage. Some characteristics, such as color, mechanical and rheological properties, thermal and electrical resistance, water content, and other physical quantities give excellent description of product quality. According to physical properties estimation, numbers of methods are available for quality detection in raw materials and are essential for ensuring competitive agricultural product.

PHYSICAL PROPERTIES FOR SOIL CLASSIFICATION

Johan Bouma
Soil Science Department, Wageningen University,
Rhenen, CA, The Netherlands

Definition

Soil Classification is the arrangement of soils into a hierarchy of groups on the basis of their similarities. There are many National Classification systems for different countries and two widely used international ones, Soil Taxonomy in the USA (Soil Survey Staff, 1998) and the World Reference Base (FAO, ISRIC and IUSS, 1998). Attention will be focused here on these two systems.

Introduction

General descriptions of soil classification systems and the underlying philosophy are well summarized in Eswaran et al. (2003) and in the *Handbook of Soil Science* (Summer, 2010). Attention will be confined here to the role being played by physical properties in defining the various categories. Any soil classification is the result of judgments being made as to the effects of soil formation processes that occurred in the past. Generally, five soil-forming factors are distinguished, as initially proposed by Jenny in 1941: parent material, topography, climate, biological factors, and time. Regarding the time aspect, some red tropical soils are millions of years old, while soils being formed in recent deposits are very young. Anything in between may be found in terms of age, whereby soil-forming processes in the past may have resulted in soils that can again act as parent material when the climate changes or when the original soil erodes and soil formation starts again after deposition at another location. Soils form in a given parent material by interacting physical, chemical, and biological processes, whereby physical processes related to water and temperature regimes are key driving factors. Topography has a major effect on the magnitude and direction of these processes as well as on the soil stability in a landscape. Water and temperature regimes during soil formation and the resulting physical soil properties are therefore logical choices when discussing physical properties for soil classification. Sometimes "man" is added as a sixth soil-forming factor because of his major impact on the earth and its soils. However, in the context of a geological time frame, man has only rather recently arrived on earth while his major (or better, often devastating) impact has only been felt after the industrial revolution. When discussing soil classification, three particular features may be surprising to outsiders and need therefore special consideration.

1. Soil classification focuses on the natural, undisturbed soil. This requires, for instance, mixing the top 30 cm of soil before a classification is made, to avoid possible changes in classification of a given soil as a result of

frequent human activity such as plowing. Be that as it may, different soil management may result in quite different properties of a given soil even if the classification remains the same and the land user will be particularly interested in such effects of management. The only aim of classification is, however, to correctly classify the soil being considered according to the system being followed. To avoid common misunderstandings about the aims of soil classification, Droogers and Bouma (1997) proposed the term *genoform* to represent soil conditions as defined in soil classification and the term *phenoform* for different functional properties as a result of different types of management in any given particular type of soil, such as, e.g., permanent pasture, arable land, and organic farming.

2. Modern soil classification systems try to use morphometric field characteristics as much as possible to allow on-site determination of the proper classification. If a classification would only be based on mineralogical, chemical, and physical analyses, the system would lose much of its attractiveness as the procedure would become very slow and discontinuous. The classifier is confronted with a given soil profile and is forced to hypothesize about the kind of interactions between soil-forming factors that are likely to have resulted in the soil being observed with all its morphological features. He has his experience to go by including analyses and observations of comparable soils and landscapes elsewhere, including measurements. There is, however, no possibility for experimental verification of hypotheses if only because conditions of the past cannot be reproduced. Examples to be discussed later will show that easily observable patterns of iron mottles (*Redoximorphic Features*) and occurrence of particular types of soil horizons can give indications about water and temperature regimes.
3. The relation between soil classification and soil mapping is not always clear to users of soil information. Soil maps show how natural soil bodies occur within a landscape. The delineated boundaries reflect the constraints of map scales and the conceptual landscape model of the surveyor who can only make a limited amount of soil observations by augering. The classification system is used to classify the soil bodies that have been observed in strategically localized soil pits or augerings. Broadening the interpretation from a point observation to the area of the mapping unit involves substantial generalization as map units may be quite heterogeneous, while sharp lines on the map separating different units are often arbitrary. The surveyor defines so-called "representative soil profiles" for a given map unit that is next being classified. This, however, involves largely unknown generalizations. Still, this step from point observation to mapping unit is very important for land users as the soil map report presents suitability assessments for any given mapping unit for a range of land uses. Land users will not be

particularly interested in soil classification, as such, but it is an important tool for soil survey as it helps to organize soil knowledge transferring it from point to point in a landscape.

The US soil taxonomy system

The US Soil Taxonomy system (Soil Survey Staff, 1998) consists of six categories: Orders, Suborders, Great Groups, Subgroups, Families and Series. For example, the soil studied by Droogers and Bouma (1997) was a loamy, mixed, mesic Typic Fluvaquent.

Order: Entisol: ..ent.

Suborder: Aquent: ..aqu.

Great Group: Fluvaquent: ..Fluv

Subgroup: Typic Fluvaquent: Typic...

Family: Texture (loamy), mineralogy (mixed), temperature regime (mesic)

Series: Not distinguished in the Netherlands. In the USA, the name of localities is often used where the soil occurs, e.g., Tama silt loam.

A number of differentiating characteristics are distinguished to allow placement of any soil into the classification system: (1) diagnostic epipedons (surface horizons), (2) diagnostic subsurface horizons, (3) other diagnostic soil characteristics, (4) soil moisture regimes, and (5) soil temperature regimes. These differentiating characteristics will now be discussed, emphasizing physical properties related to the water and temperature regime.

Ad (1): The *Folistic* epipedon (L.folia = leaf) contains high amounts of organic C but is not saturated with water for more than a few days after heavy rains. In contrast, the *Histic* epipedon (Gr.histos = tissue) is commonly saturated with water for long periods.

Ad (2): The *Albic* subsurface horizon (L.albus = white) is an eluvial horizon with a color that is largely determined by the color of the primary soil particles rather than of their coatings of iron and clay that have been removed by pedogenesis. The *Cambic* horizon (L.cambiare = to exchange) is formed by limited physical and chemical transformations, including effects of temporary saturation with water, leading to some limited mobilization of iron and manganese. The *Duripan* (L.durus = hard) is cemented by illuvial silica. The *Fragipan* (L.fragilis = brittle) is not cemented but very slowly permeable, resulting in stagnating water and limited root growth. The *Petrocalcic* (Gr.petra = rock) and *Petrogypsic* horizons are cemented by calcium carbonate and gypsum, respectively.

Ad (3): *Aquic conditions* arise in soils that currently experience continuous or periodic saturation and reducing conditions, mobilizing manganese and iron that may again oxidize in characteristic patterns when aeration occurs during drying. The soil matrix that has lost iron and manganese becomes grayish. The combination of gray and red colors (which is specifically defined in terms of color chromas and values) is called: *Redoximorphic Features*. Several types of saturation are distinguished:

Episaturation describes a perched water table on top of a slowly permeable subsoil horizon; *Endosaturation* describes saturation by a true water table as part of a continuous aquifer; and *Anthraquic* saturation describes controlled flooding such as that used to grow rice and cranberries. Each subtype is characterized by different types of *Redoximorphic Features*.

Ad (4): Six soil moisture regimes are distinguished:

- (a) Aquic: Signifies saturation with a reducing regime free of dissolved oxygen (to be observed by *Redoximorphic Features*).
- (b) Aridic: Occurs in arid climates; dry in more than half of the growing season and moist in less than 90 consecutive days.
- (c) Udic: Occurs in climates with sufficient rain in growing season. Rain plus stored moisture equals or exceeds evaporation.
- (d) Perudic: In climates where rainfall always exceeds evaporation in all months when the soil is not frozen.
- (e) Ustic: Is moister than Aridic and drier than Udic.
- (f) Xeric: In climates with cool moist winters and warm, dry summers.

Moisture conditions are defined in terms of soil water potentials, but regimes are usually estimated from limited experimental data, particularly with regard to the climate. Saturated conditions are estimated by observing *Redoximorphic Features*. For most Soil Orders, the moisture regime is used to determine placement of a soil at Suborder level.

Ad (5): Five soil temperature regimes are distinguished:

- (a) Cryic: Mean annual soil temp <8°C
- (b) Frigid: Same as previous but with higher summer temperatures
- (c) Mesic: Mean annual soil temperature between 8°C and 15°C
- (d) Thermic: Mean annual soil temperature between 15°C and 22°C
- (e) Hyperthermic: Same but >22°C

When the difference between mean summer and winter temperature is less than 6°C, “iso” is added to the name, e.g., isomesic. Soil temperature is used at the Family level of Taxonomy.

The world reference base for soil resources (WRB)

Since its endorsement by the IUSS (International Union of Soil Sciences) in 1998, the World Reference Base for Soil Resources (WRB) has established itself as a comprehensive soil correlation system. It has been translated in nine languages and is used all over the world. WRB is increasingly used as a soil classification system.

Much similarity exists with the US Taxonomy classification system, discussed above. Both systems try to use as many morphometric soil characteristics as possible to allow classifications in the field. But there are some differences as follows.

1. Soil Taxonomy uses climatic factors for its taxa but this is avoided in WRB, where using detailed climatic data as an overlay over soils data is preferred when preparing land evaluations.
2. WRB distinguishes 30 reference soil groups at the highest level of their system, whereas Soil Taxonomy has only 12 orders at the highest level.
3. WRB uses two categorical levels: Reference Soil Groups and Soil Units, the latter based on a set of diagnostic criteria “qualifiers,” while Soil Taxonomy uses six, as discussed above. WRB is “broad and shallow,” Soil Taxonomy is “small and deep.”
4. WRB uses more diagnostic horizons and properties than Soil Taxonomy.
5. Though there is considerable similarity between names of diagnostic horizons in WRB and Soil Taxonomy, the differences in definitions may be large as WRB has made an effort to simplify analytical requirements for classification. WRB also considers at the highest-level physical processes such as prolonged saturation with water (hydromorphy), while Soil Taxonomy does so at the second Suborder level. On the other hand, Soil Taxonomy defines and uses soil moisture and temperature regimes that are not being considered in WRB.

Physical properties and soil classification

Overall, physical properties play a relatively minor role in defining Taxa in soil classification systems. There are two notable exceptions: (1) soil saturation, as evidenced by *Redoximorphic Features* augmented by the measurements of water table levels, is clearly distinguished. Only Soil Taxonomy distinguishes soil moisture regimes at all levels, while soil temperature regimes are considered at family level. (2) Hardness of cemented soil horizons formed by soil processes displacing and accumulating silica, gypsum, or calcite, is also a notable physical property. But in general, chemical and biological processes rather than physical processes play a dominant role in defining differentiating criteria and, therefore, soil Taxa. Of course, chemical and biological processes can only occur when soils contain water and when water acts as a transporting medium. It is, therefore, difficult and somewhat artificial to separate the physical, chemical, and biological processes when defining different types of soil.

For practical applications, the reverse question as to how application of an existing soil classification system to a newly exposed soil profile can help define its soil physical properties is quite interesting as we will explore next.

Does soil classification allow relevant predictions of physical properties?

Both Soil Taxonomy and the WRB present a system that allows classifying soils all over the world. Several diagnostic criteria used in both systems to classify soils contain information about physical properties or processes, as

discussed above. Whether or not this allows relevant predictions depends on the spatial scale being considered. Land use studies at world level or for large regions depend on information obtained from soil classification as applied in small-scale soil maps because usually the alternative is to have no information at all. Here, soil classification and associated soil mapping is most valuable. For smaller areas, such as countries or regions within countries and certainly farms, the conclusion is often different because information from classification may be too qualitative, descriptive, or speculative to be of value for the specific management questions being raised. For example, when studying precision farming at farm level, we found that new quantitative approaches were necessary and that soil classification was of no value (e.g., Bouma et al, 2008). However, in regional studies, interpretations based on soil classification can be quite useful as a starting point for discussions with land users and politicians. Again, the alternative is to have nothing at all to start with, and interpretations based on soil maps are cheap and can be rapidly obtained, the more so since Geographic Information Systems are increasingly being used, even in developing countries. Interpretations can next be improved by initiating specific measurements or computer modeling studies that are, however, costly. But a cost/benefit analysis should always be made to balance the cost of additional procedures versus the added usefulness of new information obtained. Sometimes, qualitative information is adequate to answer certain questions and application of sophisticated simulation models represents overkill. Applying additional techniques can be done in steps and can in the end of the knowledge chain involve application of sophisticated state-of-the-art models and monitoring procedures (e.g., Bouma et al, 2008). Bouma (2001) has called this the “step-by-step” approach that also works well to gradually involve users of soil information into the decision process. Input of soil maps and soil classification in regional modeling studies can be quite helpful to improve the overall quality of the work because the implicit underlying assumption of flow equations being used in hydrological models is that porous media are isotropic and homogeneous, which they are not. Soil maps can help to better define boundary conditions for models in terms of occurrence of soil horizons and different soil units. Basic soil survey data can also be used to derive *Pedotransfer functions* that relate simple soil characteristics from the soil survey report to parameters used in simulation that are difficult and costly to measure (Pachepsky and Rawls, 2004).

Recently, Hydropedology has been proposed as an activity to combine pedological expertise in classification and mapping with expertise in measuring, monitoring, and modeling in soil physics and hydrology. This combines the best of two worlds: hydrologists can thus obtain more realistic representations of land areas for their models, while pedologists can improve their interpretations of soil maps by moving beyond qualitative and descriptive procedures (Lin et al., 2006). A representative example for

hydropedology was presented by Vepraskas et al. (2006), combining an analysis of *Redoximorphic Features* with use of a simulation model for regional water dynamics.

Summary

Soil physical properties play a minor role in defining differentiating criteria for soil classification. But soil moisture regimes, including saturation as deduced from *Redoximorphic Features*, and soil temperature regimes are being used as well as the hardness of various soil horizons with accumulations of silica, gypsum, and carbonate. Application of an existing soil classification system to a new soil allows estimates of physical soil properties of various soil horizons that are useful as a first step for regional characterizations of water and solute movement that can next be improved by computer simulation. The new discipline of hydropedology thus combines descriptive, often qualitative, expertise from soil mapping/classification with quantitative expertise from hydrologists.

PHYSICAL PROTECTION OF ORGANIC CARBON IN SOIL AGGREGATES

Tiphaine Chevallier

UMR Eco&Sols, Functional Ecology and Biogeochemistry of Soils and Agro-Ecosystems, Institut de Recherche pour le Développement (IRD), Montpellier, France

Definitions

Soil organic carbon (SOC): Soil organic carbon refers to the carbon occurring in the soil organic matter (SOM). In soils, carbon is either organic (SOC) or inorganic (mainly carbonates, CaCO_3). SOM comes from all living and dead organisms (roots, litter, fauna, microfauna, and microorganisms).

Soil aggregates: Soil aggregates are organic and mineral particles bound to each other more strongly than to adjacent particles (<http://soils.usda.gov/sqi/management/fils/RESQIS3.pdf>; http://ed.fnal.gouv/trc_new/pdandp/soil_research/soilaggregates.html). Aggregates are often separated with their ability to resist stresses such as wetting followed by shaking in water (Yoder, 1936; Kemper and Rosenau, 1986; Kay and Angers, 1999). They are named water-stable aggregates. There are also named after their size: macroaggregates ($>250 \mu\text{m}$) and microaggregates $50–250 \mu\text{m}$ (Tisdall and Oades, 1982; Elliott, 1986) ([Soil Aggregates, Structure, and Stability](#)).

Physical protection of soil organic carbon in soil aggregates: This term pools all the physical processes that limit microbial activities and then explain the stabilization or the accumulation of SOC in soil aggregates (Balesdent et al., 2000; Six et al., 2002).

Introduction

Sufficient soil organic matter (SOM) must be retained for biological, chemical, and physical soil functioning. Appropriate levels of SOM ensure soil fertility, maintain soil structure, minimize soil erosion, and preserve soil biodiversity (Feller and Beare, 1997). The sequestration of carbon in soil is also becoming increasingly important because of concern over rising levels of CO_2 in the atmosphere (Feller and Bernoux, 2008). Because soil is considered to be a larger pool of carbon than biomass and atmosphere, many studies try to identify and quantify the processes that limit soil carbon mineralization. Three main processes are usually distinguished: SOC can be (1) physically stabilized, that is, protected from mineralization by aggregation, (2) stabilized physically and chemically by intimate association with mineral particles, especially clays ([Clay Minerals and Organo-Mineral Associates](#)), and (3) biochemically stabilized by the formation of recalcitrant organic compounds (Six et al., 2002). The first process, physical protection of SOC in soil aggregates, is indicated by the positive influence of aggregation on the accumulation of SOC (Angers, 1992). Indeed, SOC

can be protected from microbial decomposition within macroaggregates ($>250\text{ }\mu\text{m}$) and within microaggregates ($<250\text{ }\mu\text{m}$) (Bossuyt et al., 2002; see Figure 1).

SOC protection

Tisdall and Oades (1982) and Elliott (1986) initiated many studies on the interaction between soil aggregates and soil organic matter dynamics (see *Organic Matter, Effects on Soil Physical Properties and Processes*). In the 1990s and even recently, lots of papers established SOC turnover with their location, inside or outside water-stable soil aggregates (Puget et al., 1995; Besnard et al., 1996; Puget et al., 2000; Six et al., 2000; Denef et al., 2004; Six et al., 2004). The lower turnover of SOM signed a protection from microbial attack when located in soil aggregates. Those studies displayed lower turnover for plant residues (particulate organic matter, POM) located in soil aggregates (40–49 years) compared to plant residues not located in soil aggregates (19–27 years) (Golchin et al., 1995). The main site of SOC protection seems to be especially situated in microaggregates with a SOC turnover of 209 ± 95 years compared to a SOC turnover within macroaggregates of 42 ± 18 years (Six et al., 2002; Denef et al., 2004; Pulleman and Marinissen, 2004).

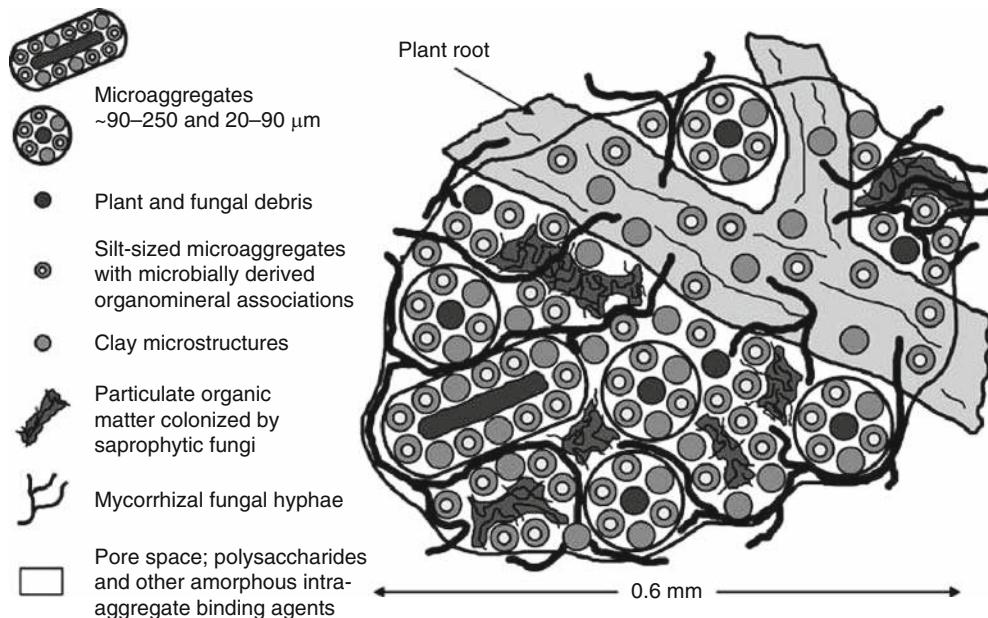

In addition, other studies evaluated the pool of aggregate-protected SOC by comparing crushed and uncrushed soil mineralization (Gupta and Germida, 1988; Beare et al., 1994; Balesdent et al., 2000; Chevallier et al., 2004; Pulleman and Marinissen, 2004; Razafimbelo et al., 2008). The additional carbon mineralized with soil crushing is considered to be the amount of aggregate

protected SOC. Protected SOC within aggregates is about 1–2% of the total SOC (Balesdent et al., 2000), but it can represent up to 40% of easily mineralizable SOC (Chevallier et al., 2004).

The main explanations for this protection against microbial decomposition are

- Substrates are inaccessible to microbes or enzymes because adsorbed on clay surfaces, or located in pores small enough to protect SOC against enzyme attack by physical exclusion (Sollins et al., 1996; Strong et al., 2004; Zimmerman et al., 2004).
- Poor water and air conditions to microbial activity (Sexstone et al., 1985; Young and Ritz, 2000).
- Hydrophobicity of SOM in soil aggregates (Chenu et al., 2000; Goebel et al., 2005).
- A Lack of appropriate microbial population to decompose SOM, indeed (microbial biomass, activities, and genetic structure are modified in soil aggregates) (Elliott, 1986; Gupta and Germida, 1988; Ranjard et al., 2000; Mumey et al., 2006).

Physical protection of SOC in soil aggregates depends on aggregate dynamics and aggregate formation, which depend on soil type, especially the amount of clay and oxyhydroxyde particles, soil management, i.e. soil tillage, soil occupation (see *Management Effects on Soil Properties and Functions*), root and soil fauna activities (see *Earthworms as Ecosystem Engineers*), and drying–rewetting or freezing–thawing events (Six et al., 2004). However, SOC stabilization is a combination of different mechanisms: physical, biochemical, and chemical mechanisms that do not play separately. The degree and amount

Physical Protection of Organic Carbon in Soil Aggregates, Figure 1 Conceptual diagram of aggregate hierarchy illustrating microaggregates inside a macroaggregate (Jastrow et al., 2007).

of protection of SOC depends on the chemical and physical properties of the mineral matrix and the morphology and chemical structure of the organic matter (Baldock and Skjemstad, 2000). Although organizing and quantifying the different processes are still difficult (Kogel-Knabner et al., 2008; Von Lützow et al., 2008), soil aggregation can be a master integrating variable that both controls and indicates the SOC stabilization status of a soil (Plante and McGill, 2002; Six et al., 2004; Jastrow et al., 2007). Soil aggregation is initiated by microbial decomposition of plant residues (Martens, 2000; Abiven et al., 2007) (see *Microbes and Soil Structure*). Indeed the microbial activity enhances the internal cohesion and hydrophobicity of aggregates, that is, the aggregates' stability (Cosentino et al., 2006). Within soil aggregates, particulate organic matter and SOC turnover are slowed down, so other SOC stabilization mechanisms can occur, such as getting a chemical recalcitrance and/or being adsorbed to clay particles (Baldock and Skjemstad, 2000; Kaiser and Guggenberger, 2000; Puget et al., 2000; Balabane and Plante, 2004; see Figure 1).

Conclusion

With respect to enhancing SOC protection against microbial mineralization, the main goals should involve maximizing the stability of soil microaggregates, the main site of soil physical protection of SOC, with an optimum rate of soil macroaggregate turnover to allow incorporation and stabilization of fresh SOC (Plante and McGill, 2002). Further studies on SOC stabilization should try to specify the combination of the different processes, i.e. physical, chemical, and biochemical processes. What are the main different combination with the soil type, occupation, and management?

PHYSICAL (MECHANICAL) WEATHERING OF SOIL PARENT MATERIAL

Stefan Skiba

Department of Pedology and Soil Geography, Institute of Geography and Spatial Management, Jagiellonian University, Cracow, Poland

Definition

Physical (mechanical) weathering is the granular disintegration of rocks and soils.

The processes of rock and mineral breakdown and disintegration taking place in the upper part (surface) of the lithosphere; minerals and rocks, which are the result of magmatic processes, diagenesis and metamorphism are not stable in the conditions on the surface and near the surface of the earth: they undergo changes that lead to the formation of new stable phases. Physical (mechanical) weathering is disintegration of rocks into blocks and grains of different size (block weathering, granular disintegration). Mechanical weathering leads to alterations in

Physical (Mechanical) Weathering of Soil Parent Material,
Figure 1 Insolation weathering on Hamada (Sahara Desert).

Physical (Mechanical) Weathering of Soil Parent Material,
Figure 2 Block weathering in Bieszczady Mts (Carpathians).

the rock cohesion, and the main causes are temperature (insolation, frost weathering) and humidity changes (salt weathering, clay rocks weathering). As a result of physical (mechanical) weathering, covers of various fraction are formed (rock, rubble, sand, silt, clay), and they provide parent material for pedogenesis. Genesis of the weathering covers, together with their evolution within the morphodynamic and soil-forming processes, determines the variety of taxonomical units that form the actual soil cover and its agrotechnical properties.

PHYSICO-CHEMICAL METHODS FOR REMEDIATION OF CONTAMINATED SOILS

Toshko Raytchev, Svetla Rousseva
Nikola Poushkarov Institute of Soil Science,
Sofia, Bulgaria

Definition

Contaminated soils are soils with increased content of compounds with harmful impact on vegetation, animals, and humans. Major contaminants are associated with heavy metals, organic compounds (mostly polyaromatic hydrocarbons, polychloride biphenyls, or chlororganic pesticides), and fertilizers.

Remediation technologies of contaminated areas are based on several basic approaches:

Activation of physico-chemical interactions, leading to the development of appropriate structural formations between the contaminants, the soil adsorbent, and the applied ameliorants. The aim is to influence the mobility of the contaminants.

Decreasing the mobility of the contaminants by their precipitation or co-precipitation in a form of chemical

compounds, which are less available for the vegetation. Organo-mineral liming is a traditionally applied method used mostly for detoxification of soil acidity as well as for soils contaminated with heavy metals and arsenic.

Increasing the mobility of the contaminants by intensification of their extraction through phytoextraction or applying of modified electrokinetics methods. Two strategies have been suggested: (a) *chelating* – addition of complex synthetic agents such as diethylene-triamine-penta-acetic acid/DTPA, nitrile-triacetic acid/NTA, or other natural products and (b) *soil acidification* – application of organic or inorganic acids (acetic or nitric) or fertilizers (as ammonium). Weakness – possibility for leaching of the contaminants toward subsoil or deeper layers.

Phytoremediation uses plants for transfer, stabilization, or annihilation of soil contaminants. It includes:

Phytostabilization – growing plants, which are tolerant to contaminants in the existing limits and stabilize the surface of contaminated soils.

Phytostimulation – is applied when the plants are stimulated by the existing excessive levels of the element or the group of compounds and/or their higher concentrations.

Phytoextraction – is using the opportunities of certain plant species to extract from soil or substrate excessive quantities of certain ions or compounds.

Phytoremediation is mainly applicable to contamination with heavy metals, pesticides, and petrochemicals. Weakness – the time requirements for economically viable recovery.

Electrokinetic remediation involves the application of direct current of low voltage through the soils between ceramic electrodes. Metal ions, ammonium ions, and positively charged organic compounds move toward the cathode. Anions (chlorine, cyanides, fluorine, nitrate and negatively charged organic compounds) are moving toward the anode. Extraction of contaminants is achieved by electroplating of the electrodes, precipitation or co-precipitation on them, pumping water from the space around electrode, or formation of complexes with ion-exchange resins.

Soil leaching – separation of contaminants from the selected soil volume in water system based on the size of soil particles. The leaching water may contain detergents, weak acids, or chelated agents to enable displacement of organics and heavy metals. Disadvantages – the method alone is not sufficient for remediation of contaminated soil.

In situ thermic methods are ways to transfer or mobilize of contaminants in soil and groundwater by heating. Movement through the soil is directed to underground drills for collecting and transferring toward the surface and subsequent implementation of some of the many available methods for remediation. The major advantage is the possibility for soil treatment without its digging and shifting.

PHYSICS OF NEAR GROUND ATMOSPHERE

Evgeny V. Shein, Tatiana A. Arkhangelskaya
 Department of Soil Physics, Moscow State University,
 Moscow, Russia

Synonyms

Micrometeorology

Definition

Physics of near ground atmosphere is a branch of science studying physical processes within the near ground atmosphere mostly affected by the Earth surface.

Introduction

Physics of near ground atmosphere studies the processes of solar energy absorption and transformation in *soil–plant–atmosphere continuum*, and the regularities in forming the wind regime of plant environment. *Near ground atmosphere* is characterized by drastic changes of meteorological elements with height: the vertical gradients of wind speed, air temperature, and air humidity within the *near ground atmosphere* are tens and hundreds times greater as compared to corresponding gradients in the upper air layers. These gradients originate from *surface phenomena* – the interactions between soil, vegetation, air, and both short-wave and long-wave radiation. Physical processes, which take place within the *near ground atmosphere*, influence directly the agroecosystems' functioning and determine their productivity. So, we may point out that it is quite necessary for agrophysics both to develop the qualitative studies of the physical mechanisms of micrometeorological processes and to carry out the quantitative estimations of the intensity of energy and substance fluxes within the *near ground atmosphere*.

Physical processes

The Sun is a primary source of energy which is supplied to and redistributed in the *soil–plant–atmosphere continuum*. Solar radiation is a thermal radiation by its physical nature. Its spectrum and intensity are determined by the solar surface temperature (about 6,000 K) and are described by the laws of Stefan-Boltzmann, Planck, and Wien. About 99% of solar radiation is a shortwave radiation with wavelengths of 1×10^{-7} to 4×10^{-6} m. Solar spectrum includes the visible light with wavelengths $4-7.6 \times 10^{-7}$ m (47%), the infrared radiation with wavelengths of more than 7.6×10^{-7} m (44%), and ultraviolet radiation with wavelengths shorter than 4×10^{-7} m (9%). The maximum of the solar spectral intensity corresponds to the wavelength of 4.75×10^{-7} m in the green-blue area of visible spectrum (Khromov and Petrosyants, 1994).

Practically, all ultraviolet solar rays with wavelengths shorter than 2.9×10^{-7} m are entirely absorbed by ozone

when propagating through the Earth atmosphere and therefore do not achieve the Earth surface. Besides, the water vapor present in the atmosphere absorbs radiation within several intervals of visible and near-infrared spectral areas. So, the resulting spectrum of solar radiation coming to the Earth surface differs to some extent from that at the upper boundary of atmosphere.

The solar radiation income onto any surface is quantitatively characterized by the amount of energy supplied to unit surface area per unit time interval (W m^{-2}). In the case of parallel rays coming from a remote source, such as the Sun is for the Earth, one may speak about the intensity of radiation flux, which is equal to the amount of radiant energy, passing across the unit area section perpendicular to the direction of rays per unit time interval (W m^{-2}).

The intensity of solar radiation flux at the upper boundary of atmosphere varies throughout the year due to annual variability of the Earth–Sun distance. The average Earth–Sun distance is 1.496×10^{11} m; the corresponding value of solar radiation flux intensity is the solar constant $S_0^* = 1.367 \times 10^3 \text{ W m}^{-2}$ (Khromov and Petrosyants, 1994). About 30% of radiation coming to the upper boundary of atmosphere is reflected by the upper edge of clouds and is dissipated back to the cosmic space. Another 23% of incoming radiation is absorbed by water vapor, clouds, aerosol particles of atmospheric impurities, and ozone. Some of the remaining solar radiation is scattered within the atmosphere by atmospheric gases and aerosols. Due to these processes, the Earth surface gets both the direct solar radiation coming right from the Sun disk without changing the direction of rays while propagating through atmosphere and the diffuse sky radiation coming from the whole sky – from all directions possible. According to the Rayleigh law, the intensity of scattering of solar radiation within the atmosphere is inversely proportional to the wavelength of scattered rays: ultraviolet and blue rays are scattered much more effectively than red and infrared rays. Maximum of spectral intensity of scattered radiation is in the blue area of spectrum. This results in blue color of sky. The spectrum of direct solar radiation which avoided scattering is shifted to yellow area. The closer is the sun disk to the horizon and the longer is the way passed by solar beams propagating through atmosphere, the greater is the portion of scattered blue rays and the more yellow or even red is the Sun disk as seen by the on-ground observer.

The amount of direct solar radiation coming to the unit surface area per unit time interval is referred to as direct insolation of this surface. The direct insolation of a horizontal surface S' and the direct solar radiation flux S are related by formula $S' = S \sin h_{\text{sun}}$, where h_{sun} is the height of the Sun. The sum of direct insolation S' and the diffuse sky radiation D is (global) insolation, or global radiation Q : $Q = S' + D = S \sin h_{\text{sun}} + D$. The direct insolation of horizontal surface typical for July midday in Moscow is about 700 W m^{-2} for a clear sky and about 400 W m^{-2} for average cloudiness. The corresponding

values for global insolation are about 820 W m^{-2} and about 550 W m^{-2} .

Part of solar radiation is reflected from the Earth surface. The percent of reflected radiation Q_r depends on surface properties. The ratio $Q_r/Q = \alpha$ is the surface albedo (%). The albedo of a fresh snow is 80–85%, the albedo of dry soil varies between 15% and 35%, and the albedo of moist soil varies between 5% and 14%. The less the albedo is, the greater portion of solar energy is absorbed. Therefore, the lessening of surface albedo results in some extra amount of heat supplied into soil. In agrophysical practice, albedo is decreased by covering surface with dark films or black materials such as peat, soot, and the like.

It is important for agrophysical purposes and for the studies of production process that part of both incoming and reflected solar radiation may be accumulated during plant photosynthesis (Larcher, 2003). This part is a photosynthetically active radiation (PAR) with wavelengths $3.8\text{--}7.1 \times 10^{-7} \text{ m}$. About 50% of total solar radiation income to Earth surface is photosynthetically active radiation. But, only 1–3% of PAR is accumulated in the products of photosynthesis, and only rarely, in the cases of tropical forests, the sugarcane plantations and similar this value approaches 5%, and in the artificial conditions, 8% (Shein and Goncharov, 2006).

Most of the total shortwave solar radiation income is absorbed by the Earth surface and is transformed into heat. The heated surface emits its own thermal radiation with spectrum and intensity obeying the laws of Stefan-Boltzmann, Planck, and Wien – i.e., the same laws which describe the thermal emission of the Sun. But the temperature of the Earth surface is about 300 K, which is much less than that of the Sun surface. So the spectrum of Earth surface radiation is shifted to the long-wave interval of 4×10^{-6} to $1.2 \times 10^{-4} \text{ m}$ with maximum of spectral intensity at $1 \times 10^{-5} \text{ m}$. The intensity of surface long-wave radiation B_s depends on the surface temperature T_s and may be calculated using formula $B_s = \delta\sigma T_s^4$, where $\sigma = 5.7 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$ is a Stefan-Boltzmann constant, $\delta = 0.95$ is emissivity factor for the gray body. For $T_s = 15^\circ\text{C} = 288 \text{ K}$, the intensity of surface thermal radiation $B_s = 373 \text{ W m}^{-2}$.

The long-wave surface radiation has a far lower air penetrating capability as compared with the shortwave solar radiation. The atmosphere is almost transparent for short-wave radiation and is almost opaque for long-wave radiation. So, about 80% of Earth surface thermal radiation is absorbed by *near ground atmosphere*, which results in heating of the latter. *Near ground atmosphere* is also heated due to the absorption of solar energy, though the portion of solar energy absorbed in the atmosphere is relatively small – about 15% of the whole income. The convective heat exchange within the *soil-plant-atmosphere continuum* and the condensation of water vapor evaporated from the Earth surface or transpired by plants also add to heating of the *near ground atmosphere*. But the main mechanism of this heating is the absorption of

long-wave radiation. The heated atmosphere also emits long waves obeying the same physical laws of thermal emission which describe the thermal emission of the Sun surface and the Earth surface. As the temperature of *near ground atmosphere* is close to the temperature of the Earth surface, the spectrum of atmospheric thermal radiation is close to that of the Earth surface. Atmosphere emits invisible long-wave radiation in the middle and the far-infrared spectrum areas. Due to the low penetrability of atmosphere for the long waves, they are absorbed and reemitted within the Earth-atmosphere continuum for many times before leaving the atmosphere and dissipating in the cosmic space. The part of atmospheric thermal radiation returns back to the Earth surface. This long-wave back radiation of atmosphere B_a is practically completely (95–99%) absorbed by the Earth surface being an important source of heat in addition to the solar radiation.

The radiation balance R of the Earth surface is a sum of all shortwave and long-wave radiation coming to and from the Earth surface:

$$R = S' + D - \alpha(S' + D) - B_s + B_a.$$

The difference between the Earth radiation and the back radiation of atmosphere is an effective radiation of Earth surface: $B_{\text{eff}} = B_s - B_a$. Taking into account $Q = S' + D$, the expression for the radiation balance may be rewritten as:

$$R = Q(1 - \alpha) - B_{\text{eff}}.$$

The radiation balance of Earth surface varies throughout day and night: in the daytime R is positive, during nighttime R is negative. The annual changes of the diurnal pattern of radiation balance are caused by changes in the height of the Sun and the day length. In Moscow, the clear sky midday radiation balance is about 500 W m^{-2} in July and only about 40 W m^{-2} in January. Radiation balance R is positive from 5 a.m. to 19 p.m. in July and from 10 a.m. to 14 p.m. in January (Khromov and Petrosyants, 1994). When speaking about the long-term average planetary data, the radiation balance is an incoming part of the Earth surface heat balance. All-planetary yearly Earth surface radiation balance is positive (Slatyer and McIlroy, 1961).

The essential constituents of Earth surface heat balance are the convective heat exchange between the Earth surface and the *near ground atmosphere* and the heat spent during evapotranspiration or released during condensation of water vapor.

Natural and forced convection are different: the natural convection is related to the upward movement of heated air, and the forced convection is related to wind and the wind-caused additional mixing of air masses. So, the intensity of convective heat exchange between the Earth surface and the *near ground atmosphere* depends on the surface temperature, the air temperature, and the wind speed.

It is important to accentuate the role of wind as a factor playing an important role in the formation of both heat and

humidity balance between *near ground atmosphere* and soil (Van Wijk, 1963). Lateral incomes of heat and water vapor and the heat exchange in the air layers are based on wind – the horizontal movement of air. The wind is a result of nonuniform heating of Earth surface. Therefore, the movement of air masses transfers heat from the places which are more heated by the Sun to the cooler places. In agrophysics, the local circulation is usually studied. It is necessary to distinguish between the horizontal and the vertical mass and heat transfers. The vertical transfer is primarily based on the mechanism of turbulent diffusion and the horizontal one, on advection. Turbulent diffusion is the result of movement of some air volumes, air currents at the boundaries between air layers. In laminar layers, the heat and vapor transfers are realized through the molecular diffusion due to the chaotic Brownian movement of molecules. At turbulent diffusion, these transfers are much faster and, say, more effective due to the mechanism of air currents. In most cases when studying phenomena at the landscape scale, the average free path of separate currents is of much higher order than that of separate molecules. So, the intensity of mass and heat transfer by turbulent diffusion is much higher than that by molecular one.

It should be said separately about the phenomenon of advection – the movement of air masses from other parts of the Earth to the place of interest. If the incoming air has a higher temperature, one can speak about the advection of heat; if the incoming air has a lower temperature, one can speak about the advection of cold. Due to the advection, the convective heat exchange is an incoming part of the planetary surface heat balance (Slatyer and McIlroy, 1961). This fact may seem to contradict the physics of absorption and redistribution of heat in *near ground atmosphere*: indeed, the sunlight passes through the atmosphere almost without being absorbed and therefore almost without heating the atmosphere. The absorption of solar energy and its transfer to heat occurs at the Earth surface, which is heated and therefore emits the long waves. It is this long-wave radiation emitted by the Earth surface which is the main source of heating the *near ground atmosphere*. Therefore, the *near ground atmosphere* is heated by the Earth surface, and the opposite is not true. The fact that the average planetary convective heat flux is directed from the *near ground atmosphere* to the Earth surface is related to advection: air which was heated after absorbing the surface radiation in the hot areas of planet moves to the cooler areas and transmits the heat it brought to the local surface by means of convective heat exchange.

So, both the radiation and the convection are the incoming components of the annual heat balance of planet surface. An essentially negative, spending component of the surface heat balance are the heat losses related to evapotranspiration. These heat losses depend on the surface temperature, air temperature, surface moisture conditions, air humidity, and wind speed. They distinguish between the evaporation from soil or water surface and vegetation

transpiration; the combination of these two processes is evapotranspiration.

The last part of the Earth surface heat balance is the heat flux into the soil G . The heated surface transmits the heat not only to the *near ground atmosphere* but also into the deep soil layers too. The amount of energy transferred to the deep soil layers depends both on the micrometeorological conditions at the surface and on *soil physical properties*, which are related to such relatively permanent soil properties as *soil bulk density*, *soil texture*, *parent material*, *organic matter*, *soil aggregation*, and *surface roughness*. Besides, *soil physical properties* are continually changing during *wetting and drying of soil*.

The surface heat balance equation may be written as follows:

$$Q(1 - \alpha) - B_{\text{eff}} - H - LE - G = 0,$$

where H is the convective heat flux, E is the intensity of evapotranspiration per unit surface area, $L = 2.514 \times 10^6$ J/kg is the specific heat of evaporation for water.

In the daytime Q is always positive and at night $Q = 0$. The effective radiation of the Earth surface B_{eff} may be both positive and negative, depending on the state of *near ground atmosphere*. The convective, evaporative, and soil heat fluxes also may be both positive and negative.

The physics of interactions between the *near ground atmosphere* and the Earth surface is basically the same for any types of this surface. The physical mechanisms discussed above work for bare soil, for the soil covered by vegetation or by snow, and even for open water surface. The same mechanisms determine the heat fluxes within the vegetation cover and the *energy balance in agrosystems*.

Conclusions

The physical processes in *near ground atmosphere* are interrelated processes. Besides, they are quick processes: the physical picture of what is happening in the *soil–plant–atmosphere continuum* may change dramatically within a few seconds. Examples are the abrupt change of the Sun disk state or a sudden blast. The physical processes in the *near ground atmosphere* are also characterized by the spatial variability, which is related to the *spatial variability of soil physical properties*, the vegetation cover properties, and the microrelief conditions. Open question is the quantitative estimation of energy and substance fluxes in *soil–plant–atmosphere continuum* for small time and space scales, which is required to forecast the ecosystem functioning during possible *climate changes* and also to create artificial agroecosystems.

PHYSICS OF PLANT NUTRITION

Evgeny V. Shein
 Department of Soil Physics, Moscow State University,
 Moscow, Russia

Definition

Physics of plant nutrition is the part of agrophysics that deals with the physical processes of mineral nutrient exchange, migration, and root consumption from soil.

Introduction

Being a part of agrophysics, physics of plant nutrition deals with the physical fundamentals of exchange of ions in diffusive double layer (DDL), their transfer to roots and within plants. As a rule, studies and the description of mentioned processes are conducted on a microscale; they consider equilibrium exchange and transport of separate ions in soil and root, special features of this transport, connected with characteristics of ions, soil solid phase and porous media, and root systems as well (Shein and Goncharov, 2006).

In some amount or other, 16 elements, forming groups of macro-, secondary, and microelements, are needed by a majority of plants. Each element plays its specific role. However, the fact that 95% of a plant consists of C, H, and O, which are received by plants from CO₂ of air and soil water, should be considered. The rest of the 13 elements are taken out by plants from soil solute in ionic form, though sometimes plants can take out and assimilate S and Cl from air in the form of SO₂ and Cl₂. A unique ability of leguminous plants to fix atmospheric nitrogen due to symbiosis with *Rhizobia* in root zone should be remembered as well. Sodium, silicon, cobalt, and vanadium can promote yield growth, but they do not determine its forming. Sometimes Na performs the function of K,

i.e., in beet plants, and Co can play a significant role in generating B₁₂, which takes part in nitrogen fixation by *Rhizobia*.

The importance of this part of agrophysics is determined by the fact that the physics of plant nutrition is central to the scientific regulation of the production process, the use of mineral fertilizers, evaluation and prognosis of plant growth in relation to features of nutrient transport in soil, and their availability to plants.

Physical processes

Two processes – convection and diffusion – are the main physical processes providing nutrient delivery and transfer to roots in ionic form. Convection is a movement of substances with solute mass flux. This flux to a vegetating plant is always supported by transpiration. That is why this mechanism of ion transport to root and throughout the whole plant is quite possible. Additionally, plants are able to take up selectively some ions, which are most important for their growth and development. This transfer is affected by concentration drops, as ion concentration in and around roots is less than that in soil solute, and the lower it is, the higher is the demand. Correspondingly, the more is concentration gradient between root surface and soil solute, the faster is a diffusive flux, and at that a plant is able to consume the most part of positively charged biophile elements from absorbed state by means of exchange reactions on DDL–soil solute and soil solute–root surface interfaces. Appropriate nutrient ions are delivered due to diffusion and convective solute flux to roots. A presence of these ions in soil solute is regulated by exchange reactions with corresponding DDL ions, which in their turn are also adjusted by activities (concentrations) of consumed ions in a solute.

The important role of *convection* in substances movement and their uptake by roots was revealed in the experiment, undertaken by Barber (1988). It might be suggested, that as a large amount of soil solute is delivered to plants to support transpiration flux, this very transfer would provide a receipt of a major part of nutrients. Barber used the balance method: knowing element content in a plant and its transpiration ratio (amount of water needed to form a unit of dry biomass), a concentration of this element in soil solute, necessary to draw up a balance, was calculated. Furthermore, a concentration of an element obtained in this balance calculation was compared with its real one in soil solute. If element concentration in soil solute is higher than the rated one, a supply of this element for plants can be provided by a convective flux alone. If lower, and element is taken by means other mechanisms, primarily by diffusion. The results of Barber experiment are given in Table 1.

Thus, it is obvious that K and P ions are taken from solute more rapidly than by convection. These ions are transferred by means of diffusion. It should be noted therewith, that ion diffusion in soil is a rather long-term process. Indeed, the diffusion coefficient for a majority of solute

Physics of Plant Nutrition, Table 1 A possibility of element takeover by plants in the form of convection with total transpiration flux

Element	Content in plants (mg g ⁻¹)	Necessary rated concentration in soil solute (mg L ⁻¹)	Real concentration in soil solute (mg L ⁻¹)	Possibility of element supply by means of convection
Ca	2.2	4.4	33.0	Possible
Mg	1.8	3.6	28.0	Possible
K	20.0	40.0	4.0	Impossible
P	2.0	4.0	0.5	Impossible

ions is no more than $1.73 \text{ cm}^2 \text{ day}^{-1}$. This coefficient is 1.71 for K^+ , 1.64 for NO_3^- , and 0.67 and $0.6 \text{ cm}^2 \text{ day}^{-1}$ for Ca^{2+} and Mg^{2+} respectively. At the same time, with porous media tortuosity and real water content in soil taken into account, it becomes necessary to use the effective coefficient of salt diffusion, which is usually two to three orders lower, instead of the diffusion one. According to Barber (1988), an ion of potassium can move no more than on 0.13 cm a day by means of diffusion, and H_3PO_4^- can move on yet less – only 0.004 cm a day. Thus, not only do ions move toward a root due to diffusion, but also a root itself is to “move,” to grow in order to get the needed amount of nutrients. Evidently, this factor of active root growth and development of new spaces in soil may determine nutrient supply for plants, and not just physical processes of convective and diffusive transfer of nutrients to roots. It is rather difficult to estimate the significance of this factor in direct experiments, as it is hard to separate processes of nutrient transfer to root due to a diffusion and root growth toward higher ion concentration. This kind of research can be held only with the help of mathematical modeling, making possible to assign individual parameters characterizing particular processes, and then to evaluate a relative influence of each parameter on resulting substance uptake one after another, assuming others to be constant. Let us look at this kind of model analysis with the help of mathematical model of nutrient consumption by root, developed by Barber and Cushman (1981).

Two major processes of ion transfer to root, a diffusion $(\frac{\partial c}{\partial t})_{\text{diff}}$ and a convection $(\frac{\partial c}{\partial t})_{\text{conv}}$, are described by the following equations:

$$\left(\frac{\partial c}{\partial t}\right)_{\text{diff}} = -D_h \frac{\partial^2 c}{\partial r^2}, \quad (1)$$

$$\left(\frac{\partial c}{\partial t}\right)_{\text{conv}} = v \frac{\partial c}{\partial r}, \quad (2)$$

where c is an ion concentration in pore solute, t is time, D_h is a hydrodynamic diffusion coefficient, r is a radius of a zone where nutrient consumption takes place, v is a macroscopic velocity of solute flux (i.e., an averaged movement velocity in soil capillaries).

In addition, an exchange of dissolved and absorbed ions takes place by a mechanism of instant linear absorption, i.e., according to the following equation:

$$c_3 = k_d \cdot c, \quad (3)$$

where c_3 is a concentration of an ion in absorbed state, k_d is a distribution constant.

This process produces an additional source-and-flow factor – J_s . As a whole, nutrient transfer to root can be expressed by an already known convective-diffusion equation, but written in cylindrical coordinates, as a flux to root is directed along a radius to a centrally set root

$$\frac{\partial c}{\partial t} = -\frac{1}{r} \cdot \partial \partial r \left(r D_h \frac{\partial c}{\partial r} + v c r_0 \right) \pm J_s, \quad (4)$$

where r_0 is a root radius.

A growth factor in the form of root growth coefficient K_r is also input, as well as a condition on root boundary in a form of nutrient consumption (J_r) according to Michaelis–Menten equation

$$J_r = \frac{J_{\max} \cdot K_m c}{1 + K_m c} - c_{\min}, \quad (5)$$

where J_{\max} is a nutrient flux in a root, maximum possible for a particular plant, K_m is the Michaelis constant, equal to an ion concentration in solute, at which the absorption reaches a half of its maximum value ($0.5 J_r$). Physically, this constant shows, how actively a plant can uptake nutrients from solute; the higher it is, the more active is a nutrient uptake by plant, c_{\min} is a minimum concentration of nutrients in solute, at which its uptake is possible.

Model development is based on the assumptions that soil is homogeneous, hydrodynamic diffusion and linear sorption rates do not depend on concentration, a root is cylindrical, and there is no microbial activity. These combined assumptions help to develop a numerical model and conduct its test for the sensitivity to particular parameters. A sensitivity test is a study of change in ion uptake by root at alternating change of each of model parameters. In a resultant notation, these parameters, both of plant and soil, are presented in Table 2.

Regarding these parameters, the analysis of K^+ uptake model results into the following. K^+ uptake mostly depends on root growth rate and radius (K_r and r_0 correspondingly), and it is these parameters change that causes maximum increase of the consumption. Soil parameters have much less influence on of K^+ uptake. At the same time, the Michaelis constant rise causes uptake decrease, which is the required result, as this parameter denotes a

Physics of Plant Nutrition, Table 2 The parameters of a model of ion uptake by plant roots

Plant parameters	Soil parameters
r_0 – root radius	c – nutrient concentration in pore solute
c_{\min} – minimum solute concentration, at which an uptake is possible	D_h – hydrodynamic diffusion
J_{\max} – the maximum possible uptake	K_d – distribution coefficient
K_m – the Michaelis constant	v – water flux to root
K_r – the parameter of root growth rate	

concentration, at which the absorption reaches a half of its maximum value. The more is this concentration, the less is the ability of a plant to uptake nutrients. The suggested physically validated model underlines parameters importance in regulation of ion flux in plant nutrition.

Conclusions

Nutrients delivery to roots, determining plant nutrition, goes in the form of convective and diffusive fluxes. Biophile elements like Ca^{2+} and Mg^{2+} can be transferred to roots by a convective flux simultaneously with total transpiration flux of solutes within a plant. Other biophile elements (potassium, phosphorus) are delivered to roots by means of diffusion.

Nutrients uptake rate is mostly determined by parameters like roots growth rate and their average diameter. This rate increase is much less at that of nutrient concentration in pore solute (c), hydrodynamic diffusion (D_h), distribution coefficient (K_d), and microscopical velocity of water flow to roots (v), which are physical transport parameters, related to soil conditions.

Mechanics of plants

Definition

Biomechanics – mechanics of living body; science of mechanical aspects of living bodies; *plant biomechanics* – interdisciplinary science describing behavior of plants subjected to forces and displacements at the level of molecules, cells, tissues, organs, whole organisms, and ecosystems. Because plant cells are surrounded by cell wall which gives the cells their shape and protection, it is the mechanical properties of the cell wall and its building materials which are of special interest to plant biomechanics studies. Mechanical changes in cell wall subjected to internal and external forces influence plant cell growth and morphogenesis.

Historical perspective

Some special mechanical features of the plant tissues and organs have been long known to man. Egyptians knew that dry wood when watered expands generating high forces. The same principles was used in many cultures for building different sorts of barrels. For more than 2,000 years it was known to man that the best material for making bows (the English longbow) was yew (*Taxus* species). It could take up to 4 years to make a good bow. The inner side of the bow consisted of heartwood (more resistive to compression) and the outer side of sapwood (more resistive in tension). This was one of the first

laminates used by men for the construction of a composite bow. The only other bow with comparable range and draw force was that Mongol bow of Genghis Khan – that was another composite made of horn (compression) and tendon (tension) (<http://www.huntingociety.org/MongolArchery.html>).

One of the first descriptions of the importance of mechanical factors (water flow) in plant growth and function was given by Leonardo da Vinci (<http://www.britannica.com/EBchecked/topic/336408/Leonardo-da-Vinci/59786/Mechanics-and-cosmology>).

In the second half of the nineteenth century many botanists performed experiments with the mechanical influence on the growth of algae, herbaceous plants, and trees. Julius von Sachs invented clinostat and used it in research on gravitropism and gravimorphism (Sachs, 1879). First experiment on the effect of mechanical traction on growth of sunflower seedlings was performed by Hegler (1893). In this experiment plants grew under longitudinal pull for 2 days. After this time their breaking strength increased nearly two times in comparison to their original breaking strength. Hegler noticed anatomical changes in plants grown under tension. They developed thicker cell walls and more mechanical tissue as he called epidermal and subepidermal cells. Plant biomechanics was greatly advanced by Wilhelm Pfeffer (Bunning, 1989; Pfeffer, 1904). Later the work on mechanical factors in plant development and adaptation to mechanical stimuli was continued by Bordner (1909), Newcombe (1895), Ball (1904), and many others. With increase of interest in biochemistry, plant biomechanics was not present in main stream botanical research for many years. With onset of the space race between east and west, more and more scientists investigated gravitropism and gravimorphism. Modern interest in plant biomechanics was catalyzed by the fact that biochemistry alone was not able to explain basic growth, development, and adaptation phenomena observed in plants. The most important contributors which brought plant biomechanics to mainstream botany were Niklas (1992), Vincent (1992), Steudle et al. (1977), Speck et al. (1996), Spatz et al. (1999), Mattheck (1998), Hejnowicz and Sievers (1995a, b), Cosgrove (1986, 1993), and many others.

Plant biomechanics

Plants in their environment are subjected to mechanical factors like gravity, wind, water flow, friction, and changes in temperature, pressure, and humidity. Plant biomechanics measures the mechanical response of plants and their building blocks to these mechanical factors and in reverse plant biomechanics explains how mechanical factors influence growth and development of plants.

Research in plant biomechanics focuses on the cell wall (Whitney et al., 1999) because it determines the shape of cells, tissues, organs, and whole plants. In a single celled plants the mechanical properties of cells depend on positive hydrostatic pressure (turgor) exerted by protoplast

on cell wall (Cosgrove, 1986). The simplest model representing this behavior would be balloon filled with water. Protoplast is compressed and cell wall is stretched. In herbaceous plants mechanical properties of organs depend on turgor and on tissue stresses. Tissue stresses arise in effect of interplay between tissues that differ mechanically – simplest case thick walled epidermal cells with small protoplast and thin walled parenchymal cells with large protoplast. As a result one tissue (for example epidermis) is under tension and other (parenchyma) under compression (Hejnowicz and Sievers, 1995a). In woody plants, in addition to turgor and tissue stresses, there are growth stresses that govern mechanical behavior of organs.

Studies on single intact cells can be performed using pressure probe technique developed by Steudle et al. (1977) and Tomos and Leigh (1999). This technique enables to measure mechanical properties of cell wall and turgor/cell wall deformation relations.

It is possible to measure local properties of cell wall at the scale of nanometers using nanoindenters. Some researchers measure mechanical behavior of single cells on universal testing machines (UTM). Instead of using small machines it is possible to use extra large cells of algae, for example, *Chara* species. Mechanical test using UTM can be performed also on isolated tissue in vitro and on whole organs (isolated or in vivo). Universal testing machines can be used both for the induction of mechanical stimulus and for measurement of plant response to that stimulus. Because modern UTM are computer controlled by very sophisticated software they can accurately reproduce any mechanical stimulus by precise application of force and displacement, stress, strain, energy, etc. UTM have very high displacement and force resolution. Standard force sensors (load cells) of 0.1 N capacity have 0.001 N accuracy. Standard displacement accuracy is about 1 μm. Recent developments in optical measurement techniques enable scientists to measure displacement and strain with unprecedented accuracy. Techniques of Digital Image Correlation (DIC) and Electronic Speckle Pattern Correlation (ESPI) enable full field (3D) displacement and strain measurement. For example, ESPI systems can measure area of 10×20 mm with 30 nm resolution.

UTM can be equipped with special chambers controlling accurately temperature, humidity, water flow, pH of the media. Measurements with UTM can be further enhanced by the use of special grips, gages, and adapters.

In situ plant tissues are rarely subjected to uniaxial stress; therefore, some researchers use specialized material testing machines capable of applying bidirectional stress to plant material – for example, isolated plant epidermis. This technique enables creation of planar biaxial stress field which more closely mimics the real stress field to which some tissues are subjected *in situ*.

Some biomechanical laws apply to the whole population of plants. The trees growing at the peripheral part of the forest are usually smaller because they are subjected

to stronger winds than trees deeper in the forest. But at the same time these trees are tougher than the tall trees inside forest. One could say that the trees at the periphery protect trees inside forest from strong wind.

From the perspective of material sciences plant cell wall is a highly complex anisotropic polymer. Most of the plant tissues can be considered as cellular solids which exhibit viscoelastic behavior. Many plants take advantage of the prestresses to optimize the use of the material (tissue) without compromising their mechanical strength. This building principle is widespread in all living organism at many different levels and is termed tensegrity (Ingber, 1998). Living plant cells, tissues, and organs have few important features which differentiate them from even most advanced man made materials. Their ability for self repair, self optimization, self cleaning, adaptation to mechanical environment, and biodegradability make them most sophisticated material known to men. Using biomechanical approach to plant structure and function we can learn a lot not only about plants but we can copy some of their patents and create materials with some of these features (biomimetics, bionics).

Summary

Plant Biomechanics is a large field of research with wide range of interest but which is unified by the tools and mathematical definitions used by physical sciences and mechanical engineering. Today it is a main stream research helping to understand plant growth, development, as well as structure–function relationships. Plant biomechanics help to understand evolutionary trends and adaptation to wide variety of physical conditions that exist in water, air, and soil. Niklas et al. (2006) divide plant biomechanics into subfields interested in cell wall and plant growth, tissue mechanical properties, mechanoperception and posture control, tree biomechanics, hydraulics and wood anatomy, and ecology. Plant Biomechanics gained a lot from engineering approach to plant structure and function but today we also see a reversed trend – the more we know about mechanics of plants the more nature inventions find practical use in modern technology (biomimetics, nanotechnology) (Milwiche et al., 2006; Forbes, 2008).

PLANT DISEASE SYMPTOMS, IDENTIFICATION FROM COLORED IMAGES

Anyela Valentina Camargo Rodriguez, Jan T. Kim
School of Computing, University of East Anglia,
Norwich, UK

Definition

Apoptosis: Programmed cell death.

Attribute: A categorical or numerical characteristic of a target object (region).

Classification: Designation of a class label to an object, or to multiple objects.

Classifier: A function that designates class labels to input objects, thus performing classification.

Generalization: The ability of a classifier to designate correct labels to samples that are not part of the training set, i.e., to “predict” the correct label.

Learning (or training): Computational construction of a classifier.

Mathematical morphology: Thinning (erosion) or expansion (dilation) of a region. It assesses pixel similarity by estimating a measurement of distance between two neighboring pixels.

Overfitting: Object misclassification due to poor generalization.

Pathogen: An agent that causes disease, e.g., a microorganism such as a bacterium or fungus.

Postprocessing: Enhancement of regions for attribute determination.

Preprocessing: Enhancement of a raw image for segmentation (or other subsequent process).

Segmentation: Subdivision of an image into different regions.

Supervised learning: Learning based on labeled training data. Supervised learning aims to learn how attributes determine the class label.

Training data: Data used for training. Each data sample consists of a given set of attributes. Labeled data also provide the correct class label for each sample.

Unsupervised learning: Learning based on unlabeled training data. Unsupervised learning includes generating class labels, e.g., by partitioning the training data into clusters.

Introduction

Plants are constantly attacked by pathogen-related diseases and pests. Plants have developed complex, coordinated, and targeted mechanisms of defense that produce responses specific to the attack or stress. For example, plants induce apoptosis when attacked by a biotrophic pathogen, thus depriving it of food. On the contrary, plants do not induce apoptosis when attacked by necrotrophic pathogens which feed on dead tissue. They instead fight off the pathogen by using most of their energy sources to the protection of the affected area (Glazebrook, 2005).

Plants show different responses to stress. Depending on the attack they are under, different defense mechanisms are triggered. Under some circumstances plants might turn pale, slow down their development, or shed their fruits before time. Conspicuous visual signs of stress include cankers, streaks, and spots on leaves, stems, and fruits (Camargo and Smith, 2009). These visual symptoms of a disease can sometimes be perceived by the naked eye at an early stage. They can be used as the first step in a disease identification program where digital images of diseased regions of a plant are used to assess, by automatic or manual means, the current state of the crop. The ultimate purpose of this analysis is to reduce the economic loss that is caused when a disease is not countered in time (Chakraborty et al., 2000). The use of methods for the early detection of plant diseases have become increasingly important as social and biological factors such globalization, climate change, human mobility, and pathogen and vector evolution have forced plant pathogens to adapt to new environments more rapidly. The consequences of this rapid adaptation can be gauged by the way disease outbreaks are nowadays more frequent, more rapid and more severe.

Plant disease identification by the computerized assessment of colored images can be used as a tool to help farmers identify the presence of a disease when it is still possible to control it (Qin et al., 2009; Boissard et al., 2008; Gómez-Sanchis et al., 2008; Pydipati et al., 2006).

Machine vision for image classification

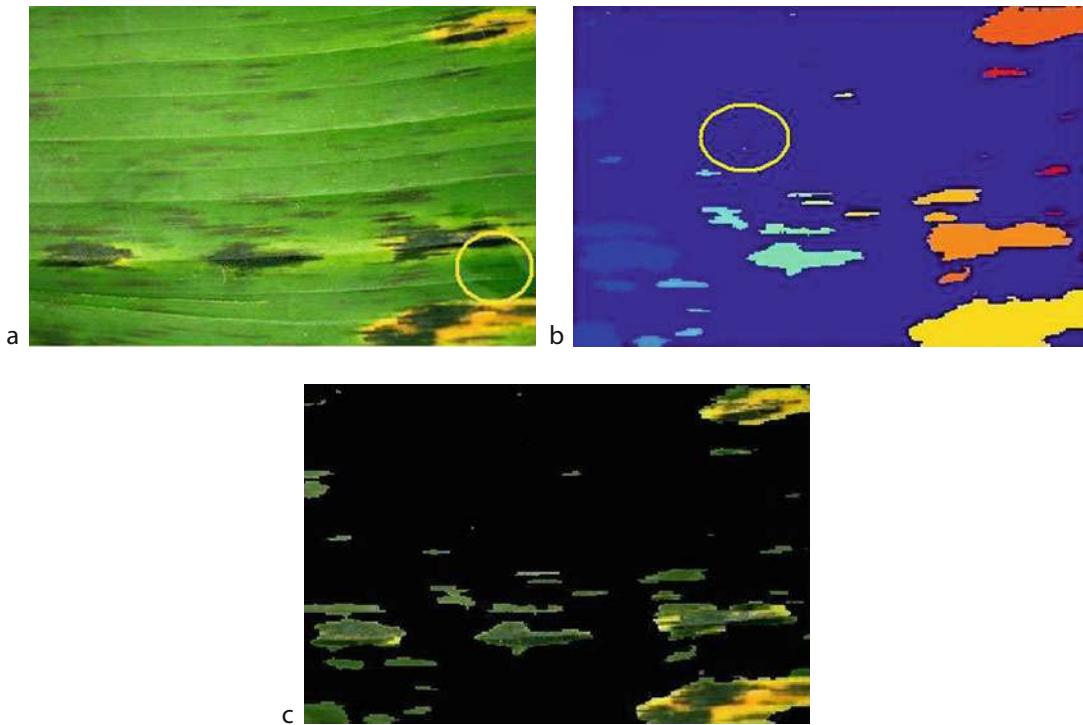

A machine vision system takes images as input and classifies them. A typical image analysis procedure includes the steps of (1) preprocessing the image, (2) segmenting the image to extract regions of defined relevance for classification and postprocessing the regions, (3) using a fixed set of attributes to characterize each region, and (4) using a classifier to designate a label to each region, based on its attributes. The choice of the segmentation method and of region attributes is critical for the performance of a machine vision system. For plant disease classification, segmentation is typically designed to identify regions that are affected by the disease (e.g., necrotic zones), and attributes are chosen to reflect characteristics such as color or aspects of shape. Figure 1 shows a raw image, segmentation, and the raw regions.

Distances

Many methods for image segmentation and for classification are based on distance measures. Such measures provide non-negative values that characterize how far two objects are apart. The Euclidean distance

$$d(\mathbf{x}, \mathbf{y}) = \sqrt{(\mathbf{x} - \mathbf{y})^T (\mathbf{x} - \mathbf{y})} = \sqrt{\sum_i (x_i - y_i)^2} \quad (1)$$

of two vectors $\mathbf{x} = (x_1, x_2, \dots, x_n)^T$ and $\mathbf{y} = (y_1, y_2, \dots, y_n)^T$ is one of the most well-known distance measures and widely used for various purposes in image processing. Alternatives to the Euclidean distance

Plant Disease Symptoms, Identification from Colored Images, Figure 1 Visual disease symptoms of Black Sigatoka (*M. fijiensis*) on leaves of Banana Plantain (*M. parviflora*). (a) Original Image. Yellow circle indicates human fingerprint. (b) Disease symptoms are segmented out. Yellow circle indicate a region wrongly segmented. (c) Segmented image is postprocessed to avoid including false positives (regions with similar characteristics to the target regions that in reality are part of the background).

include correlation-based divergences. Distances and divergences may be weighted by a weight vector $\mathbf{w} = (w_1, w_2, \dots, w_n)^T$. As an example, the weighted variant of the Euclidean distance is

$$d_{\mathbf{w}}(\mathbf{x}, \mathbf{y}) = \sqrt{\sum_i w_i (x_i - y_i)^2} \quad (2)$$

Preprocessing

The objective of preprocessing is to improve the visual traits of an image so that segmentation can be more efficient. The success of segmentation is determined by the accuracy with which target regions (in this document targets are visual symptoms of disease) are correctly identified. Two of the most popular methods used for image enhancement are intensity transformation and spatial filtering which operates on the Fourier Transform of an image (Gonzalez et al., 2009). A straightforward approach to intensity transformation is based on histograms and aims to produce a more even distribution of intensities. In the case of spatial filtering, there are several methods that can be used to suppress either low or high frequencies (intensities in histogram that are more or less frequent as opposed to those whose frequencies are around the average). For example, the Gaussian filter is a low-pass filter

that suppresses high frequencies to produce a smoother image. The degree of smoothing is determined by the convolution kernel size which is the standard deviation of the associated probability distribution. In general, the selection of what method to use very much depends on the image's characteristics and its quality. When dealing with images that are taken in the open, as is the case presented here, effects upon the digital image such as light intensity and shade can introduce noise to the original image. Therefore, raw digital images must be preprocessed before segmentation is carried out.

Image segmentation and postprocessing

Segmentation clusters image pixels into contiguous regions. For disease identification, segmentation typically aims to divide the image into foreground regions that contain plant parts that exhibit disease symptoms, and background regions, comprised of plant parts not affected by the disease and unrelated objects). Simple yet useful segmentation methods use reference points in color space and designate pixels to regions based on the distance of a pixel's color to these references. Even more simply, the space of colors or intensities may be partitioned, and contiguous pixels that fall in the same partition are combined into a region.

More sophisticated techniques can be used if the image is rather complex, for example, pixel clustering can be combined with a tree-search-like technique to connect spatially distant regions. [Figure 1](#) is an example of a complex image: the picture depicts a leaf of banana plantain (*Musa spp.*) showing the symptoms of the Black Sigatoka disease. Note that because every streak is different in shape, size, and intensity, a segmentation procedure that relies on intensities selection only might render inaccurate results. As an example, there is a fingerprint mark in [Figure 1a](#). That mark might have the same R, G, or B intensity as one of the target segments and therefore can be erroneously extracted as a disease symptom.

Further to segmentation, morphological binary open functions are used to join regions, fill holes, and remove small and isolated regions. [Figure 1b](#) shows that small regions wrongly segmented (yellow circle) were deleted after postprocessing. The picture also shows that as a result of applying a dilation procedure, some regions were expanded (bottom right) and therefore joined.

Attribute extraction

An attribute represents a categorical or numerical characteristic of a region in an image. Examples of attributes include the overall brightness of the object, its shape, texture (given by measures of energy, inertia, entropy, homogeneity and correlation which are calculated according to an angle and distance between two neighbor pixels) or size. As in segmentation, the selection of which attribute to extract will depend on the characteristics of the object. As illustrated by [Figure 1](#), characteristics of shape, intensity, and texture might be a good set of attributes representing any of the targets regions highlighted in [Figure 1c](#). Further useful attributes include solidity, extent, major axis length, minor axis length, eccentricity, centroid, diameter, lacunarity, and fractal dimensions. Each feature aims to capture an aspect of a visual symptom of the disease (Black Sigatoka in the example shown). It is important to mention that as well as representing image characteristics, attributes should be invariant to translation and rotation because images are normally captured from different angles and distances. Furthermore, lighting conditions are subject to variation that is irrelevant for disease classification. Therefore, attributes should be invariant to lighting conditions to the extent possible. The same set of attributes is determined for each region. As a result, each region r is characterized by an attribute vector $\mathbf{a}_r = (a_{r1}, a_{r2}, \dots, a_{rm})^T$.

Disease classification

Regions are classified based on distances or divergences between attribute vectors. Classifiers obtained by supervised learning may straightforwardly label regions with the disease that most likely causes the symptom shown by the region. Simple classifiers of this type contain reference attribute vectors. Each reference vector represents a symptom that is typical for a disease. Given an attribute

vector of a region from an image, the classifier determines the closest reference vector and designates the corresponding disease as the label of the region. The classification of an image is subsequently based on the classification of the regions in that image.

Construction of classifiers

Constructing classifiers for plant disease identification by supervised learning requires a set of training data, i.e., of images for which a human expert has determined and labelled regions. As an example, reference vectors may be computed by finding groups of regions in the training data which have the same label and are close in attribute space, and choosing their mean as the reference sample to represent that group. Weighted distances are a suitable and efficient approach where some attributes are more important for classification than others.

Simple classifiers operate on the attribute vectors directly and attempt to separate groups of samples using a linear hyperplane of separation. However, linear separation is not always possible. Where linear classifiers are not satisfactory, nonlinear classifiers, such as Artificial Neural Networks (ANNs) or Support Vector Machines (SVMs), may be used. SVMs notionally operate by nonlinearly mapping n -dimensional attribute vectors to a feature space of much higher dimensionality. The added dimensions enable construction of classifiers that are not feasible using linear techniques. However, this added power increases the risk of overfitting, i.e., of constructing a classifier that performs well on the training data but generalizes poorly to input that is not contained in the training data. Generally, a larger quantity and higher quality of training data is required to train a more powerful classifier, otherwise the classifier may produce unreliable results despite performing well on the training data.

Unsupervised learning may be useful where data is not fully labeled by human experts as its greatest strength is knowledge discovery from unknown data. As an example, consider a data set where the disease shown on each image is stated, but images are not segmented and consequently there are no labels for regions. In this situation, segmenting the images and clustering the regions may identify clusters of attribute vectors that represent visual symptoms of a plant disease but will not indicate to which diseases those cluster correspond.

Summary and outlook

In summary, while image based computational identification of plant diseases involves many challenges, a carefully designed image analysis pipeline can well complement and support disease assessment by human experts. The identification of the symptoms of plant diseases by means of a machine vision system may help to identify early symptoms of plant diseases. Here we described how digital images showing diseased regions of plants can be used as a tool for disease identification. These and other similar tools could become more useful

and widespread if they are available over the Internet as it has been shown that today's worldwide farmers (including those in poor countries) have more changes of accessing the Internet.

We also emphasized the importance of analyzing carefully the problem domain so as to select the best technique for each step in the pipeline that lead to the identification of plant diseases from colored images.

Plant disease detection ideally should not rely entirely on the assessment of images as visual symptoms might be similar among more than one disease (Miller et al., 2009) or might show up when it is too late to control the disease. However, machine vision systems may complement and speed up plant disease diagnosis, and it may be most beneficial to farmers in remote regions of developing countries, who have no support by agronomy or plant pathology experts, and therefore have limited knowledge of the pests and diseases that may attack their crops, but who rapidly gain access to the Internet in recent years.

PLANT DROUGHT STRESS: DETECTION BY IMAGE ANALYSIS

Istvan Farkas

Department of Physics and Process Control, Szent Istvan University, Gödöllő, Hungary

Synonyms

Plant condition; Speaking plant; Water shortage

Definition

Plant drought stress basically originated from the water shortage. That could be caused by the extreme weather conditions and/or by the insufficient amount of soil water within the rooting zone. The plants have an ability to regulate their water stress by transpiration process through stomata within a certain range.

Introduction

Drought is one of the most severe and extreme weather events affecting more people than any other form of natural disaster. According to the World Meteorological Organization nearly half of the worlds people will live in water-stressed areas by 2025. Beside desertification, climate change impacts, socioeconomic developments, and an increased agricultural production in addition to fresh water supply will further stress water resources. The International Solar Energy Society in his Solar World Congress organized in August 2005 put also the water into the focus of the discussions.

Drought stress of plants

The early and exact recognition of drought stress of crops (e.g., through extreme temperatures and water shortage) is of particular importance for sustainable crop production. However, the precise quantification of drought is difficult as no universal drought estimation method (e.g., drought indices, hydrological or soil water balance models) can be defined through the complexity of the problem. For precision farming two main features may be used for drought stress detection. On the one hand drought stress changes the leaf temperature of the plants. The leaf temperature as a result of its heat balance is linked with leaf surface characteristics, the leaf transpiration, and climatological factors such as wind speed and net radiation (Farkas et al., 2007).

Depending on the soil water content within the rooting zone and the related root water uptake, plants regulate their stomata and stop or continue their transpiration if water stress occurs. Transpiration is a means to keep leaf temperature low and protect them from heat stress. Plants differ significantly from their ability to regulate transpiration through stomata. Some drought resistant plants close their stomata at a very early stage of water stress, and some other less drought stress resistant plants will carry on with transpiration. Increased complexity results from the fact

that transpiration and stomatal resistance depend, beside soil water availability, on climatological factors such as radiation, saturation deficit, wind speed, and air temperature.

Drought stress detection by image analysis

In the last 2 decades several research experiments investigated the relationship between plant water status and visual appearance. It is a part of the speaking plant concept approach (Hashimoto et al., 1989).

Soybean leaves were studied by Oosterhuis et al. (1985) and found that soybean leaf-stem angle became smaller as the leaf-water potential and soil water potential declined.

Side projected canopy images can be used for such purposes in case of different plants as tomato, cucumber, and paprika. A camera is to be focused on the plant canopy from horizontal direction in order to obtain images covering the leaves. At defined time scales, images can be taken to analyze leaf and stem movements as the visual signs of plant state (Font and Farkas, 2008).

The image analyzing algorithm requires input files of preset operating parameters, camera position, and plants morphological features. These values should be adjusted for different plants, camera, or measurements. The leaves and stems on the image could be separated by the image processing algorithm according to the differences in their shape. A general leaf inclination value can be calculated from the local orientations at each point on the visible leaf's and stem's edge lines.

Algorithms have been developed for using side projected canopy images to determine *in vivo* and *in situ* the growth, shape, size, and leaf inclination angle of tomato and other plants in a climate-controlled indoor greenhouse along with an automatic irrigation technique.

Seginer et al. (1992) followed the vertical movement of the tip of fully expanded tomato leaves using machine vision imaging and reported that the movement can be used as an indicator of incipient drought stress before the appearance of visual wilt symptoms.

Another possibility to automated assessment of plant water status estimation is the image of the whole canopy rather than that of the individual plants or leaves. Kurata and Yan (1996) extracted lines reflecting inclinations of the rachides of tomato leaves from the whole canopy image obtained from a fixed position slightly above the canopy.

Another existing method for determination of leaf inclination is the LAI 2000 canopy analyzer. This method is based on the algorithms of LI-COR, Inc.

To draw a conclusion, the methods have been tested easily for different vegetable plants for instance tomato, paprika, and cucumber. Most of them have been tested in greenhouses and under completely controlled indoor conditions. They have not been adapted for many cultivars (e.g., maize) and also mostly not for outdoor environments.

Summary

Plant drought stress basically originated from the water shortage, which could be caused by the extreme weather conditions and/or by the insufficient amount of soil water within the rooting zone. The early and exact recognition of drought stress of crops is difficult as no universal drought estimation method can be defined through the complexity of the problem. Side projected canopy images can be used for such purposes in case of different plants as tomato, cucumber, and paprika. The images can be taken to analyze leaf and stem movements as the visual signs of plant drought state. Algorithms developed for using side projected canopy images can also be used for automatic irrigation of greenhouse crops.

PLANT LODGING, EFFECTS, AND CONTROL

Grażyna Podolska

Department of Cereal Crop Production, Institute of Soil Science and Plant Cultivation, National Research Institute, Puławy, Poland

The process by which the shoots of cereals are displaced from their vertical stance is called lodging. Lodging is a complicated phenomenon. There are many external

factors that have influence on lodging including: wind, rain, topography, soil type, forecrop, tillage, nitrogen fertilizers, diseases, sowing date, seed rate, and variety. Lodging has a negative influence on both the yield and the yield quality.

Smaller yield losses are observed when the angle of lodging is less than 90° from the vertical and when lodging occurs at the later stage of development. Artificial lodging at the ear emergence, milk, soft dough, and hard dough stage reduced yields by 31%, 25%, 20%, and 12%, respectively (Fischer and Stapper, 1987; Berry et al., 2004). Lodging during early grain filling affected grain quality, deducting falling number, thousand grain yield, and specific weight and increased the protein content (Cacak-Pietrzak et al., 2006; Stanca et al., 1979).

The resistance against lodging is associated with the plant resistance to mechanical stress and it is based on the mechanical and structural properties of the plant. Plant morphology, anatomy, chemical composition of the stem as well as the condition of the root system has an impact on the resistance against lodging. Morphological properties involved in lodging are: the length of the stem, the thickness of the bottom three internodes, as well as the diameter of the stem. Morphological properties decide upon the resistance to the pressure and forces put by wind or rain. Anatomical properties are mainly the thickness of the cell walls and the sclerenchyma width. Chemical composition involved in lodging, mainly refers to the cellulose and lignin content. Cellulose gives stiffness whereas lignins give resistance to the external pressure influencing the cell walls. Moreover the vertical distribution of the root system supports lodging resistance of the plant (Berry et al., 2004; Źebrowski, 1992).

The prevention of lodging is mainly focused on the cultivation of the resistant varieties, mainly through the introduction of so-called dwarf genes, but also by application of growth regulators (PGRs). Three major types of PGRs are currently in use, namely: chlormequat chloride, etephon, and trinexapac-ethyl (Cox and Otis, 1989).

PLANT PHYSICAL CHARACTERISTICS IN BREEDING AND VARIETAL EVALUATION

Bogusław Szot¹, Wojciech Rybiński²

¹Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland

²Institute of Plant Genetics, Polish Academy of Sciences, Poznań, Poland

Definition

The relations between agrophysics, and genetics and plant breeding are a measure of the *breeding and crop variety evaluation* progress in respect of the utilization of agrophysical studies in the creation of new plant cultivars. It has been proven that *plant physical characteristics* such as mechanical strength parameters (force, elasticity, deformation, energy) are inheritable to a very high extent and there is a possibility of selecting the parent forms in such a way as to obtain genotypes with favorable features with respect to cultivation, harvest, storage, and material quality for the food processing industry. The effects of such joint research efforts presented herein support the thesis that only interdisciplinary research may result in measurable achievements.

Introduction

The area of interest of agrophysics covers the physical processes and material properties that are important for sustainable agricultural production and for modern food processing technologies, and especially the physical and physicochemical interactions taking place in the soil-plant-atmosphere and soil-plant-machine-agricultural product systems, with special emphasis on the condition of the environment and on the quality of food products. At present, in the first decade of the twenty first century, a notable biological progress is observed, especially in the aspect of dynamic development of genetic engineering and biotechnologies, and agrophysics, which provides efficient support in solving the complex problems of the agricultural and natural sciences. As an example, knowledge of the physical properties of crop plants was utilized by mankind already in ancient times, and now knowledge of the range of physical properties of a given plant material is a necessary prerequisite for the estimation of the quality of a given plant material. From its very beginning agrophysics made extensive use of the research tools and the achievements of physics and mathematics. There is no doubt that also the natural sciences, genetics, and plant breeding included, often face the necessity of searching for interdisciplinary interpretations of mutual interactions.

Studies of the same object (e.g., a specific plant material) but at different levels of magnitude are frequently in the focus of interest of various disciplines of science. The resultant interactions are usually not simple sums of interactions taking place at different scales. As an example, the structure of cereal kernels can be accurately described in terms of their mechanical or physicochemical properties, but it is obvious that at the root of the observed variability of the physical or chemical parameters studied, there lie the fundamental transformations of genetic nature that remain in specific interactions with the environmental conditions. Hence, one of the fundamental challenges facing agrophysics is the interdisciplinary interpretation of studied interactions taking place in the natural environment, and especially in plant material.

In the interdisciplinary aspect, the plant geneticists and breeders on the one hand, and agrophysicists on the other, have now at their disposal modern research tools that permit in-depth determination of the genetic variability of traits and of the physical and physicochemical interactions taking place in the environment of plant growth and development in the broad sense. Irrespective of the two disciplines of science mentioned, the genetic-breeding aspects as well as the physical ones are analyzed in close relationship with the soil-plant-atmosphere system. This is a significant interdisciplinary bond that permits undertaking attempts at combining the results of genetic-breeding experiments with the effects studied in the field of agrophysics of plant materials. Doubtlessly, it is of interest to find out to what extent genetic-breeding experiments may contribute to elucidation of physical phenomena taking place in plant material, and vice versa, and how much the physical processes may help in the interpretation of a number of phenomena of genetic and breeding nature. To give an example, the process of pod cracking and seed shedding is closely related with processes of physical character that take place in the pod under specific environmental conditions, but on the other hand that phenomenon is genetically determined and specific for particular species, cultivars, or lines. Hence, the knowledge of the physical aspect of pod cracking with an accumulation of specific climatic factors (temperature, precipitations, air humidity etc.) is undoubtedly a significant element in studies on genetic improvement of crop plants.

In studies aimed at the introduction of new, high-yield cultivars resistant to biotic and abiotic stresses, both geneticists and plant breeders concentrate on the fundamental quality and quantity features of plants that guarantee high market competitiveness of new cultivars. Whereas, they do not have at their disposal precision research tools that would allow them to obtain basic information, e.g., on the physical (mechanical) properties of plant stems or stalks in the aspect of improving their resistance to lodging or the resistance of seeds to mechanical loading, which later has its consequences in the processes of harvest, storage, and processing of agricultural products. To meet the requirements of contemporary economy, crop plant cultivars used in agricultural production should permit the

obtainment of material and biological product that has to meet specific standard and requirements with simultaneous limitation of losses. This is closely related with the biological progress whose intensification, especially in recent years, is observed already on the global scale. The biological progress encompasses improvement of plant and animal organisms, and increase in the number of plant and animal species that are useful to man. In contemporary agriculture there are a number of concepts used alternately for the description of the progress brought in by the new cultivars – the most commonly used ones include genetic and varietal progress. The advances contributed by new crop plant cultivars form a part of the biological progress understood as improvement of living organisms. Among other things, the breeding progress is important that can be considered as all improvements related with breeding research and that may relate both to the development of specific breeding techniques and to the actual effects of breeding experiments, i.e., new plant cultivars. Breeding progress in relation to crop plants can be considered in the aspect of improvements to the yield quality indices – expressed, among other things, in increased content of protein, improvement of its amino acid composition, elimination of significant reduction of the content of anti-nutritional substances, as well as in improvement of the yield structure, reduction of the vegetation period, increased resistance of plants to lodging, drought, or pest or disease infestation. The ultimate effect aimed at by plant breeding is increase in crop yield and improvement of its quality features. An element that hitherto has been under-appreciated and little known is the degree of seed resistance to physical factors, expressed in the mechanical properties of kernels, which is – in turn – related with the limitation of losses involved in the harvest, transport, and storage of seeds. To meet this requirement, an attempt has been undertaken to estimate the physical properties of seeds in the context of the breeding progress as evidenced in the final product of the breeders, i.e., crop plant cultivars as well as strains, lines, mutants, or hybrids in the first generations after crossbreeding, obtained at early stages of breeding work. That study is an attempt at combining the breeding progress as exemplified by the abovementioned breeding materials with evaluation of their seeds in terms of their physical properties, mainly in the aspect of their resistance to mechanical loads. The study has been based on literature results relating to cereals and leguminous plants.

When the classical breeding methods are applied, the time elapsing from the first crossbreeding to the registration of a new cultivar is at least 10 years. The initial stages of the breeding cycle include the selection of the most promising genotypes which, in subsequent generations, are multiplied and tested in field experiments. The condition for effective selection is to obtain the broadest possible range of variability of traits, which permits selection of genotypes possessing properties sought by the breeder. Hence, it is important for the breeder to have at his disposal, already at early stages of the breeding program,

information on the breeding value of selected objects in terms of the most desirable traits, with the inclusion of the resistance of seeds to mechanical loads in the selection evaluations, a property often underestimated and neglected by the breeders but truly indispensable in the development of the optimum model of a new plant cultivar or variety. The valuation information obtained permits to limit, in the initial generations of a breeding cycle, the abundant crossbred material to the most valuable and promising genotypes. Among other things, this is of a measurable financial significance as it permits the limitation of the scope and therefore also the costs of breeding programs in progress.

Cereals

Evaluation of materials at early stages of breeding

An example of estimation of the resistance of kernels to mechanical loads at an early stage of wheat breeding can be a study by Milczak et al. (1977) with relation to generation F₂. The hybrids were obtained by crossbreeding the wheat line Z-70 (P₁) with the cultivated variety Kaukaz (P₂). Apart from the evaluation of the parent material and the F₂ hybrids in terms of their weight of kernels per year, weight of kernels per plant, weight of 1,000 kernels, grain vitreosity, and protein content, a novel element was the inclusion of kernel resistance to mechanical loads in the scope of the estimations. That last trait was analyzed on an apparatus designed at the Institute of Agrophysics, PAS, permitting systematic recording of increasing force values as a function of strain. This allows readings of the instantaneous force compressing the kernel, and of strains

within the range of linear elasticity. The levels of values of the studied traits P₁, P₂, and F₂ and the range of their variability are illustrated in Table 1. Comparison of mean values indicates high phenotypic similarity of both parental forms. In the context of the studied traits, considerable differences were observed with relation to the grain resistance to mechanical loading, which is closely related to the susceptibility of the grain to mechanical damage. The range of variability of that trait was notably different for P₁ (43.6 – 61.9 N) than for P₂ (65.0 – 96.0), which indicates genotype-inherent resistance of the parental forms with respect to that feature. The result of the separateness of the parental forms was the obtainment, through recombination, of considerable variability of grain resistance to mechanical loading in plants of generation F₂, the highest within the group of traits under study. This is confirmed by the coefficient of variation of ca. 9%, compared to 18.6% for the hybrids of F₂. Closely related with the range of variability of traits is an index that is very important in the prediction of genetic progress – heritability (H). The highest proportion of genotype variation with relation to phenotypic variation was found for the resistance of grains to static loads (H = ca. 78%). The obtained variability of grain resistance to mechanical loads at a high level of heritability of that trait in hybrids permits the selection of the most resistant forms from generation F₂ and their use for further crossbreeding and proper orientation of the breeding program. An important element in breeding is to identify the relations between the evaluated traits as expressed by the index of phenotypic correlation (Table 2).

Among the 21 correlations under study a particularly practical breeding aspect is represented by the relationship

Plant Physical Characteristics in Breeding and Varietal Evaluation, Table 1 Mean values and range of variability of studied traits of winter wheat (Milczak et al., 1977)

Trait	Generation	Mean value	Range of variability (from – to)	Coefficient of variation V (%)	Coefficient of heritability (H)
Weight of kernels per spike (g)	P ₁	2.50	1.2–3.9	28.2	0.418
	P ₂	2.70	1.9–3.9	17.5	
	F ₂	2.60	1.0–4.7	30.6	
Weight of kernels per plant (g)	P ₁	39.20	14.2–82.2	33.0	–
	P ₂	20.30	15.0–32.2	22.0	
	F ₂	27.60	15.0–55.4	32.5	
Weight of 1,000 kernels (g)	P ₁	35.80	28.9–43.4	11.2	0.567
	P ₂	35.40	30.3–39.4	7.6	
	F ₂	37.70	24.2–52.7	13.9	
Vitreosity of kernels (%)	P ₁	16.90	7.0–23.0	22.8	0.389
	P ₂	15.40	8.0–26.0	32.5	
	F ₂	16.70	7.0–30.0	35.2	
Protein content (%)	P ₁	15.30	13.0–18.0	8.2	0.402
	P ₂	15.90	14.0–18.5	8.5	
	F ₂	13.70	11.0–18.2	11.5	
Resistance to static loads (N)	P ₁	53.00	43.6–61.9	9.1	0.784
	P ₂	80.00	65.9–96.0	8.8	
	F ₂	63.20	34.8–92.1	18.6	
Elastic deformation (mm)	P ₁	0.29	0.20–0.40	21.5	–
	P ₂	0.41	0.35–0.52	19.0	
	F ₂	0.34	0.22–0.55	18.3	

Plant Physical Characteristics in Breeding and Varietal Evaluation, Table 2 Coefficient of phenotypic correlation (r_{xy}) for population F_2 (Milczak et al., 1977)

Trait	Weight of kernels per spike (g)	Weight of kernels per plant (g)	Weight of 1,000 kernels (g)	Kernel vitreosity (%)	Protein content (%)	Resistance to static loads (N)	Elastic deformation (mm)
Weight of kernels per spike (g)	—						
Weight of kernels per plant (g)	0.524*	—

in population F_2 between the resistance of kernels to static loads and their vitreosity ($r_{xv} = 0.537$). For the breeder, this relation is of particular value as grain vitreosity is a trait easy to assess and can be used in selection as a morphological marker of grain resistance to mechanical damage. The dependence of the mechanical strength of grain on its vitreosity, long known in grain milling practice, has found support in literature data. The identification of the above marker is a good prognostic for breeding programs that take into account grain resistance to mechanical loads in the modeling of new cultivars. The presented results, based on the evaluation of breeding materials at early stages of creation of cultivars, are valuable in the sense that there is a general lack of studies of this kind and a review of literature has not yielded any pertaining publications.

The expression of traits observed and evaluated in breeding is based on changes of genetic nature, including modification caused by the effect of the environment. At present, for numerous plant species genetic maps are available, giving the precise location of a large number of genes on the chromosomes. Apart from the effect of specific genes on the expression of traits, studies are also conducted on the effect of additional chromosomes. This can be exemplified by the wheat-rye addition lines obtained by numerous researchers (e.g., Evans and Jenkins, 1960; Miller, 1973; Bernard, 1976). Series of addition lines have no practical application, and many authors analyzed the effect of additional chromosomes of rye on the process of meiosis and on plant development, and on the physiological and biochemical properties of wheat lines with additional rye chromosomes (Sears, 1967; Tnag and Hart, 1975; Schlegel, 1978; Liu and Gale, 1989). In spite of the existence of abundant literature on the subject, there is a lack of studies on the physical properties of kernels of wheat lines with additional rye chromosomes. Making use of the created series of lines of wheat cv. Grana with a set of additional chromosomes of

rye cv. Dańskowskie Złote and branches of chromosomes 1R, 2R, 3RS, 4R, 5R, 6R 6RL and 7R, a study was made of the properties of kernels of those lines as well as of the initial forms: wheat cv. Grana, rye cv. Dańskowskie Złote, and an octoploid triticale (Grana x Dańskowskie Złote). The authors (Miazga and Szot, 1996) studied, among other things, the internal damage to kernels using for the purpose an X-ray apparatus and analyzing the obtained X-ray images. Estimations of the resistance of the kernels to mechanical loads were performed with the use of the INSTRON model 6022 strength tester. The physical properties of kernels are determined by their morphology and anatomical structure, as well as by their chemical composition, which at the same time affects their physiology. Among the primary causes for the appearance of cracking in kernels one can mention the gradient of moisture related to the weather conditions (dew, rainfall-drought) in the phase of full ripeness of kernels and in the course of uneven filling of kernels which causes local weakening and cracking of endosperm. Internal damage to the kernels was evaluated on the basis of the index, with no effect of external forces. It was found that all the addition lines, including the triticale, were characterized by notably higher index of damage compared to kernels of wheat cv. Grana, while no damage to rye kernels was noted. Differentiation in internal damage in the addition lines was shown by defining the location and extent of damage to the kernels. In view of the fact that the environmental conditions in the field experiment were identical for all tested objects, the observed differences resulted from the genetic effect of the additional rye chromosomes in the addition lines. Kernel surface roughness (coarseness), in the physical aspect, is subject to the effect of forces causing various levels of friction and abrasion during threshing, transport, cleaning, and storage. Moreover, rough-surfaced kernels retain water (moisture) longer after rainfall or dew. The surface roughness (coarseness) of kernels was estimated by means of a microscope (BK 70 × 50) and the

results were given in micrometers. All addition lines were characterized by lower surface coarseness than the initial forms. The results related to surface coarseness alone, and not to kernel surface wrinkling, were observed for kernels of triticale. The results of compressive strength of kernels are given in Table 3. The values of the maximum force, i.e., force causing kernel destruction, varied from 65.9 N for line 4R, through 83.5 for line 3R, to 104.9 N for line 6R. Forms that were the most resistant to compression included lines 6R, 6RL, and 2R. The results suggest that probably those chromosomes include genes responsible for the mechanical strength of rye kernels. This trait may be related with the endosperm structure. Simmonds et al. (1973) describes the differences in endosperm structure between rye, wheat, and triticale, with special attention to the distribution of proteins and starch in the endosperm. The values of maximum force correspond with maximum strain at the point of damage to kernels and vary among the lines in the range from 0.18 to 0.28 mm, depending on the line. Rye kernels, being the strongest, require the greatest energy during crushing (25.0 mJ). All addition lines, with the exception of line 3R, required greater energy for kernel crushing compared to wheat. Concluding, the authors emphasize that, with high probability, the genes that determine the mechanical strength of rye (initial form Dańskowskie Złote) are found on chromosomes 6R, 6RL, and 2R, which constitutes significant information for geneticists and breeders in the process of selection and obtaining, at further stages of breeding work, of cultivars with increased resistance to mechanical damage.

The variability of the animated world is a result of the processes of recombination and mutation. While the subject of utilization of hybrids created through crossbreeding

followed by recombination has been discussed earlier in the text on the example of wheat, the application of induced mutation for the assessment of mechanical loading of kernels of hull-less barley is presented by other authors (Rybniński and Szot, 2006). Mutations and mutation breeding are a valuable complement to conventional breeding methods (Campbell et al., 1994). Mutations can be used for the creation of additional variability of traits, used by breeders for the development of cultivars with specific properties and with specific adaptive capabilities under given environmental conditions. Kernels of the hull-less bred line 1 N/86 were treated with a chemomutagen (MNU), and kernels not subjected to the effect of the mutagen constituted the control treatment. Mutant selection was conducted in generation M₂, and after a several-year cycle of multiplication kernels from a field experiment with selected mutants were assessed in terms of their geometric properties of resistance to mechanical loads. For comparison of the physical properties of kernels, estimations were also performed for hulled forms of spring barley. It was demonstrated that the mutagenic agent induced an extension of the range of variability of physical properties of the mutants compared to their initial form 1 N/86. Among other things, this concerned the geometric parameters of the kernels (thickness, width, and length), and especially their resistance to mechanical loads expressed by values of force, deformation, and energy. To give some examples, the mean value of force required to destroy a kernel of the initial form 1 N/86 was 168.5 N, and for the mutants it varied from 125.3 N to 227.3 N. The obtained variability permitted the selection of hull-less mutants that differed from the initial form in the geometric parameters and in greater resistance to

mechanical loads. The selected mutants may constitute valuable initial material for the development of improved cultivars of hull-less barley. An interesting insight is provided by comparison of physical properties of kernels of hull-less mutants with those of the hulled forms. On average, the mutants were characterized by longer kernels and by higher compressive strength (141.2 N for the hulled forms and 175.0 N for the hull-less mutants), and by higher values of energy required – 25.6 and 38.2 mJ, respectively. The elimination of the hulls from the kernels, constituting 13% of the weight of a single kernel, is highly advantageous in the feeding of monogastric animals as it permits saving of energy that has to be expended on digestion of the hard to digest hulls composed mainly of fiber and cellulose. Hence, hull-less cultivars of barley provide a valuable complement to the array of hulled cultivars commonly used in animal feeding. However, the elimination of hulls results in reduced protection of the germ, which causes that incorrect settings of the threshing machine amplify the risk of damage to the germ, and that, in many cases, leads to disqualification of the grain as qualified sowing material.

Another batch of hull-less mutants were analyzed with regard to the status of damage to the parenchyma as measured by the number of cracks (recorded on X-ray film), and also, using mechanical tests on kernel sections under uniaxial compression, determinations were made of the strength of the kernels, their modulus of elasticity, deformation, and specific work during deformation (Woźniak et al., 2006). Kernels of the initial form 1 N/86 were characterized by low susceptibility to internal damage, at an average of three cracks per kernel. The mutants were characterized by decreased resistance, but a few forms with increased strength were also selected. This indicates that the mutagen caused a broadening of the range of variability of that trait. The observed cracks, however, did not cause any greater decrease in the compressive strength of kernels. Most of the mutants were characterized by kernels with modulus of elasticity values significantly higher than in the initial form. In the conclusion of the study, it was shown that mutation of barley permits the obtainment of forms with improved kernel strength parameters.

An important element of the quality of cultivars is their resistance to lodging. Strong tendency of plants to lodge causes notable losses in grain yield and leads to a significant deterioration of their quality (Jeżowski, 1981). The physical parameters of the stem affect the degree of lodging. For mutants of barley measurements were made of plant height, outer diameter of stem, stem wall thickness, and the ultrasonic method was employed to determine the index of stem elasticity – the Young modulus. The range of variability of the trait of plant height in the mutants was from 61.8 to 113.4 cm, with plant height of the initial form at 92.5 cm. High values of coefficient of variability were obtained for the traits that determine the resistance to lodging – stem wall thickness (14.8%) and Young modulus (13.3%). The relation between the degree

of lodging (measured in a scale from 1 to 9; 1 – no lodging, 9 – full susceptibility to lodging) and the values of traits determining resistance to lodging was reflected in high, significant values of correlation coefficient. For stem wall thickness and for the Young modulus, those values were $r = -0.695$ and $r = -0.902$, respectively. High value of the coefficient of correlation between the degree of lodging and stem elasticity, measured by the value of a physical parameter, the Young modulus, constitutes significant information for the breeder, permitting him to use the index of stem elasticity in the selection of forms with improved resistance to lodging. Such mutants have been created that, thanks to greater stem elasticity, displayed lower susceptibility to lodging than their initial forms. What needs to be emphasized here is that the factor that determines the degree of lodging is not only plant height (stem length), but primarily the physical parameters of the plant stem.

While the hybrids of generation F₂, addition lines and mutants discussed above are evaluated by the breeder at the early stages of the breeding cycle and selection, the last stage of the work prior to the submission of a form for cultivar registration tests is the evaluation of the selected breeding strains. The study on strains comprised, i.e., two lines of triticale – 46 and 51 – and in comparative estimations wheat cv. Grana and rye cv. Dańskowskie Selekcjyne were used (Szot and Tarkowski, 1977). Apart from evaluation of the geometric features of kernels, also the instantaneous resistance of single kernels to static loads was determined with accuracy of 1 N. Among the most valuable issues was the estimation of strength parameters of line 45 taking into account the kernel thickness fractions. A unique methodological approach in the aspect of breeding practice and technology was the attempt at relating the thickness of kernels to their resistance to static loads. It was demonstrated that the critical values of force increased with increase in the kernel thickness fractions. Significant differences were proved even between neighboring fractions. Mean values varied from 22.66 to 77.5 N, with kernels with thickness above 3.0 mm indicating a certain drop in strength. In the summary of results, the authors emphasize that the thickness and width of kernels of octoploid triticale and of the hexaploid lines 45 and 51 fall in between those of winter wheat cv. Grana and of rye cv. Dańskowskie Selekcjyne. Moreover, the instantaneous resistance of kernels to static loading increases with their thickness, and the absolute values obtained suggest that they are closer to those of wheat than of rye. This indicates that the strength traits in question are inherited to a greater degree on the part of wheat than of rye. A negative feature of triticale kernels is their frequent surface wrinkling that is genetically determined. It was observed that well-filled kernels were less susceptible to mechanical damage than wrinkled ones. Hence, breeding studies should aim at elimination of endosperm wrinkling and at increase content of lysine in the triticale as well as in barley kernels (Rybicki and Patyna, 1984).

Estimation of physical parameters of kernels on the example of commercial cultivars

The best breeding lines, with high yielding and the most advantageous utility features (and especially with improved resistance to biotic and abiotic stresses), are registered as cultivars and introduced on the market. As cultivars are the end product of breeding, their evaluation with regard to the geometric parameters and resistance to mechanical loads can be used as additional information for the users, for grain processing process engineers, or for breeders who can use the best cultivars in their own crossbreeding programs, treating them as parental components. The quality of agricultural products, or more generally agricultural materials (e.g., cultivars), is usually associated with their utility value as the essence of quality is their suitability for nutritional or extra-nutritional purposes. Estimation of the quality of a given material requires knowledge of the range of variability of its physical properties. New research programs already include even the level of a single kernel (Single Kernel Technology), which supports the sense of undertaking research programs aimed at determination of physical properties of individual kernels of particular cultivars, not only within a given material for the processing industry, but also with respect of materials used in breeding programs. It is important to determine changes in the values of physical properties of individual kernels in spikes of wheat (*Triticum aestivum* L.) of commercial winter and spring cultivars. The scope of the study included field experiments, and the selection of wheat cultivars for the study was based on the criterion of "quality" that defines the limit values of physical or technological traits of grain and determines its being qualified in a suitable quality type. The winter forms were represented in the evaluation by the quality wheat Zyta (type A), and the bread-fodder forms by cv. Kris (type B/C). Among the spring forms the selected cultivars were Nawra and Broma, meeting the same criteria as above. Among the numerous physical parameters of individual kernels on the length of a spike the determinations included the parenchyma damage index that provides information on the state of its destruction under the effect of moisture gradient. X-ray images of the kernels did not reveal any damage in the material under examination. This indicates that under the conditions of the field experiment the cultivars analyzed displayed notable genetic resistance to internal damage in kernels. A significant element of the evaluation was the distribution of hardness of successive kernels in spikelets on the length of the spike (Grundas, 2004). Kernel hardness was estimated on the Single Kernel Characterization System analyzer as hardness index, which is an abstract value and has no physical interpretation. Based on the mean hardness values of the first, second, third, and fourth kernels in the spikelets it was concluded that it is a trait that is highly correlated with hardness understood as the resistance of a kernel to the effect of static mechanical loads. As results from the study, kernel

hardness is largely determined by internal features. This follows from the fact that the successive kernels do not display the typical decreasing trend in the direction of the tip of the spikelet that is characteristic of the other traits. Moreover, apart from the bread-fodder wheat cv. Kris, all other cultivars are characterized by a fairly even level of that trait. In accordance with the rule confirmed in other studies, kernels of spring wheat are harder and more resistant to mechanical damage than kernels of winter wheat, which is especially visible in cv. Kris. Improvement of kernel hardness in certain winter wheat cultivars may be one of the selection criteria in breeding programs.

Estimations were also made of the physical properties of successive kernels on the length of spikes of triticale forms and of wheat cv. Grana and rye cv. Pancerne. Analysis was made of the kernel to spike bond force, and the measurements covered five spike zones to determine the distribution of force variability on the whole spike length. It was demonstrated that the bond forces, depending on the cultivar, varied within the broad range from 0.93 N to 1.94 N. The strongest set were the kernels in the lower zones of the spike, and the weakest – in the tip section of the spike. The notable differences between the forms under analysis indicate that they are susceptible to shedding to various degrees – from easily shedding to hard to thresh.

An important element of physical assessment of kernels used for examination of commercial cultivars is the compressive strength of kernels, specific work, and modulus of elasticity as related to the level of moisture, as illustrated in a study on wheat cv. Henika (Woźniak, 2003). The study showed a ca. 50% decrease in the values of those parameters as a result of wetting of the kernels. A negative correlation was found between the traits studied and the time of grain wetting. That correlation did not relate to deformation. Moreover, kernels with vitreous type of parenchyma were characterized by higher values of mechanical parameters than mealy kernels. Estimation of the effect of kernel wetting time in parenchyma cracking and mechanical damage was also continued for hull-less barley cv. Rastik. A notable susceptibility of the hull-less kernels to parenchyma cracking was observed, with mean number of cracks in the control sample (dry kernels) being 13.6 and increasing with increase in the time of prior kernel wetting up to 15.8 (after 3 h of wetting). Wetting lasting more than 3 h caused a decrease of modulus of elasticity by 15% and of compressive strength by ca. 10%. Moreover, changes in kernel strain and in specific energy caused by prior moistening were similar. A very important conclusion of practical significance in breeding and processing is the demonstrated lack of correlation of the mechanical parameters with the number of internal cracks.

In studies continued also for commercial cultivars of spring barley – Berac, Gryf, Kosmos, and Polon, kernels after harvest were wetted to 12, 18, and 22% moisture (Styk and Szot, 1984). It transpired that kernels of all cultivars responded negatively to the effect of mechanical

loads, both at the conditional moisture and when moistened to the level of 18 and 22%. Increase in the mechanical load level from 4 MPa to 8 MPa resulted in a considerable decrease in the germination capacity that fell within the range from 23% to 35%, depending on the cultivars and moisture content levels. Kernels with increased moisture content proved to be more susceptible to damage. The period of storage had a significant effect, lowering the biological value of kernels, and that phenomenon was especially pronounced in material that was earlier subjected to mechanical loads of the level of 8 MPa at higher initial moisture. Those conditions caused that the seeds of all cultivars germinated at the rate of 52–61%. Such a considerable decrease in germination capacity indicates high sensitivity of sowing material to the effect of external forces, and the inter-variety (genetic) differences, varied fertilization, as well as seed moisture are those elements that may largely shape the resistance of kernels to mechanical loads, causing a variety of damage to the seed coat, the germ, or the parenchyma.

Leguminous plants

The problem of worldwide deficit of protein fodders relates both to their quantity and quality. The basic fodders in this respect are the seeds of high-protein leguminous plants. In the context of the onset of the BSE disease, the effect of elimination of high-value fodders of animal origin and the controversies around genetically modified soybean (GMO) may further aggravate the deficit of proteins in animal feeding. Ensuring high quality proteins in human and animal feeding is a priority topic in the EU countries. At present in those countries, 70% of plant proteins is imported, mainly in the form of extraction meal and soybean seeds, primarily transgenic. Unfortunately, the area of cultivation, both in Poland and Europe (respectively 1% and 3% in the crop structure), does not correspond to the unquestionable advantages of high-protein leguminous plants, important, i.e., due to their binding of atmospheric nitrogen (reduced requirements for nitrogen fertilization), positive effect on the soil structure, and plant succession in crop rotation systems. Among the numerous and already mentioned in part advantages that make growing of legumes an attractive proposal, a less known, undervalued, and attributed only a marginal significance element is the physical properties of their seeds. Knowledge of the physical properties of seeds is of special significance for the optimization of harvest, drying, and storage, and is related with minimization of quantitative losses and mechanical damage.

Evaluation of materials at early stages of breeding

Sowing grasspea (*Lathyrus sativus* L.), as a high-protein leguminous plant, is characterized by exceptional resistance to biotic and abiotic stresses. In particular, this relates to resistance to drought, the highest among all leguminous plants and also other crop plant species. In the

aspect of the global climate change and the mentioned resistance to drought, grasspea has been accepted as the model plant for the needs of sustainable agriculture (Vaz Patto et al., 2006). Hence, an attempt was undertaken at performing an estimation of the genetic variability of the utility features of that little known species, and especially a study of the resistance of its seeds to mechanical damage, to fill a gap in the world literature (Rybniński et al., 2004). The object of the study was young breeding material – mutants obtained through subjecting seeds of the Polish cultivars Derek and Krab to the effect of chemomutagens. Selected utility features were analyzed on the basis of a field experiment and, after harvesting the seeds, their resistance to static loads was determined as expressed by the force (N), deformation (mm), and energy (mJ). It was found that induced mutation is an effective tool for expanding the genetic variability of utility features in mutants. Apart from the selection of grasspea mutants with utility features improved with relation to the initial cultivars, selection of forms with increased resistance of seeds to mechanical loads was also performed. With the mean force value (N) for seeds of cv. Krab being 279.2 N, the range of variability of that trait in the mutants was from 238.0 for mutant K 14 to 328.4 N for mutant K 50. The broad range of genetic variability of mutant seeds resistance to mechanical loads, in conjunction with the favorable values of utility features estimated in the field experiment, permits the breeder to effectively select the most desirable forms as initial material for further breeding work, combining in a single genotype the improved utility features with increased seed resistance to mechanical loads.

In many cases, in order to extend the genetic variability of features and to introduce new ones, currently not available to the breeder, breeding programs make use of unique material collected at world Gene Banks. In view of the fact that such collection materials represent practically all the regions of the world, the breeders have at their disposal unique materials that are characterized by features not found in local materials. Frequently, due to their specific adaptive capabilities and exotic origin, not all collection materials can be applied under the conditions in which the breeder introduces new cultivars that are to be used by farmers under similar conditions. The above can be exemplified by a study that used collection lines of sowing grasspea originating from the regions of South and Central Europe for the estimation of phenotypic features, seed yield structure, geometric properties of seeds, and their resistance to static loads. The estimations comprised the variability of 32 objects, 21 of which originated from Italy, five from Spain, two each from France, Germany, and Poland (Rybniński et al., 2008). The material under estimation was characterized by a broad range of phenotypic variability, field structure parameters, geometric parameters of seed, and its resistance to mechanical loads (Table 4). In terms of their morphology, the plants and seeds of forms from Central Europe (Germany, Poland) differed the most from forms from Italy and Spain. The greatest variability

was recorded for the number of seeds per plant and the weight of 100 seeds, at coefficient of variability values of 45.6 and 35.3%, respectively. A broad range of variability of seed resistance to static loads was accompanied by similar levels of variability of other mechanical parameters, with the exception of the modulus of elasticity. Similar, though lower, values of coefficient of variability were obtained for seed thickness and width. It was noted that next to the small-seeded forms originating from France, Germany, and Poland, large-seeded forms came only from Italy and Spain. In breeding work, the relations between the evaluated features, as expressed by the value of coefficient of correlation, provide important information for the breeder (Table 5). A number of significant correlations were demonstrated between the utility features concerning plant morphology and the yield structure of the plants (traits Nos. 1–12 in Table 5). For the breeder estimating those features in his own field experiments it is important to know to what extent they are related with the resistance of seeds to mechanical loads. A lack of significant correlations between was demonstrated, which means in practice that estimations of morphological traits and yielding cannot be a basis for conclusions concerning the degree of seed resistance to mechanical damage. Whereas, a strong and significant correlation was observed between the particular parameters of mechanical loads (traits Nos. 13–18 in Table 5), with the exception of an insignificant correlation between maximum strain and energy and modulus of elasticity, and between the modulus and elastic strain. All geometric parameters of seeds

were correlated with one another (traits Nos. 18–21 in Table 5), as well as with certain morphological features, yield structure parameters, and mechanical load parameters. Noteworthy is the obtainment of a positive correlation between seed thickness and elastic strain, and a negative correlation between seed thickness and modulus of elasticity. The notable differentiation of forms with relation to their geographic origin is supported by the positioning of the objects on the plane in the system of two first canonical variables with respect to the analyzed traits of yields and mechanical loads combined. The most different from all other forms is the Polish cultivar Derek, followed by cv. Krab and the objects from North France and Germany. A notable separateness within the group of forms from Italy and Spain is characteristic of the Italian forms. With respect to resistance for mechanical loads cv. Derek is similar with forms from France and Germany whereas cv. Krab - with Italian forms.

Estimation of physical parameters of seeds on the example of commercial cultivars

Lentil is a member of the family of papilionaceous plants (*Papilionaceus*) – (*Fabaceae* = *Papilionaceae*) comprising 18,000 species. Compared to other species popular in agriculture, such as pea, vetch, soybean or lupine, and lentil – as the mentioned sowing grasspea (*Lathyrus sativus L.*) is a species with rather a marginal importance in European agriculture. Lentil seeds are characterized by a high content of proteins (even up to 30%) and high nutritional

value, which causes that in many countries lentil is now rediscovered by dieticians and nutritionists, who now classify it among so-called "safe foods" (Bhatti, 1988; Dębski and Dębska, 1989; Lampart-Szczapa, 1997). In spite of the unique nutritional qualities of its seeds, lentil is characterized by utility features that require genetic improvement in the process of breeding. One of such features is pod cracking. It takes place during ripening, when lentil pods tend to crack causing seed shedding. Seed losses resulting from this may reach up to ca. 20% of seed yield per hectare, and two-phase harvest reduced those losses to 14.2% compared to single-stage harvest (Sosnowski et al., 1993). In regions of East Asia and Africa, those losses may reach even 55% of the total yield of lentil seeds (Sidhamed and Jaber, 2004). Some literature data point out certain attempts at limiting lentil seed shedding or even total elimination of that unfavorable trait. Until the problem of premature cracking of pods and seed shedding has been solved through the creation of genetic resistance, one of the ways of reducing the levels of losses is the application of preparations inhibiting pod cracking under field conditions (Szot et al., 2005). Suitable measuring apparatus permitted the estimation of susceptibility of lentil pods to opening (in the phase of full ripeness), expressed by values of maximum force and energy causing the pods to break open. The measurement of both parameters, under the effect of opposing forces applied to both lateral sides of the pod, ended at the moment of its full opening. Measurement results were obtained for the commercial lentil cultivars Tina and Anita, for pods not subjected to the effect of desiccating agents (control treatment) and for pods after the application of such preparations. The results indicate varied responses of the cultivars as expressed by values of force required for pod opening – from 0.71 N for cv. Anita to 0.89 N for cv. Tina. When the desiccating preparations were applied, the best results were obtained using the spraying preparation Spodam and potato starch. With the application of Spodam, the force values increased by 0.32 N (36%) for cv. Tina and by 0.12 N (17%) for cv. Anita compared to the control treatment. Other preparations proved to be less effective, especially in the case of wheat starch and Reglone. The coefficient of variability for the preparations applied varied within the range from 41% to 60%. In spite of the positive results obtained for the Spodam preparation, it will not replace attempts by breeders at obtaining genetic resistance of pods to cracking and seed shedding. Nevertheless, the information from agrophysicists on the values of force required for pod opening relating to world collection materials, lines, and cultivars will permit better selection of parent components in crossbreeding aimed at the creation of cultivars with enhanced resistance to seed shedding. It is also important to demonstrate that the resistance of seeds to the effect of external forces is closely related with the level of damage to the seeds in the processes of harvest, transport, and at various stages of post-harvest processing, such as seed behavior in the course of various technological processes

to which seeds are subjected as raw material. Damage to seeds may be an important element of reduced germination capacity and lead to the disqualification of a seed batch as qualified sowing material. Differences between cultivars were observed in response to mechanical loading of seeds with moisture content of 9%. With respect to the force destroying seed structure, seeds of cv. Tina required the application of average force values at the level of 90 N, with range of variability from 53.7 N to 135.7 N. Seeds of cv. Anita proved to be more resistant, with mean force value of 125.5 N, minimum of 67.2 N and maximum of 194.0 N. Moreover, a rapid decrease in the force values was demonstrated for seed moisture increase from 9% to 15%, reaching even the level of 10 N. Noteworthy are the inter-variety differences in response to static loads, indicating their role in the estimation of seed quality for consumption purposes and as raw material for the food industry. The study was conducted for seeds of only two cultivars, demonstrating that their proneness toward shedding and mechanical damage had a genetic background. One can expect that examination of a large group of collection forms from various Gene Banks and cultivars will permit the selection of forms with the highest resistance. Data from agrophysical laboratories should provide valuable information that, given to the breeders, will help in finding proper directions in lentil breeding aimed at its genetic improvement.

Estimation of the physical properties of seeds of the most popular species of leguminous plants permits not only the assessment of varietal differentiation within a species, but also identification of differences between different species. Within the scope of particular species, farmers or the processing industry have at their disposal a large array of commercial cultivars representing a broad range of intra-species variability of traits, primarily in the aspects of their yielding capacity, chemical composition of seeds (e.g., protein, its amino acid composition, content of anti-nutritional substances), as well as resistance to biotic and abiotic stresses. The properties of cultivars regarding the abovementioned traits are generally available, mainly in the form of advertising material and cultivation recommendations published by plant breeding and seed producing institutions. The user of cultivars, however, will not find there significant information on the resistance of seeds to mechanical loads, for the simple reason that the author of a given cultivar has no data on that subject and, as a rule, does not conduct selection programs aimed at genetic improvement of that resistance. On the other hand, there are not many agrophysical publications that would present studies on a larger number of breeding materials (lines) or commercial cultivars. An example here may be a review of inter-cultivar and inter-species differences in the geometric parameters of seeds and their resistance to static loads. The object of the study were commercial cultivars of white, yellow, narrow-leaf and Andean lupine, and of sowing pea, sowing grasspea, lentil, and vetch. In total, 24 cultivars of those species were subjected to estimations. The results concerning the resistance to static loads indicate a broad range of variability

of the respective parameters. The calculated coefficient of variability shows that the most variable parameter was energy, and the least – elastic deformation. Similar values of the coefficient of variation were characteristic of the geometric parameters of seeds, as measured by their thickness, width, and length. An exception was the low coefficient of variability for seed length. With relation to the estimation of intra-species differences (among cultivars within a single species) in regard of the resistance of seeds to mechanical loads, it was demonstrated that the highest values of maximum force are characteristic of white lupine, followed by pea, and then by yellow lupine and narrow-leaf lupine. Notably different from all three lupine species are the low values of the Andean lupine, typical of South America. Analysis of other parameters of static loading confirmed the occurrence of the highest values for seeds of white lupine, indicating its genetic separateness from the other species and cultivars of lupine, as well as from the other species and cultivars of leguminous plants studied. A significant element is the estimation of relationships between the traits under study. With the exception of the modulus of elasticity, all remaining five parameters of mechanical loading (maximum force, force of elasticity, maximum deformation, elastic deformation, and energy) were positively and statistically significantly correlated with one another at the level of $\alpha = 0.001$. The modulus of elasticity was positively correlated only with the force of elasticity. Except for the modulus, all other load parameters were positively and significantly correlated with seed width. Seed thickness, in turn, was positively correlated with the force of elasticity and with elastic deformation. Seed length was not correlated with any of the parameters under assessment.

Estimation of similarity of all cultivars and lines in terms of mechanical loading of seeds, treated jointly in spatial form and in the system of two first canonical variables, showed that the most isolated spatial positioning was characteristic of two white lupine cultivars – Boros and Butan. The positions of the remaining cultivars indicate their greater mutual similarity and considerable separateness with relation to the white lupine cultivars.

Conclusion

Summing up, it should be clearly stated that the results of agrophysical studies are highly valuable for the geneticists and for breeders of crop plants. The presented correlations and their positive effects indicate the need for intensified scientific cooperation in this field that is a necessity for modern and interdisciplinary achievement of joint targets. As it has been shown above, the physical properties of plants are inherited to a large extent, and knowledge of those parameters may play a highly important role in the creation of new cultivars. Every species or variety is characterized by its own specific genetic potential. That potential is revealed in the specific expression of the utility features, hence the importance of proper selection of suitable initial material for breeding studies (at various stages

of the breeding cycle) and its analysis in the context of its genetic potential as well as with the inclusion of the effect on plants of specific, controlled as far as possible, environmental conditions. Therefore, it should be considered a necessity that agrophysical research methods are made available to the geneticists and plant breeders so as to allow them to test the parent forms for the selection of the most favorable traits and their heritability at the earliest possible stages of breeding programs.

Synonyms

Root pullout strength; Root tensile strength; Shallow landslides; Slope stability

Definition

- Plant root strength: Maximum force per unit area, causing a plant root in strained soil to break or to become detached along the soil–root interface.
- Slope stability: Force equilibrium of resistant and driving forces acting on a soil mass that can deform freely

under the influence of gravity (e.g., on sloping surfaces), leading to limited deformation that is inconsequential for the safety or serviceability of the slope or adjacent areas.

Introduction

Root reinforcement is the interaction between mobilized root strength, root morphology, and shear strength along the soil–root interface. At the plant level, this interaction ensures the stability of the aboveground biomass while, at the stand level, the reinforced soil may contribute positively to the overall stability of natural and man-made slopes. Root reinforcement is widely recognized as the most important beneficial effect of vegetation on slope stability. However, it is just one of the many ways by which vegetation influences slope stability, either directly by affecting the loads or resistance or indirectly through the hydrology. The influence of vegetation on slope stability has been widely attested with the frequency of mass movements such as shallow landslides increasing after the removal of the vegetation and the decay of roots, reaching as far back as Pliny, the Elder (Pliny the Elder or Gaius Plinius Secundus [23–79]: Roman officer and encyclopedist) who wrote “Often, disastrous torrents are formed after the felling of mountain woods, which used to hold back clouds and feed on them.”

Root reinforcement requires that plant roots anchor the soil mantle to bedrock or that roots act as fibrous binders of soil particles (Ziemer, 1981). The major biotic determinants of root reinforcement are root strength and root architecture which are primarily dependent on plant species, while the major abiotic determinants are soil texture, depth, moisture content, the local slope angle, water table depth, and the depth of the potential slip plane (Danjon et al., 2008; Genet et al., 2005).

Mechanisms of root reinforcement

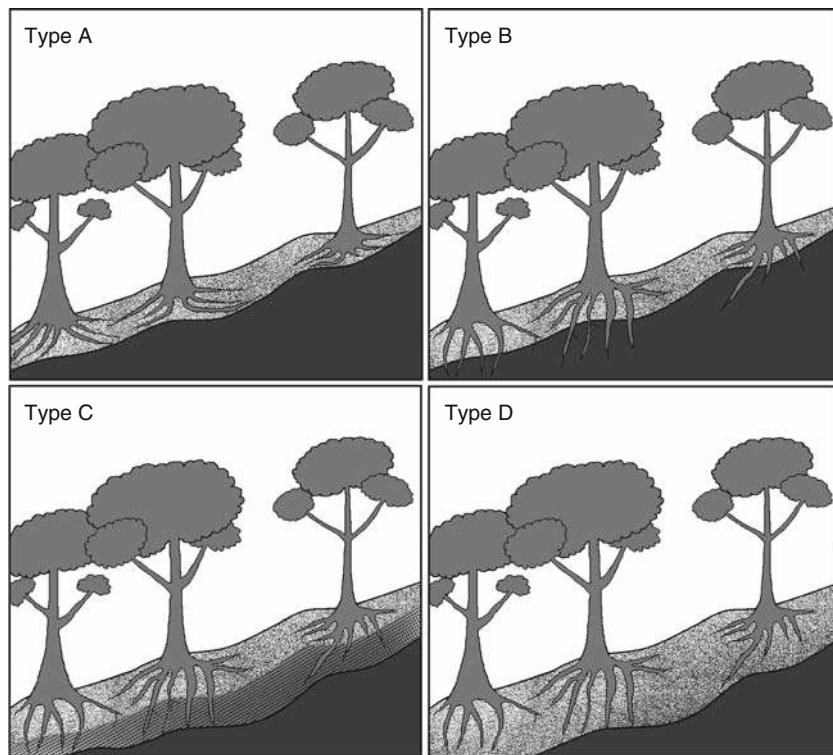

In soil possessing little if any tensile strength of its own, roots constitute elastic elements with high tensile strength. Upon deformation of the soil, elastic elongation of the roots mobilizes the available root strength. Given root orientation with respect to local displacement, total root reinforcement depends on the total number of roots loaded and the mobilized strength. Normal to the potential slip plane, root reinforcement contributes through the confining normal stress to the frictional resistance, while the tangential component reduces the applicable shear stress. With continued deformation, root reinforcement continues to increase until individual roots eventually fail by breakage or pullout (slippage). Thus, root reinforcement is only appreciable after some strain has occurred and a substantial number of roots has deformed, when those roots remain intact and bounded by the soil and when the strain is small enough to prevent the complete loss of integrity of the soil; when these conditions are not met, the slope may fail regardless without mobilizing the maximum available root reinforcement (Mulder, 1991).

Failure of individual roots occur when they rupture in tension or are pulled out from the surrounding soil. The latter usually requires less force than the former and most often in highly saturated fine-textured soils, pullout is the dominant root failure mechanism (van Beek et al., 2005; Waldron and Dakessian, 1981). Root strength of a single root segment ultimately depends on the effective normal stress acting on it, the cohesion and friction along the soil–root interface, and the area thereof in case of pullout or the root tensile strength, which is partly species dependent, partly dependent on wood age, and function. Branched roots can mobilize more strength than roots without branches that slip out of the ground with minimal resistance. Branched roots fail in two different modes, them being (1) the ones that reach a maximum strength and maintain this strength until it progressively decreases with the breakage of individual branches after crossing a threshold strain and (2) those that break with the progressive increase of force (Greenwood et al., 2004).

While root-reinforced soil contributes locally to the available shearing resistance, stable columns of soil may act as buttresses and prevent overall slope failure (Wang and Yen, 1974). Consequently, the relative location of plants with varying root architecture is an important determinant of total root reinforcement (Coutts, 1983). The presence of plants with heart roots and lateral roots is preferred along the toe and scarp of a potentially unstable

slope, while plants with tap roots that provide anchoring into bedrock or stable soil layers are favored along the mid-slopes (Danjon et al., 2008). In general, a large number of small roots will contribute more to slope stability as compared to a small number of large roots (De Baets et al., 2008). Based on the root–soil–bedrock interactions and the resultant slope stabilizing effects of roots, hill slopes can be classified into four types (Figure 1) (Tsukamoto and Kasakobe, 1984), them being:

- Type A: Characterized by shallow soil (<1 m) overlying an impenetrable bedrock. Roots grow laterally at the failure plane, binding the overlying soil and thus provide high soil cohesion, but lacks anchoring.
- Type B: Characterized by shallow soil (<1 m) overlying a bedrock with substantial density of fractures. Roots penetrate the bedrock, intersecting the potential failure plane and thus provide high soil cohesion and anchoring.
- Type C: Characterized by deeper soils (1–3 m) overlying a nondistinct weather bedrock material that acts as a hydrological transition zone, exhibiting increasing strength with depth, which in turn overlies the impenetrable bedrock. Roots penetrate the soil and the weathered parent material often through which passes the failure plane, and thus provide high soil cohesion and anchoring.

Plant Root Strength and Slope Stability, Figure 1 Four types of root reinforced hill slopes. (Modified after Tsukamoto and Kasakobe, 1984.)

- Type D: Characterized by very deep soil (>3 m) overlying an impenetrable bedrock. The failure plane in such slopes being very deep, often the roots do not intersect them and thus lacks any anchoring; however, given a certain root density there may be moderate soil cohesion.

Root strength measurements

Quantification of root reinforcement requires information on root densities, orientation, diameter, and species as well as on the available strength. For individual root segments, soil–root bond has to be measured by mimicking pullout, while root tensile strength has to be measured by loading a root segment in tension until failure occurs.

Root tensile strength

Root tensile strength is measured by subjecting a single root segment to elongation until the root breaks. The load at failure can be measured using a universal tensile and compression testing machines generally used for fiber tensile strength testing (De Baets et al., 2008) or specialized equipment (Ziemer, 1978) which can apply a constant strain rate to the clamped root. To avoid stress concentrations around the clamped ends, the overall length of a root segment should be several times its diameter and sufficiently large to provide for clamping (approximately 5 cm on either side). For roots under 10 mm, a total length of 15 cm often suffices. Clamping a root is a delicate work, and roots often either slip from the clamps or break where the root gets crushed by it. Epoxy resin or Plaster of Paris reinforcement at the tips can prevent this. A tensile strength test is counted successful if the breakage is at the middle nonreinforced part of the sample. Care has to be taken to avoid root desiccation or root decay during the period between sampling and testing. Roots should be kept as close to their original moisture content as possible or at least soaked for 24 h to approximate their green strength (Cofie and Koolen, 2001).

For most plants, the tensile strength is known to increase with a decrease in the diameter of roots based on a power law having the form

$$T_{ri} = aD^{-b},$$

where T_{ri} is the tensile strength of an individual root (measured in units of pressure, usually MPa or kPa), D the diameter of roots (measured in units of distance, usually mm), a the relationship constant, and b the scaling exponent.

Table 1 provides the parameters of the tensile strength-diameter power relationships for various plant species from published literature. **Figure 2** shows this relationship of five tropical plant species.

Root pullout strength

Pullout strength has to be measured in situ either by measuring the total strength necessary to pull out a whole plant

(Nilaweera and Nutalaya, 1999) or by testing individual root threads (van Beek et al., 2005). Studies have shown that there exists a theoretical threshold diameter between root pullout and root breaking. Above this threshold, the friction between the soil and roots exceeds the root tensile strength and below it, if the force required to break the root–soil friction bond is less than the force required to break the root, the roots will slip off the soil (Pollen, 2007). Pullout strength test needs minimum 10 cm of root protruding outside the soil. Ideally, the sample should be at least 0.5 m away from the base of the tree. A pullout strength test is counted successful if successive straining decreases the stress, indicating the loss of soil–root bond. If the roots break during a pullout test, they are registered separately, so as to identify the threshold diameter between root pullout and root breaking. Pullout strength is more site specific compared to the tensile strength because of the spatial variations in root-soil bond which in turn is influenced by factors such as soil cohesion, soil saturation, slope and root type (Schmidt et al., 2001).

Root reinforcement models

There are three models that abstract root reinforcement. The first and the most commonly used approach called simple perpendicular root model considers root–soil interaction within a shear band through force equilibrium (Waldron, 1977; Wu et al., 1979). The root reinforcement is translated as an additional amount of cohesion in the Coulomb equation, which depends on the amount and strength of roots present in the soil and assumes the form:

$$C_r = T_r(\sin\theta + \cos\theta\tan\phi)\left(\frac{A_R}{A}\right),$$

where C_r is the total root-induced cohesion, T_r is the average tensile strength of roots per unit area, A_R/A (unit less) is the root area ratio, ϕ is the angle of internal friction of the soil, and θ is the angle of deformed roots with respect to the shear surface. Based on the extensive sensitivity analysis, the value of $(\sin\theta + \cos\theta\tan\phi)$ is approximated to be 1.2 for most practical situations (Wu et al., 1979). As calculating, C_r necessitates site-specific information such as soil depth and root density, it is not attempted herein. The amount of additional cohesion induced by roots of a given species of plant presented in **Table 1** can be found in the respective articles.

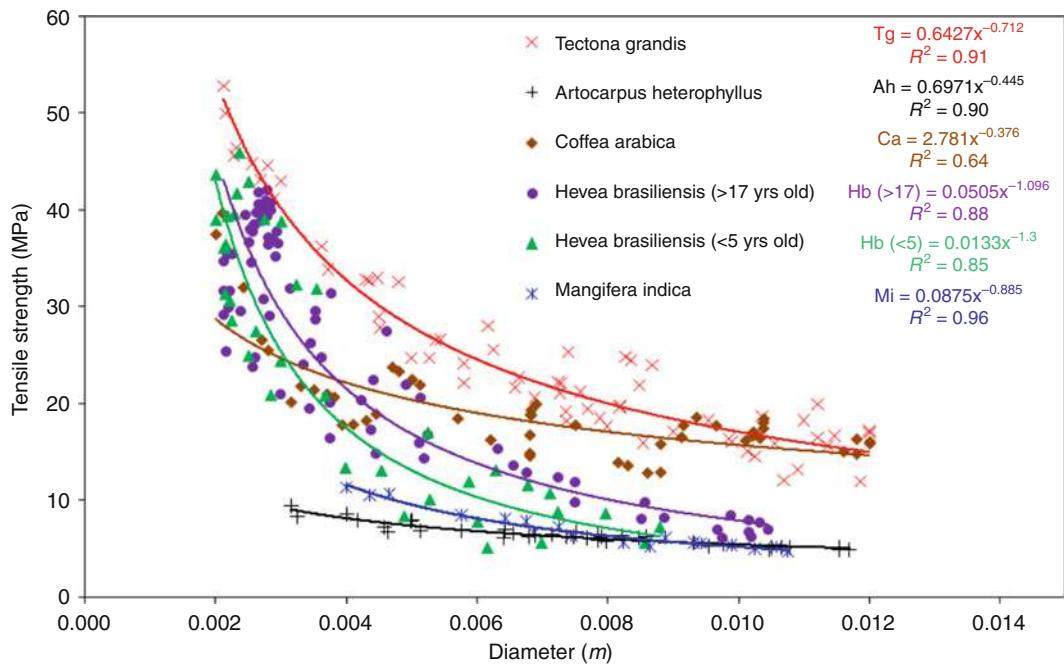

The second model considers root-included soil matrix as a composite material with a homogenous macroscopic behavior (Michałowski and Zhao, 1995). The third model (named RipRoot model) is based on the concept of fiber-bundle models in material sciences and attempts to capture the progressive breakage of roots having varying tensile strengths, with an associated redistribution of stress as each root segment breaks (Pollen and Simon, 2005).

Natural variability is the major source of uncertainty in computing root reinforcement. Root strength of different

species of the same family can be considerably different (Greenway, 1987). Such high variability can also be observed with the strength of roots of the same species growing in different terrain conditions (Gray and Sotir, 1996).

Reliability of root reinforcement

Increased infiltration and permeability, desiccation of soil due to plant intake which results in large macropores, surcharge due to the presence of overgrown trees, and wind loading are some of the detrimental effects of vegetation on slopes susceptible to failure (Coppin and Richards, 1990). Such effects are clearly outweighed by the mitigating effects of root reinforcement (Fan and Su, 2008). However, the presence of roots does not increase the stability of slopes indefinitely. Root count rapidly decreases with increase in soil depth (Cammeraat et al., 2005), and hence root reinforcement is limited in such slopes (Type D slopes). Studies indicate that the root reinforcement on natural slopes is limited to a small range of critical hydrological conditions (van Beek et al., 2005).

In anthropogenically intervened landscapes, root development is significantly hampered by cyclical slope modifications and when trees are cut, the root system begins to decay, leading to the progressive weakening of soil–root fabric (Schmidt et al., 2001). Such decayed roots also act as preferential flow conduits, which transport water

directly to the potential failure planes. So also, after the reestablishment of vegetation in clear felled forests, it takes almost 3 decades for soil to regain the strength of that in the uncut forest (Ziemer, 1981).

Conclusion

It is evident from Table 1 that research on root reinforcement offered by plants is limited. Very little efforts have been directed toward understanding the relationships between the cellulose content and the tensile strength of roots. Most researchers consider root reinforcement as additional cohesion based on the first model, while the second and third models are not widely applied or researched upon. The root reinforcement model is by itself limited in certain aspects. For example, fine roots are not very flexible to be loaded in compression which in reality will affect root–soil bond and thereby limit the mobilization of root pullout strength. Laboratory studies are still lacking in this direction (van Beek et al., 2005). A significant root strength parameter, the Young's modulus (measure of the stiffness of root thread as an isotropic elastic material), is less frequently measured than the tensile strength (Wu, 2007).

Studies are limited on the three-dimensional (3D) distribution of woody roots, which is often not accountable by means of conventional methods for deriving the root area ratio. This will result in an over or under estimate of

net root reinforcement by trees growing on mountain slopes (Danjon et al., 2008). Root reinforcement does not assure long-term stability in anthropogenically modified landscapes. In natural forests, forest fires and plant diseases may lead to the eventual loss of root reinforcement. Despite such limitations, plant roots can provide considerable reinforcement and is the most cost effective means to increase the stability of natural and modified slopes.

Definition

Roots anchor plants, provide access to water and nutrients, and store energy and carbon. Soil structure is the arrangement of pore space and solids. Soil without plants is extremely rare. Emerging from the coevolution of plants and soil is a complex and intermingled system that is often specific to the situation and its history. Agricultural and ecosystem management strategies tend to treat these as separate systems and consider the bulk soil and average plant root properties as representative of the function of the whole. Consequently, many problems arise because in fact local conditions and plant strategies to exploit these are a far better representation of the real conditions experienced and therefore reflect plant performance more accurately. Separation of soil structure and plant roots restricts man's capability to most effectively and sustainably manage soil production systems.

Introduction

Soils are highly complex environments that encompass physical and chemical heterogeneity across a wide range of spatial and temporal scales (Pierret et al., 2007). They bridge the mineral world with all the other trophic levels in the biosphere. Soil structure is central to such a fundamental linking role, as it provides the habitat for an extraordinary array of organisms (Young and Crawford, 2004; Watt et al., 2006) and the pathway for essential resources on which they depend for their survival. In turn, soil biological activity is one of the main drivers of soil structure and fertility formation and maintenance. Among the myriad of soil life forms, plants, through root growth and functioning, play a pivotal role with regards to all other soil processes. Plants deposit considerable amounts of carbon in the soil: up to about a third of photosynthates allocated to roots could be lost to the soil as cap cells, mucilages, soluble exudates and lysates, and decaying tissues (Hawes et al., 2003; Hutsch et al., 2002). Due to roots' inherent nutritional value as a carbon substrate and the wide range of metabolites that they secrete into the soil (Rovira, 1965), rhizosphere soil and root surfaces are also the main habitats for many soil organisms (Stewart et al., 1999).

The plant species that make up the vegetation in a given ecosystem have evolved to occupy different niches and thus often deploy different (both complementary and competitive) soil exploration strategies. A root system can be

regarded as a population of individual roots behaving (1) differently and independently from each other (Waisel and Eshel, 1992) (although coordinated to some degree at the root system level), (2) as a function of tissue differentiation, and (3) in response to changing environmental conditions (plasticity). The rooting pattern of a given plant species in a given environment represents an evolutionary response to the spatiotemporal variability in resource availability and the resulting constraints to growth. Roots of higher plants and their associated microbes play a major role in soil formation processes; as such they have coevolved plastic responses to their environment and thus differentiated as organs optimized to explore and utilize heterogeneously distributed soil resources (Leyser and Fitter, 1998) throughout geological times (Raven and Edwards, 2001). The interactions between plant roots and soil structure are of two types (1) root response to the heterogeneity of local soil conditions and (2) variations in root soil contact. The former includes reduced growth due to soil strength (Whalley et al., 1995) or low water and/or nutrient availability, and root proliferation in nutrient hotspots or in macropores (e.g., Tardieu, 1988)

Plant root types and functions

Roots are the organs of vascular plants that bear neither leaves nor nodes, and which are generally located below the soil surface. Roots have two major functions (1) the absorption of water and inorganic nutrients essential to plant growth and (2) the anchoring of the plant to its substrate. Roots also often function as storage organs. Roots are classified into several categories according to their ontogenesis and functions. Details about nomenclature used to describe root types and root system architectures can be found in Klepper (1992), Pagès et al. (2000), and Zobel (2005). Different root types play different functional roles (e.g., Navara, 1987; Mistrik and Mistrikova, 1995). Significant changes in physiological properties and activities also occur along individual roots, often as a function of root ontogenesis (Clarkson, 1996; Lazof et al., 1992). Root ability for water uptake varies according to (1) tissue differentiation, namely suberization, which affects the radial pathway (i.e., water transport from soil to xylem vessels) and xylem maturation (axial pathway, i.e., water transport along roots) (Steudle, 2000) and (2) transient changes in root water carrying capacity (short-term changes in xylem resistance Zwieniecki et al., 2003 or embolism Shane and McCully, 1999). There is good evidence that the few centimeters of unsuberized root tissue just behind root tips often act as active sinks through which soil water is absorbed while older parts of roots may predominantly be involved in carrying water extracted by younger and finer roots to the plant (Varney and Canny, 1993; Doussan et al., 1998). Together with litter fall, root production is believed to be the dominant input of organic carbon to soil and to correspond to a carbon stock more than twice that existing

above ground (Jackson et al., 1996). Among root types, fine roots may be the prominent sink for carbon in soils (Jackson et al., 1997; Norby et al., 2004).

Soil structure

Soil structure refers to the arrangement of the solid constituents of the soil and of the voids between them (Marshall and Holmes, 1979). It results from a range of factors such as the nature of the parent material from which soil constituents formed; the environmental conditions under which the soil formed; the mineralogy and organic matter content of the soil; the foraging activity of soil fauna; microbiological interactions; and the recent management history. Depending on soil mineralogy, the formation of zones of highly heterogeneous soil strength can result from purely physical processes such as cracking and swelling or freezing – thawing cycles. Human activities, such as agricultural practices, induce soil structural modifications that, although generally limited to the first 10–30 cm of the soil profile, are more rapid than natural processes, such as compaction due to tillage, wheel traffic or trampling by cattle, formation of plow pans, slotting, and deep ripping (Whalley et al., 1995). Soil particles combine into aggregates held together by binding forces exerted by clay particles and organic matter, shrink/swell dynamics, and cementing processes. The size, form, and strength (or persistence under degrading forces) of aggregation is used to characterize or describe soil structure. A well-structured soil will generally provide habitat for a wide range of life forms, conduit for fluids (air, water), preferential pathways for root growth, and reactive surfaces suitable for biochemical exchange and/or storage. Plant growth is both strongly influenced by soil structure and is one of the factors from which soil structure arises.

Root foraging strategies as a function of variable soil conditions

Hutchings and John (2004) outlined that most studies on root growth follow the premise that soil conditions are homogeneous, leaving serious gaps in our understanding of how plants function under natural and managed conditions and how they take advantage of patchy soil conditions. It has long been established that root system architecture of plants grown *in situ* is generally more complex and subject to greater inter- and intra-specific variability than that of roots grown in laboratory conditions (e.g., in agar). Soil is a physical environment where it is often difficult for roots, microorganisms, and soil fauna to move, and where resources (water, air, nutrients) are frequently scarce and patchy, with considerable spatial and temporal variability. Even when abundant, soil resources are often poorly available to organisms due to the capacity of the soil matrix to bind water and nutrients (Strong et al., 1999).

Variable soil conditions experienced locally by plant roots trigger, within species-specific limits, a range of physiological responses that help the plant minimize the

potential stress arising from soil heterogeneity and enable it to take advantage of “better-than-average” conditions (Drew, 1975; Robinson et al., 1999). Such plastic root responses to heterogeneous supplies of nutrients have been extensively reviewed by Hodge (2006). Plants have developed a range of complex strategies to exploit the soil’s inherent patchiness, such as proliferation, segregation, aggregative root placement (Bartelheimer et al., 2006), or preemption of nutrient supply (Craine et al., 2005).

Depending on local environmental conditions, a single species may deploy subtle combinations of foraging strategies. For example, one plant species was shown to switch between dichotomous and herringbone root architectures, the former topology being advantageous to compete for scarce nutrients while the latter restricts root length thus helping to minimize exposure to toxic compounds. The existence of opportunistic strategies has been confirmed experimentally: soil patchiness triggers costly “root races” between competing plants, in which large amounts of assimilates are spent into producing a great profusion of roots in an effort to secure exclusive benefit from resource enriched spots (Hodge et al., 1999). It has also been reported that rapid physiological plasticity consisting of opportunistic changes in nutrient uptake rates could be an important process for the capture of patchy resources by plants (Jackson et al., 1990).

Plant root growth in structured soil

The presence of zones of high mechanical resistance is one of the most common physical limitations to soil exploration by roots (Hoad et al., 1992). In soil volumes of higher mechanical strength, the development of soil structure is of paramount importance to root penetration (Tardieu and Manichon, 1986; Tardieu, 1988; Tardieu and Katerji, 1991); increases in soil strength reduce root elongation and alter root diameters and the average number of lateral roots that stem from primary axes (Dexter, 1987; Bengough, 1997) with direct consequences for resource acquisition by plants (Lynch and Nielsen, 1996; Pagès, 2002; Pagès et al., 2000). In very hard soil, the uptake of water and nutrients may become limiting because roots have difficulty penetrating the soil. In very soft soil, root length is not affected, but some have argued that the contact between the root and the soil may be so low that transport of water and nutrients is restricted (Herkelrath et al., 1977; Kooistra et al., 1992). In soils that impede root growth (e.g., because of high resistance to penetration), successive generations of roots tend to reuse paths of least mechanical resistance, such as preexisting structural features like cracks, biopores, or casts excreted by soil macrofauna. This co-location of roots and macropores (Stewart et al., 1999) leads to the formation of a specific environment that differs significantly chemically and biologically from the bulk soil (Pierret et al., 1999; Pankhurst et al., 2002).

Quantification of the root–soil interplay

Passioura (1985, 1991) hypothesized that roots are not evenly distributed throughout the soil matrix and are possibly trapped in large pores. This has been termed the root clumping model. Comparing plant growth in uniformly hard soil and in hard soil containing biopores, Stirzaker et al. (1996) found that while large biopores can provide the plant with access to extra water and nutrients from depth, this is offset by problems related to poor root–soil contact in biopores and impeded laterals in the compacted biopore walls. Based on microscopical observations of roots in thin sections of undisturbed soil, Kooistra et al. (1992) proposed the first detailed quantification of the relationship between soil structure and root–soil contact. Root–soil contact was found to increase nearly proportionally to soil bulk density. Plants can maximize root–soil contact in loose soil through branching (with some degree of species-specific variability); for example, in porous topsoils, very small roots (<0.1 mm radius) tend to explore the denser parts of the system (aggregates) (Moran et al., 2000). Yet, soil compaction significantly affects root–soil contact, which in turn influences plant uptake efficiency (Veen et al., 1992).

Combining microscopy and image analysis, Krebs et al. (1994) quantified the spatial distributions of roots relative to the locations of soil structural features such as channels, cracks, and pores and provided a first quantification of the spatial association between plant roots and soil structure. Stewart et al. (1999) assessed the root clumping model by comparing the frequency of roots in macropores with the frequency expected if the roots were randomly located in the soil volume. Some clumping was observed, however, a more significant effect was the location of a large proportion (80%) of roots in the soil within 1 mm of macropores. They termed the portion of the soil surrounding macropores with which roots are associated the macropore sheath. It was later found that the macropore sheath represents a local environment, only a few millimeters thick, that supports a biological activity and diversity orders of magnitude higher than that which prevails in the bulk soil (Pierret et al., 1999; Pankhurst et al., 2002). From this result, it was concluded that measurements of bulk soil properties may not be a good reflection of the environment experienced by the root system, and thus the plant, because the macropore sheath is a small proportion of the total soil. Using high resolution X-ray imaging, Moran et al. (2000) confirmed that roots are not spread evenly throughout the subsoil and showed that, as they grow preferentially in soil less dense than the soil bulk density, roots probably exploit a limited portion of the soil resources.

A conceptual model for root growth based on soil structure as the primary control for soil exploration was proposed by Pierret et al. (2005) to explain data published in that paper and by Moran et al. (2000). The most important data from X-ray analysis of thin soil slabs, showed that almost no roots occupied soil with density as great

as the average soil bulk density; roots (of all radii) strongly preferentially occupy low-density regions of the soil. Their model proposes that not only is root presence and length distribution likely controlled by the soil heterogeneity, as described earlier, but root radius as well. In brief, their model contends that the plant matches root radius to available pore size and thus exploits the soil resources through the structure rather than waste assimilate unnecessarily creating pores. As an example of supporting data, root radius was found to be smaller in denser soil and vice versa. This is the opposite of what is found using conventional experiments in which massive (structureless) soil or sand materials are equilibrated to a range of soil water tensions, seeds germinated, and root radius and elongation measured. This work demonstrates the importance of not relying on simplified physical models of soil to understand interactions with plants. A similar misunderstanding arises when soil biological and nutrient status measured from bulked soil samples are linked to root system characterization, because, as indicated earlier, the environment in the vicinity of roots can be radically different to the bulk soil.

Summary

There exists significant evidence in the literature that soil structure and plant roots can barely be considered separate entities. Plant root form, length distributions, radius distributions, branching, and overall plant vigor have all been demonstrated to be heavily influenced by soil structure. This has been illustrated using a number of different techniques in the laboratory and in the field. Similarly, characterization of soil structure has shown that plant roots and their associated local chemical and biological environments are strong determinants of the character of soil structure. The mineral nature of the soil, wetting and drying frequency, and intensity and disruption management history are the other major factors. Plants show tremendous plasticity in root system responses to heterogeneous soil conditions. Individual species and plant communities have evolved mechanisms to very effectively exploit available soil resources. In introduced monocultures, the evolved efficiency delivered by communities is absent and inefficient soil resource exploitation can be observed. There are many examples where measurements of bulk soil chemical, physical, and biological properties indicate that there should be sufficient resources for plant vigor but plants seem to suffer poor performance. Without a good understanding of the soil structure plant root interplay, it is unlikely that maximum plant performance will be achieved and over-allocation of resource such as fertilizers and water via irrigation will continue to be a heavy-handed risk mitigation strategy to avoid crop failure. For maximum carbon sequestration into soil that is stable into the long term, it is also likely that lessons regarding the strong interrelationships between soil structure and plants roots will need to be exploited.

PLANT TEMPERATURE

Piotr Baranowski

Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland

Definition

Plant temperature is the measure of its ability to exchange heat energy with surrounding (air, soil, water). It is an important quantity influencing plant growth and yielding. It is also an indicator of water availability for rooting system and the occurrence of abiotic or biotic stresses.

Biochemical reactions, cell growth and division, cell differentiation (generative/vegetative), and cell elongation depend on the temperature distribution within the plant and its daily variation. The actual value of plant temperature is continuously modified by changing environment and physiological activity. Meteorological parameters and soil temperature are the main factors modifying the temperature of particular plant organs and are responsible for considerable differentiation of temperature distribution within the whole plant. Roots of land and water plants possess temperature close to the surrounding (soil or water reservoir) temperature. The temperature of above-ground parts of plant often deviates considerably from air temperature. Plant temperature response to environmental factors, especially of leaves and stem, is regulated by stomata opening and closing mechanism, which is responsible for tuning transpiration intensity and gas exchange (Chalerle et al., 2005). Heat loss associated with transpiration is the result of energy demand for this process and equals the product of the rate of transpiration and the latent heat of vaporization of water. Transpiration is able to lower plant temperature by several degrees. Leaf cooling through transpiration may be regarded as beneficial for plants which are at high temperatures until water loss is made up by sufficient water uptake from soil. The energy balance equation for a leaf is fundamental for understanding the temperature regime in plant (Baranowski et al., 2005). Increase of plant temperature as result of stomata closing (especially, when compared with a reference plant surface temperature or actual air temperature) is an indicator of occurring stress. Depending on the origin or type of plant stress, it manifests itself through a local or overall increase of plant temperature. Thermal imaging is the most efficient way of

measuring plant temperature, being a powerful tool for the study of spatial variation in plant and canopy temperatures (Jones, 2004).

PLANT TROPISMS, PHYSICS

Fernando Migliaccio, Alessio Fortunati, Paola Tassone
 Institute of Agro-Environmental and Forest Biology (IBAF), National Research Council, Monterotondo, Rome, Italy

Definition

Plant tropisms are directional movements of plant organs, generally due to growth, induced by an external factor. The movement can be toward or away from the inducer, but the path is not predetermined as in the nastic movements. The most common kinds of tropisms are gravitropism and phototropism.

Introduction

Despite the fact that plants are usually seen as stationary organisms, they do, in fact move continuously in different ways, and for different reasons, among others: in search of light, water, nutrients, defense against predators, and reproduction. Several kinds of movements are recognized but the principal ones are nastic, circumnutational, and tropic. In the latter, the plants move in a direction, under an external stimulus, which induces a different elongation on opposite sides of an organ. The best known, most common, and most easily observable tropisms are gravitropism and phototropism. Although these are the main subjects of this contribution, other kinds of tropisms, known as thigmotropism, hydrotropism, and autotropism have also been described.

The fact that plants move has been known since antiquity (Larsen, 1962). However, apparently the first consistent experimental work on tropisms was carried out by

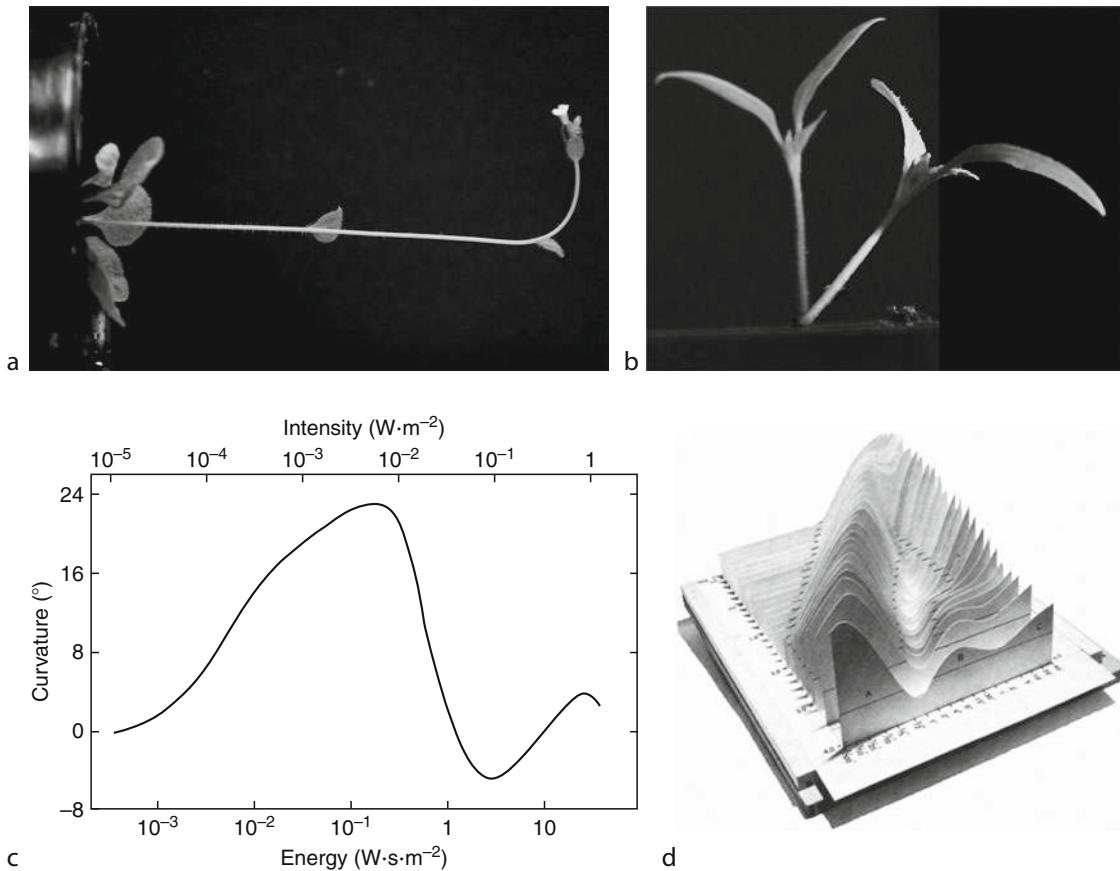

T.A. Knight in 1806. He thought, correctly as it turned out, that the movement induced by the gravitational force could be mimicked by the application of a centrifugal force (really a centripetal force). He built a device consisting of a wheel that could be rotated at different speeds and discovered that plant seedlings, rotated at a speed that produced about 3.5 times the earth gravity, ignored the gravitational force and redirected their shoots toward the center of the wheel, and the root away from it.

In the nineteenth century, experimentation on tropisms (and plant movements) progressed rapidly, but the seminal contributions were made by von Sachs and by Darwin. von Sachs invented and built the clinostat, a disc on which plants are fixed, that rotates at moderate speeds and thus does not produce centrifugal force. It does, however, simulate the absence of gravity, because the stimulation of the plant from all directions practically suppresses the gravitropic effect. Subsequently, the process of plants movements (and among them tropisms) was submitted to the powerful scientific mind of Darwin. The results of these researches were reported in a book about the movements of plants (Darwin, 1880). At about that time a large amount of research and experimentation on tropisms began.

Gravitropism

The term gravitropism (previously geotropism) applies to the process by which a plant grows with the shoot directed up and the root, downward (Figure 1a). This form of gravitropism is known as orthogravitropism, but other forms exist, such as plagiotropism, in which case the branches grow at an angle to the gravity vector. More precisely, the different organs of a plant keep a gravitationally set angle, to which they return if moved away (Digby and Firn, 1995). Plants, however, do not respond only to gravity but also to centrifugal force, as already mentioned, so that a more exact term for the process would be barytropism (Larsen, 1962).

Gravitropism has been traditionally classified into three steps: detection of the stimulus, transduction of the signal, and response. In this process some physical descriptors can be established: one is the *sine law*, which establishes that the response or curvature of the organ is the product of 1 g (acceleration of gravity on earth) and the sine of the angle made by the organ with respect to the gravity vector (response = $1 \text{ g} \times \sin a^\circ$). This law is not always respected. A second parameter is the *dose of stimulus*, i.e., the product of time of stimulation and intensity. In addition, the so-called presentation time, i.e., the time that a plant requires to respond after a gravistimulation at 90°. This parameter was at first calculated from the time of appearance of a curvature in 50% of the studied coleoptiles. In later work, however, plotting the extent of curvature against increasing periods of stimulation and extrapolating the curve back to zero time produced presentation times between 12 and 30 s (Volkman and Sievers, 1979). More sensitive methods, such as the submission

Plant Tropisms, Physics, Figure 1 (a) Response to gravity of an *Arabidopsis* plant. (b) Response to a lateral light source by a pea seedling. (c) Curvature of oat coleoptiles as a function of increasing light fluences. Exposure time: 30 s. (After Blaauw and Blaauw-Jensen, 1970.) (d) Curvature of oat coleoptiles as a function of both fluence rates (increasing from *back to front*) and exposure time (increasing from *left to right*). (From Blaauw and Blaauw-Jensen, 1970.)

of roots to periods of 1 s of gravistimulation, with intervals of 0.5 s revealed a further reduction of the presentation time. This can be taken as an indication that plants start responding almost immediately (Pickard, 1985). The *threshold angle*, i.e., the inclination of an organ with respect to the gravity vector also gives a value of the gravitropic response. Usually a deviation of 0.5–10° is sufficient to evoke a response, but the maximum of effectiveness normally is at 90°. These experiments are generally performed on shoots and roots that respond to a deviation from a plumb line. Different, however, is the case of cereals, where the responding part is the basal pulvinus of the shoot, which resumes elongation when the plant lies horizontal, and returns the shoot to vertical. As regards the minimum of g acceleration that can evoke a response, experiments on clinostats and biosatellites with lettuce hypocotyls and roots, indicate values of 2.9×10^{-3} – 1.5×10^{-4} (Halstead and Dutcher, 1987).

In the case of the root, the zone responding to gravity is different with respect to shoots and consists of only a few millimeters above the root cap, which cells

(statocytes), detecting the stimulus, carry the statolyts (amloplasts). The gravitropic message then moves basipetally down the root inducing the response in the elongation zone. Two zones have been described in roots, i.e., the distal elongation zone and the central elongation zone (Wolverton et al., 2000). On the contrary, in shoots the zone responding to gravity is relatively large, and the statocytes seem to be located around the vascular tissue.

Regarding the mechanism of gravity sensing, in the past it was thought (Volkmann and Sievers, 1979) that the statolyts (starch accumulating plastids), by way of their sedimentation to the bottom of the cell, were the detector of the stimulus, because no other organelle shows such sedimentation in cells. Recently however, considering that even the starchless mutants of some plants respond to gravity (though with less intensity) a new hypothesis was developed, which involves the full body of the cell in the detection of gravity (Harrison and Masson, 2008) through stretching sensors (possibly ion pumps).

To respond to gravity however, the plant's organs need to become asymmetric, through the redistribution of an inducer of growth. Already, Darwin advanced the hypothesis that an effector was redistributed, although he did not have the time to find it. It was, in fact, Frits Went who first found this unknown substance, which was able to redistribute asymmetrically in concentration in the plant organs (Thimann and Schneider, 1938). These studies were through biotests, but very soon a substance, named auxin (indole-3-acetic acid), able to dramatically accelerate growth, was found. This was the first hormone found in plants that acts at very low concentration (between 10^{-7} and 10^{-9} M). Consequently, it was not long before the hypothesis was advanced that this substance, at the right concentration, can accelerate growth on the lower part of gravistimulated shoots and slow growth on the lower part of the roots (roots are sensitive to lower concentrations). This idea is known as the Chodlony–Went hypothesis, having been advanced independently by two authors (the first a Russian, the second a Dutch). In spite of some criticism based on the grounds that the redistribution was not found in all cases, this hypothesis may be correct, and recent research using the powerful techniques of molecular biology seem to support it. Some of the work was performed by transforming *Arabidopsis* plants with a gene extremely sensitive to low concentrations of auxin, whose activation can easily be seen through fluorescence. In many cases, using this technique, increased auxin concentrations could be observed in the lower parts of shoots and roots (Li et al., 1991).

Today, a number of gravitropic mutants are known in which auxin redistribution is not apparent and which do not respond to gravity at all or only slowly. The ensemble of the data thus seems to support the Chodlony–Went hypothesis, but doubts persist in general on the function and action of this plant hormone (Trewavas, 1992). In addition, it is thought also that action potentials might be involved in the process, because of the swift, practically immediate response, shown by gravistimulated organs (Bjorkman and Leopold, 1987).

Frequently, more than one tropism acts on the same organ, so that the final growth behavior is the result of an interaction between different growth processes. For instance, the root of *Arabidopsis* shows a particular wavy pattern that seems to arise from gravitropism, circumnutation, and thigmotropism, when grown on a tilted vertical agar plate (Migliaccio and Piconese, 2001).

Phototropism

Phototropism is one of the many effects that light can have on plant organisms. It is because light can modify the growth direction of a plant (Figure 1b) by inducing an asymmetry inside the plant organs (for instance coleoptiles). More frequently, plants move toward the light source, but negative phototropism also exists. Research

goes back to the nineteenth century, but the initial and most important work was brought about, as in the case of gravitropism, by Darwin, and reported in the book describing the movements of plants already mentioned (Darwin, 1880). Through large arrays of experiments, Darwin established that the most important part of the plant for the phototropic response is the shoot tip, because seedlings immersed in light sand responded only when the tip was illuminated, whereas if a tip was covered with black paper, they did not respond at all. Thereafter, matters became far more complicated, because different zones of the shoot responded even in plants whose tips had been removed. For coleoptiles it has been reported, that the most sensitive zone is 100 μ m behind the tip (Curry, 1969). Obviously, not only the seed plants respond to light, but also algae, fungi, and ferns.

The phototropic response in coleoptiles and in dicots seedlings (Dennison, 1979) to increasing light spectrum shows the following feature. In the relative graph, there is a peak of activity in the near UV around λ 370 nm, and then two peaks in the blue region, corresponding to λ 450 and λ 475, plus a shoulder at λ 420. The most important wavelength range is thus the blue. On the other hand, when the plant shoots are subjected to increasing light fluences, a first positive response is seen (Figure 1c), then a negative one, and subsequently a second positive response. Considering natural light, the most important is the second positive response.

In particular, an extremely precise investigation was carried out by Blaauw and Blaauw-Jensen (1970) (Figure 1d). Using collected data they constructed a three-dimensional graph in which increasing light fluence rates were plotted from rear to front (z-axis), increasing irradiation times from left to right (x-axis), and the coleoptile curvature in degrees vertically (y-axis). The results showed that at high light intensity, around 10 W m^{-2} ($36.8 \mu\text{mol m}^{-2} \text{ s}^{-1}$), the plot shows three peaks named by them A, B, and C, corresponding to first, second, and third positive responses, plus a negative response between B and C. In the graph sections taken from the most intense to the lower fluence, area A and B, shift to longer exposures times, as does the negative response, and this shift is in accordance with the reciprocity law (exposure time \times fluence = k). Area C instead does not shift with decreasing intensities and thus in this case the reciprocity is not respected. In addition, area B at low intensities, i.e., at 10^{-3} W about ($0.003 \mu\text{mol m}^{-2} \text{ s}^{-1}$) merges with area A, and the negative region disappears. This means that at low fluence only two positive peaks are present (area A and C), the latter notably increased.

Regarding the nature of the light receptor(s), in the past two kinds of yellow compounds (as a consequence of their absorption in the blue region) were suggested. One is a carotenoid, in which case the receptor would be close to that utilized by animals, the other is a flavonoid. Both have absorption spectra notably similar to that regarding the phototropic response as a function of

wavelength, but not identical. Subsequently, the carotenoid hypothesis was abandoned, on the grounds that the inhibition of the carotenoids synthesis by the herbicide Norfluorazon does not stop the phototropic response (Viestra and Poff, 1981). The failure of the phototropic spectra to overlap exactly that of absorption by pigments was then variously interpreted, for instance with the presence of more than one pigment. The discussion on the receptor proceeded for years, and only in 1990 was the blue light absorption receptor identified (Whippo and Hangarter, 2006), through the mutant of *Arabidopsis nph* (non phototropic hypocotyl). This and similar receptors were renamed *phototropins*. In *Arabidopsis*, there are two of these genes and the relative proteins are named PHOT1 and PHOT2. The proteins are autophosphorylating serine/threonine kinases, with two LOV domains. These domains bind flavin as a photoreceptor (Lascèvre et al., 1999). The phototropins do not only function as photoreceptors, but also have other functions, for instance in photosynthesis.

Although the phototropins are the most important receptors of light in phototropism, there is another family of photoreceptors named chriptochromes, that are sensitive to blue light and are involved principally in photomorphogenesis (Lin et al., 1998), which also interact with the phototropins. Another family of photoreceptors are the phytochromes, mainly involved in photoperiodism (PHYA to E), which absorb red light, that can modify notably the phototropic reaction (Correll et al., 2003).

As regards the mechanism of response after the detection of light, what is known is that it is probably produced through a redistribution of auxin, as in the case of gravitropism. The existence of an auxin gradient has been known for a long time (Cholodny–Went hypothesis applied to phototropism) through the study of auxin redistribution. And, even though not everybody accepts the hypothesis, today we have confirmation of the involvement of auxin in phototropism through the study of the *pin* gene family, since the corresponding proteins are auxin transporters, which concentrate on the shaded side of a plant organ in the case of positive phototropism (Blakeslee et al., 2005).

Summary

Among the different kinds of movements performed by plants, tropisms are the most common. They consist of movements of the plant toward or away from an external environmental factor. Among the various tropisms, the most evident are gravitropism and phototropism. The first is a movement made through the sensing of the gravity vector, which leads the plant organs to grow at a precise angle with respect to it. Phototropism consists of a movement of a plant, induced by a light source, normally toward it, but also in some cases, away from it. The particular physical aspects of the two tropisms are described and discussed.

PLANT WELLNESS

Istvan Farkas

Department of Physics and Process Control, Szent Istvan University, Gödöllő, Hungary

Synonyms

Plant health; Well-being of plants

Definition

Wellness refers generally to the state of being healthy. When the plants have the feeling of well-being they are more productive, and provide safe and secure food. Since plants do not change their location, temperature, humidity, CO₂, and other physical parameters of their environment are used to keep them in a healthy state. If all of these are similar to that which the plant would experience in its natural environment, it will generally fight off any insect or disease problems (Hashimoto, 1989).

Visual appearance is a useful sign for the grower, and monitoring the plant itself gives a straight diagnosis about the health of plant. Some of the wellness parameters that can be quantified by machine vision technique are plant color, growth rate, leaf and stem movement, and insect recognition (Kacira and Ling, 2001).

A computer vision method is to be used for detection and localization of leaves' wilting as a sign of visual appearance (Farkas and Font, 2008).

PLANT-SOIL INTERACTIONS, MODELING

Tiina Roose

School of Mathematics, University of Southampton, Southampton, UK

Definition

Plant–soil interaction modeling is a field of study which uses quantitative mathematical methods to assess the importance of different soil or plant properties on the interaction of plants and soil.

Modeling plant–soil interactions

The main emphasis in plant–soil interaction modeling is on describing the movement of nutrients in the soil surrounding the roots. The equations describing this typically include equilibrium nutrient binding to the soil particle surfaces, diffusion of nutrients in the soil pore water, and movement of nutrients due to water convection. The most general equation for the conservation of nutrients in the soil is given by (Tinker and Nye, 2000)

$$\partial_t(\theta c_L + c_S) + \nabla \cdot (\underline{v} c_L) = \nabla \cdot (D f \nabla c_L), \quad (1)$$

where c_L is the nutrient concentration in the soil pore water, c_S is the amount of nutrients bound to the soil particle surfaces, \underline{v} is the fluid movement velocity, D is the nutrient diffusion coefficient in water, and f is the diffusion impedance due to the tortuosity of fluid paths between the soil particles. Typically, the relationship between c_S and c_L is described either by linear, Langmuir or Michaelis-Menten adsorption isotherm, or something similar, i.e., for linear ($\alpha = 1$) and Langmuir ($\alpha > 1$) we would have $c_S = b c_L^\alpha$, and for the Michaelis-Menten we would have $c_S = f_m c_L / (k_m + c_L)$. Thus, Equation 1 is in fact a single equation for one variable c_L . In order to solve this equation one needs to describe the boundary conditions far from the plant and at the plant surface. Thus, typically Equation 1 is supplemented by a plant nutrient boundary condition describing the flow (flux) of nutrients into the root, and the most popular one of these is given by

$$\underline{n} \cdot (\underline{v} c_L - D f \nabla c_L) = \frac{F_m c_L}{K_m + c_L} - E \text{ on the root surface}, \quad (2)$$

where \underline{n} is the normal to the root surface, F_m and K_m are experimentally measured constants describing the root nutrient uptake, and E is the constant characterizing the concentration when the nutrient uptake by plant stops. The right hand side effectively means that at low nutrient concentration values the flux of nutrients increases linearly proportional to concentration, but at the high nutrient concentration values the flux is limited to a constant value.

Root systems are in general complex three dimensional objects and thus in general one would need to solve Equations 1 and 2 in three dimensions. However, it is usually unfeasible to solve Equations 1 and 2 explicitly for all specific situations. Thus, usually a certain level of simplification of root structure is needed in order to answer questions on the realistic timescale. Thus, if one wants to calculate the nutrient uptake by single cylindrical root, then one can use either numerical methods in cylindrical geometry (Tinker and Nye, 2000) or use one of the analytic solutions that has been derived for this situation (Roose et al., 2001; Roose and Kirk, 2008). For example, the simplest analytic function describing the flux of nutrient into single cylindrical root is given by (from Roose et al., 2001; Roose and Kirk, 2008)

$$F(t) = 2F_m \frac{c_0}{K_m} \sqrt{1 + \frac{c_0}{K_m} + (\lambda - Pe) \frac{L(t)}{2}} + \left\{ \left[1 - \frac{c_0}{K_m} + (\lambda - Pe) \frac{L(t)}{2} \right]^2 + 4 \frac{c_0}{K_m} \left(1 - Pe \frac{L(t)}{2} \right) \right\}^{1/2} \quad (3)$$

$$\text{Where } \lambda = \frac{F_m a}{Df K_m}, Pe = \frac{aV}{Df}, L = \ln \left(1 + 4e^{-v} t \frac{Df}{a^2(\theta+b)} \right),$$

where a is the root radius, V is the flux of water into the root, b is the soil buffer power, and v is Euler's constant.

The fact that we have an analytic expression for nutrient uptake by single cylindrical root proves to be a very powerful tool if one wants to now address questions on the root system scale. Single root solution serves as a basis on using homogenization and upscaling methods.

The challenge in plant-soil modeling is to upscale the modeling knowledge from a single root to a root branching structure scale. There are essentially two alternatives, full 3D computation or homogenization methods. Despite the increases in computing power, full 3D simulations are still not entirely realistic. In addition, one is not usually interested in the exact 3D solution since one is never measuring nutrient concentrations in 3D. Instead one is often interested in the overall uptake of nutrients or water from the soil, or in the horizontal profiles of nutrient concentration and water saturation in the soil. Thus, the method of homogenization proves to be one of the most popular alternatives (Roose and Schnepf, 2008; Fowler, 1997; Pavliotis and Stuart, 2008). This method essentially relies on the fact that one can consider many (infinitely many) simple elements in the system. The result is that one derives models describing the average concentration of nutrients or water or both in the soil and that these models contain all the necessary information about the microstructure in the system.

Summary

In conclusion, we can now firmly say that mathematics has much to offer to study of plant–soil interaction. The main challenges in this field deal with developing rigorous mechanistic multiscale models that have just the right

amount of detail in them so that they are still tractable analytically and numerically. Multiscale homogenization methods will undoubtedly be used further to answer these questions. However, this work needs to be done in a framework of experimental investigations.

PLASTIC LIMIT

Boundary between non-plastic and plastic states of matter. With soils the limit corresponds to the minimum water mass content at which a soil sample can be deformed without rupture. See also *Atterberg Limits*.

PLASTICITY

The property of a solid body (e.g., clay soil, fruits) whereby it undergoes a permanent change in shape or size when subjected to a stress exceeding a particular value, called the yield value.

PLASTICITY NUMBER

The numerical difference between the liquid and the plastic limit or, synonymously, between the lower plastic limit and the upper plastic limit. Sometimes called "plasticity index." See also *Liquid Limit (Upper Plastic Limit, Atterberg Limit)*.

POLISH SOCIETY OF AGROPHYSICS

Bogusław Szot
Institute of Agrophysics, Polish Academy of Sciences,
Lublin, Poland

The Polish Society of Agrophysics (PSA) is a professional and technical organization dedicated to the advancement of social, scientific, and educational activity in agrophysics as well as to the extension of results of research in the interest of national economy. The activity of the society is focused on: physics and physicochemistry of soil

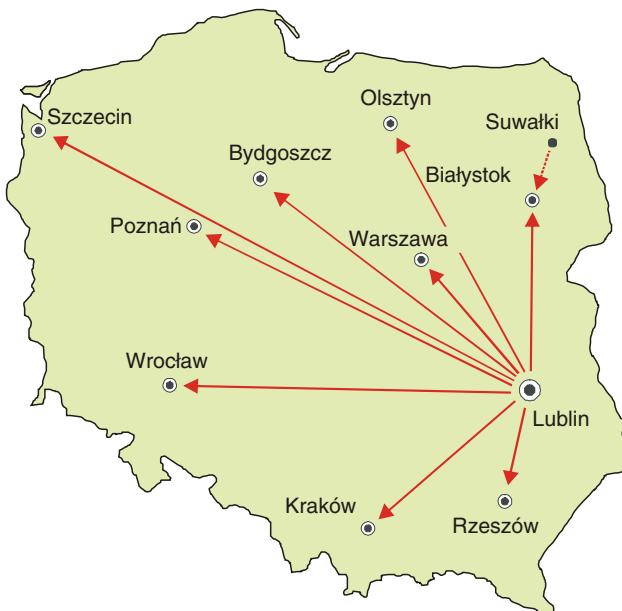

environment, physical processes in soil, physical properties of plants and crops, physical properties of foods, physical processes connected with harvesting, cleaning, drying, handling, and storing of plant products.

The goals of the Society are fulfilled by

- Organization of scientific meetings, conferences, congresses, seminars, symposia on national as well as international level
- Organization of public lectures and other forms of extension of results of investigations
- Education and popularization activity through media
- Organization and conducting of agrophysical research and development by appointed sections, committees, and working groups
- Publishing activity
- Advocating lifelong learning of the members and promoting the profession
- Issuing of opinions and expertises on the field of agrophysics
- Cooperation in advancement of unification of agrophysical terminology and standards
- Carrying out economical activity, performing investigations, analyses, expertises, and arrangement for prototype production
- Other type of activity conforming with the statute

Founded in 1996 and headquartered in Lublin, PSA comprises over 360 members, among whom over 150 hold the title of professor.

In the last 9 years, the Society grown to ten branches in major scientific centers in Poland, where agrophysical investigations are performed (Figure 1). Every year

Polish Society of Agrophysics, Figure 1 Location of PSA branches in Poland.

Polish Society of Agrophysics, Figure 2 Scientific Convention of PSA in Lublin, 2008.

branches organize meetings, seminars, and methodic symposia also for young scientists.

Until now, the society has organized nine national and international conferences with over 1,400 participants (115 of them from 29 countries outside Poland) (Figure 2). Summaries of the reports were published in proceedings, while the majority of full texts were published in International Agrophysics and Acta Agrophysica. Current information on the activity is spread through Information Bulletin of the PSA.

Statute of the PSA allows residents out of Poland to join the society. Annual dues levied on a calendar year basis is \$10. One of the member benefits is discounted meeting and conference registration fees.

PORE MORPHOLOGY AND SOIL FUNCTIONS

Marcello Pagliai

Agricultural Research Council (CRA), Research Centre for Agrobiology and Pedology (CRA-ABP), Florence, Italy

Synonyms

Pore shape; Soil porous system

Definition

The pore morphology is the shape, size, and spatial arrangement of the soil spaces representing the liquid and gaseous phases.

Introduction

Soil health is strictly related to structural conditions and many of the environmental damages in cultivated areas

(erosion, desertification, etc.) are determined by soil structure degradation.

Soil structure may be defined either as “the shape, size and spatial arrangement of individual soil particles and clusters of particles (aggregates)” or as “the combination of different types of pores with solid particles (aggregates).” Soil structure has generally been defined in the former way and measured in terms of aggregate characteristics. These can be related to plant growth only empirically. In fact, it is the shape, size distribution, and arrangement of pores that affect many of the most important processes in soil that influence plant root growth and development, the physical habitat for soil biota, such as storage and movement of water and gasses, and solute movements. Therefore, soil porosity is widely recognized as one of the best indicator of soil structure quality (Greenland, 1981; Pires et al., 2005). For this reason, measurements of pore space are increasingly being used to characterize soil structure. In fact, between the particles arranged singly or in aggregates, there is an intricate system of pore spaces on which plant roots, microorganisms, and soil fauna depend for the storage and movement of water and air.

The image analysis, among innovative techniques studying soil pore system entirely, allows to characterize soil structure by the quantification of soil porosity in all its aspects (pore shape, pore size distribution, irregularity, orientation, continuity, etc.) on thin sections, prepared from undisturbed soil samples (Bouma et al., 1977, 1982; Murphy et al., 1977a, b; Pagliai et al., 1983b, 1984; Pagliai, 1988; Mermut et al., 1992; Pagliai and Vignozzi, 2002). This morphometric technique has the advantage that the measurement and the characterization of pore space can be combined with a visual appreciation of the type and distribution of pores in soil at a particular

moment in its dynamic evolution. For this analysis, it is necessary to prepare thin sections of soil following a procedure that consists in taking undisturbed soil samples using appropriate tools, containers, and techniques taking care that the internal structure of the soil samples remains undisturbed. Then the soil samples, carefully packed, are transported to the laboratory, dried to avoid pronounced shrinkage phenomena, using appropriate methods, for example, acetone replacement of the water (Murphy, 1986), and impregnated, under vacuum, with a polyester resin, which has the characteristic of polymerizing slowly at room temperature without altering in any way the structure of the soil. Practically, this resin fills the pores of the soil. When the soil samples are hardened (generally after 4–6 weeks) they are made into vertically or horizontally oriented thin sections by using appropriate machines (Murphy, 1986). Their thickness is about 30 µm so that they can be analyzed by the microscope in transmitted light. The size depends on the kind of machines available; for porosity measurement, a size larger than 6 × 6 cm is recommended. Image analysis can be used not only on soil thin sections but also on polished faces of large soil blocks impregnated directly in the field with (fairly cheap) materials such as paraffin wax (Dexter, 1988), plaster of Paris (FitzPatrick et al., 1985), or resin (Moran et al., 1989).

The soil thin sections are analyzed with image analyzers (Murphy et al., 1977a, b; Pagliai et al., 1983b, 1984). Two-dimensional images can also be transformed into data representing three-dimensional area percentages that are representative for three-dimensional volumes. Stereology techniques have been applied to achieve this objective (Ringrose-Voase and Bullock, 1984; Ringrose-Voase and Nortcliff, 1987).

To characterize the microporosity (pores less than 50 µm), the thin sections must be covered by a layer of carbon, in order to allow conductivity to the electron beam, and analyzed by a scanning electron microscope (SEM) with a module for back-scattered electron scanning images (BESI) (Pagliai et al., 1983a). The thin sections can be examined by the SEM at several magnification. For example, if the analysis in the image analyzer starts with BESI taken at ×400 magnification, the size of the pixel will be 0.2 µm, therefore pores in the range of the storage pores 0.5–50 µm can be measured from the back-scattered electron scanning images (Pagliai and Vittori Antisari, 1993).

Basic measurements by image analysis include pores number, area, perimeter, diameters, projections, etc., and these are supplemented by derived quantities such as shape factors, size distribution, continuity, irregularity, and orientation. Detailed insight into the complexity of the pore system in soils can be obtained by using mercury intrusion porosimetry to quantify pores with equivalent pore diameter <50 µm (micropores) within the soil aggregates (Fiès, 1992).

Several methods are available to characterize soil structural attributes: image analysis and tomographic unit

profiles could successfully be used (Pires et al., 2005). X-ray computed tomography (CT-scanning) is a rapid, nondestructive method that has been applied in a variety of ways; for example, Mooney (2002) applied CT-scanning to undisturbed soil, preparing three-dimensional visualizations to quantitatively describe soil pore structure. Despite the advantages of this technique, access to scanners, resolution limitations, and the associated costs restrict its use.

Classification of soil pores

Pore shape, continuity, irregularity, and orientation A morphological distinction can be obtained by image analysis using, for example, the shape factor “roundness” [$P^2/(4\pi^*A)$] that relates area (A) and perimeter (P) of each pore.

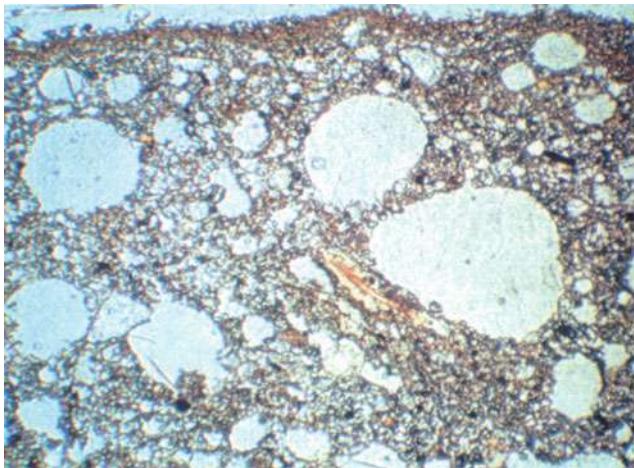

This parameter allows the division of pores into three main different shape groups such as, more or less rounded (regular) (roundness 1–2), irregular (roundness 2–5), and elongated pores (roundness >5) (Bouma et al., 1977; Pagliai et al., 1983b).

The regular pores are obviously those of a rounded shape and can be distinguished in two types according to their origin: the spherical pores formed by entrapped air during soil drying and the channels and chambers formed by biological activity (root growth and movement of soil fauna). Their distinction on soil thin sections is very evident because spherical pores (vesicles, according to Brewer [1964]) have very smooth walls, while channels, even though cut in a transversal way on thin section, present rough walls with deposits of insects’ excrements or root exudates. The presence of many spherical pores of the first type creates a vesicular structure.

Figure 1 shows an example of a vesicular soil structure. There are no single aggregates and the mass is broken up by rounded pores, “vesicles” (Bullock et al., 1985), which do not contribute to water movement. This kind of structure is an indicator of degraded soils. This is an excellent example of how it is important to characterize soil porosity, because sometime the same value of total porosity could originate extremely different types of soil structure, that behave in really different ways with respect to water storage and movement.

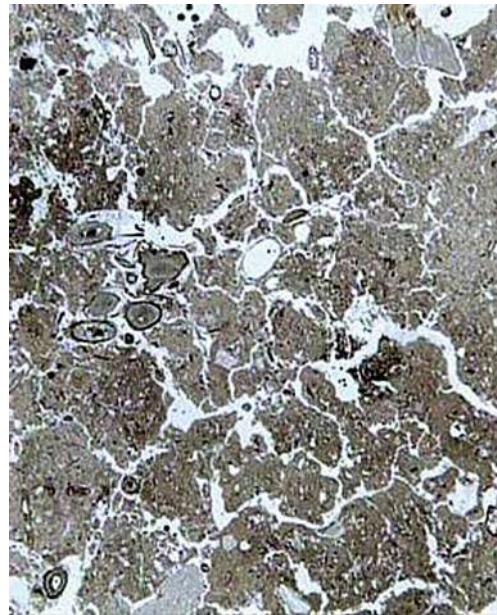

The irregular pores are the common soil voids with irregular walls (vughs, according to the micromorphological terminology of Brewer, 1964) and can be isolated (packing voids) or interconnected. The dominant presence of these pores produce the typical vughy structure (Bullock et al., 1985). In cultivated soils, these pores can be produced by the action of soil tillage implements.

Two types of elongated pores can be distinguished, cracks and thin fissures (planes). The former are typical of clay soils with a depleted soil organic matter content and they are visible at the surface when the soil is dry and has shrunk. The thin fissures are the most important, especially from an agronomic point of view, being the typical transmission pores. An adequate proportion of this

Pore Morphology and Soil Functions,

type of pore (over 10% of the total porosity) generally creates an angular to subangular blocky structure of good quality. Obviously for this to be true, it is necessary for these pores to be homogeneously distributed in the soil matrix. In fact, for the characterization of these pores by image analysis, it is necessary to determine not only their shape and width, but also their length. With the same procedure of width determination, it is also possible to determine the length of these elongated pores, which may reflect their continuity, and it is well known that the flow of water through soil depends on the continuity of large pores. An example of a good pore continuity is reported in [Figure 2](#), which represents a subangular blocky structure. The soil aggregates are separated by elongated continuous pores (planes), are of different sizes, and can be rather porous inside. From an agronomic point of view, this is the best type of soil structure because the continuity of elongated pores allows good water movement and makes easy root growth. Moreover, it is a rather stable soil structure.

Therefore, the analysis of pore patterns allows the characterization and prediction of flow processes in soils.

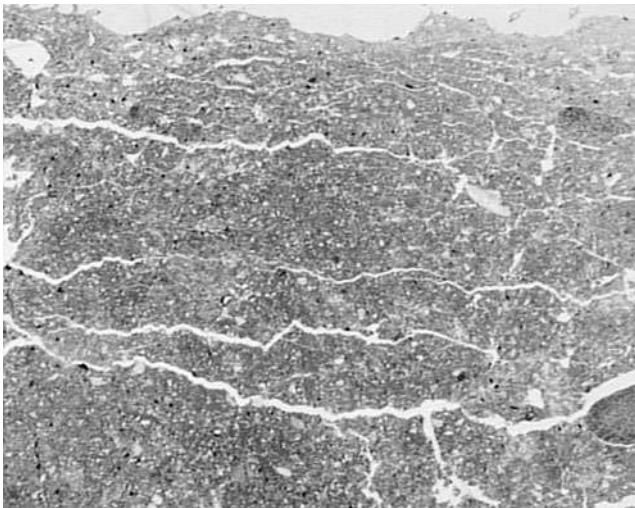

For root growth and water movement, not only the size and continuity of elongated pores are important but also their irregularity and orientation. The ratio convex perimeter/perimeter or convex area/area of elongated pores gives information about their irregularity, tortuosity, and reentrance. As regards water movement, for example, the very regular and the moderately regular elongated pores play a different role. The very regular elongated pores are flat and smooth pores with accommodating faces, which tend to seal when the soil is wet, thus preventing water movement. In contrast, the moderately regular elongated pores have walls that do not accommodate each other. Therefore, these pores permit water movement even when

the soil is wet and fully swollen ([Pagliai et al., 1984](#)). The ratio vertical/horizontal dimension gives the orientation of elongated pores ([Pagliai et al., 1984](#)). It is easily understandable that many soil processes, such as, water movement, leaching, clay migration, etc., are strongly related to the orientation of pores and these processes change dramatically depending on whether a vertical or horizontal pore orientation is dominant.

[Figure 3](#) shows an example of platy structure, that is, the thin and flat soil aggregates are separated by elongated pores oriented parallel to the soil surface and, therefore, not continuous in a vertical sense. This leads, as a consequence, to a drastic reduction of water infiltration capacity. Soils with this type of structure are subject to water stagnation or runoff and erosion depending on their slope. The platy structure is typical of compacted soils.

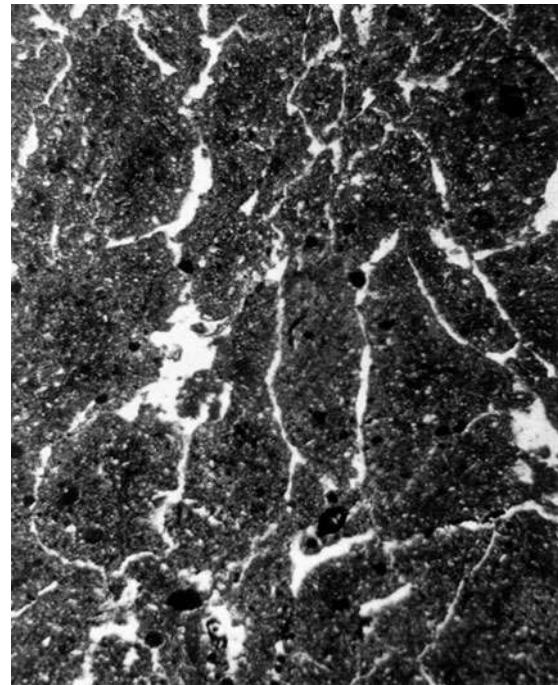

On the contrary, [Figure 4](#) shows an example of a prismatic structure, that is, the soil macroaggregates are divided into prisms separated by vertically oriented elongated pores with accommodating walls. Also, this type of structure is typical of clay soils, especially in the B horizon, and is not very stable because the swelling of the soil when wet causes the closing of pores.

Characterization of the soil pore system by image analysis of thin sections can give detailed information about soil structural conditions; moreover, if climate, agronomic, and management data are known, an evaluation of soil physical vulnerability is possible. Hence, the soil pore system can be considered a good indicator of soil

Pore Morphology and Soil Functions,

Figure 3 Macrophotograph of a vertically oriented soil thin section showing an example of platy structure. The white areas represent the pores. Frame length 5 × 3 cm.

quality, nevertheless, as for other indicators, threshold values have to be known.

According to the micromorphometric method, a soil can be classified as follows where the total porosity represents the percentage of area occupied by pores larger than 50 µm per thin section (Pagliai, 1988):

Soil very compact	When total porosity is	<5%
Soil compact	When total porosity is	5–10%
Soil moderately porous	When total porosity is	10–25%
Soil highly porous	When total porosity is	25–40%
Soil extremely porous	When total porosity is	>40%

Soil functions

The role of soil management in a sustainable environment is to provide multiple functions for the well-being of humans. In this context, the functions of soils for human societies and the environment are of special importance. According to Blum (2002), soils have at least six different functions for the social and economic development of humankind, which can be distinguished into three more ecological functions and three others directly linked to human activities defined as technical, industrial, and socioeconomic functions:

Soil ecological functions:

- Production of biomass, ensuring food, fodder, renewable energy, and raw biological materials
- Storing, filtering, buffering, and transforming substances and water, carbon sink, protecting the environment
- Biological habitat and gene reserve

Pore Morphology and Soil Functions,

Figure 4 Macrophotograph of a vertically oriented soil thin section showing an example of prismatic structure. The white areas represent the pores. Frame length 3 × 5 cm.

Soil socioeconomic functions:

- Physical basis for technical, industrial, socioeconomic, and cultural structures and their development
- Source of geogenic energy, raw mineral materials, and water
- Geogenic and cultural heritage, forming an essential part of the landscape, concealing and protecting paleontological and archeological treasures

It is obvious to underline the importance of pore morphology for the explication of soil ecological functions: the production of biomass, for example, depends on the soil structure quality and it has already been explained as the pore morphology determines the type of soil structure.

Summary

The soil pore system gives essential indications about soil health and vulnerability in relation to degradation events mainly connected with human activity. Such a characterization is especially useful in the study of the relationships between soil physical, chemical, and biochemical properties and provides a realistic basis for understanding water retention and water movement in soil.

The characterization of soil pore system, by means of image analysis on thin sections, can provide basic information for the study of soil. The major disadvantage of this technique is that the preparation of soil thin sections is both difficult and time consuming. However, many public and private laboratories are now equipped for the preparation of soil thin sections and the development of improved computer software has made the analysis of the images easy.

When the obstacle of the acquisition of soil thin sections is overcome, it is possible to benefit from the full potential of this technique, particularly valuable to quantify the changes in soil structure following human activities. Therefore, on the basis of the acquired experience, it is possible to go deep into the analysis of soil thin sections in relation to aspects of water movement. The quantification of the size, continuity, orientation, and irregularity of elongated pores allows the modeling of water movement and solute transport, or, at least, allows the prediction of the changes that can be expected following soil structural modifications, or following soil degradation due to compaction, formation of surface crusts, etc.

PORE SIZE DISTRIBUTION

Miroslav Kutílek

Emeritus Professor of Soil Science and Soil Physics,
Prague 6, Czech Republic

Definition

Soil pores vary in size and shape, and manifest an interconnected lattice. In a similar way, other porous materials can be defined but the soils belong to the most complicated porous systems. The frequency of pore sizes expressed as equivalent pore diameters when forming a continuous function is considered as a pore size distribution.

Soil porosity

The relative volume of pores is denoted as soil porosity

$$P = V_p/V_T$$

where V_p is the volume of pores and V_T the total bulk volume of soil. When this equation is multiplied by 100, we obtain P in percent. The volume of pores V_p is related to the volume of soil solid phase V_s by the void ratio

$$e = V_p/V_s$$

with mutual relations between P and e being

$$P = \frac{e}{1+e} \quad \text{and} \quad e = \frac{P}{1-P}$$

Void ratio is more appropriate than porosity if the reference term V_T is not constant as for example in clays when they swell or shrink. Estimating the proper size of V_T is obtained theoretically as the representative elementary volume (REV). Let us assume that when V_T is small enough ($V_T < V_p$) and centered in a pore, $P=1$. When V_T is centered in the solid phase and small enough ($V_T < V_s$), $P=0$. When V_T increases, we reach the situation when either $V_T=(V_p+\delta V_s)$ or $V_T=(V_s+\delta V_p)$ and porosity is neither 1 nor 0. Centering V_T in the solid phase, P is slightly above zero. With a gradual increase in V_T we obtain first a gradual decrease of P (center in the pore) or a gradual increase of P (center in the solid phase), until both values coincide. Before coincidence occurs, a damping oscillation of P may exist. At this stage of increasing V_T when porosity is independent upon the initial centering of V_T , we have reached the representative elementary volume (REV) (Kutilek and Nielsen, 1994).

Soils without structural development have an REV of about 100 cm³ or less. Because the REV of aggregated soils depends upon the size and shape of their peds, its value may be one or more orders of magnitude greater. The porosity of mineral soils lies between 0.4 and 0.6. Some organic soils have values of P close to 0.9. Porosity depends upon the composition, texture, and structure of soil. Soil structure is influenced by the content of organic matter, the quantity of inorganic cementing agents, the genesis of the soil and its horizons, and more recently by human activity. Theoretically, in the most dense arrangement of spherical particles of identical size, $P=0.26$. Although this value is sometimes taken as the theoretical minimum porosity of sands, even sandy soils are mixtures of particles of various sizes and shapes and for a model consisting of such a mixture of spherical particles the lowest value of porosity is well above 0.3. With an increase of clay content the porosity of soils rises, owing mainly to a greater opportunity for soil aggregation. The porosity of the A-horizon reaches its maximum value in loamy soils owing to the optimum conditions for aggregation. In clays, the tendency to slushiness leads to a slight decrease of P . The use of heavy machinery, the application of fertilizers in high quantities, and the decrease of organic matter in soils – all specific features of modern intensive agriculture – decrease aggregation and enhance soil compaction. In some clays and loams, P depends upon the soil water content θ as soil swells when wetted and shrinks when dried. In such soils P increases with θ . This relationship is linear for large values of θ . At smaller values of θ , P changes non-linearly with θ . In the soil profile, the maximum porosity usually occurs in the top of the A_o horizon. The porosity distribution with soil depth depends upon the development of each soil profile. For example, in the illuvial Bt horizon accumulated material causes a decrease in porosity. Or, the reduction of iron oxides and the destruction of the structure in hydromorphic gley G horizons lead to an abrupt decrease in porosity.

Classification of soil pores

The classification of soil pores should follow the laws of hydrostatics and hydrodynamics and leads to three major categories (Corey, 1977, completed by Pagliai and Kutilek, 2008).

1. Submicroscopic pores, which are so small that they preclude clusters of water molecules to form fluid particles or continuous water flow paths. Inasmuch as convection does not exist in these pores, the laws of fluid mechanics are not applicable. Pores belonging to this category are oftentimes neglected.
2. Capillary pores where the shape of the interface between air and water is determined by the configuration of pores and by the forces on the interface. The resulting air–water interface is called the capillary meniscus. The flow of water in these pores is

considered to be laminar and dominant in soils. This category is subdivided into two:

- (a) Matrix (intra-aggregate, intra-pedal, textural) pores within soil aggregates or soil blocks. The arrangement of the soil skeleton, coating of aggregates, cutans, and nodules typical for each soil taxon have main influence upon the soil water hydrostatics and hydrodynamics in the matrix domain. Hydraulic conductivity is strongly reduced when compared to conductivity of the whole soil.
 - (b) Structural (inter-aggregate, inter-pedal) pores between the aggregates, or eventually between the soil blocks. Their morphology and interconnection depends upon the shape, size, and stability of aggregates and blocks, or, generally upon the soil genesis and the type of soil use.
3. Macropores (non-capillary pores) are of sufficient size that capillary menisci are not formed. The shape of the interface between air and water is considered planar, and hence, capillary forces are nil. The flow of water inside of such pores can be either in the form of a film moving over all the irregularities of the walls induced by their roughness and shape, or in some cases, turbulent flow when the pores contain considerably more water. The shape of macropores is generally thought to be either tubular or planar. A tubular shape is caused by the action of soil fauna (e.g., earthworms) or originates after the decay of plant roots. Planar pores have the form of cracks and fissures owing mainly to cleavage planes and volume changes of the bulk soil when it dries. A more detailed classification of macropores is related to their stability and persistence in time:

- (a) Macropores formed by the activity of pedoedaphon such as decayed roots and earthworm channels. Their main characteristic is their high stability and persistence in time.
- (b) Fissures and cracks occurring as a consequence of volumetric changes of swelling–shrinking soils. They have planar form and they close when the soil matrix is saturated with water.
- (c) Macropores originating due to soil tillage. The depth of their occurrence is limited and they disappear usually in less than one vegetation season. Their persistence depends upon the genetic evolution of the soil, meteorological conditions, and the type of plants being grown.

Pore size distribution

The real size of pores, their continuity and forms are visualized microscopically on thin sections of soil. Computerized tomography (CT), nuclear magnetic resonance (NMR), and X-ray stereo radiographs offer insight into three-dimensional networks of pores. X-ray computerized tomography (CT) and nuclear magnetic resonance (NMR) produce an image of a slice of finite thickness of a soil. If there is sufficient number of successive slices in the

direction of the axis perpendicular to the slices, a three-dimensional image can be obtained. Both techniques are noninvasive and do not disturb the soil system, they are suitable for repetitive measurements on the same soil body. The form and distribution of soil pores can be quantified by the application of fractal theory and by methods of quantitative stereometry. The mercury porosimetry offers information on pore size distribution assuming that the pores are formed by cylindrical pores. Mercury is injected into the sample at increasing incremental pressures using nitrogen gas as the displacing medium. At each pressure increment, mercury intrusion is monitored while the pressure is held constant. The applied pressure is transformed to equivalent radius; the smaller are the pores, the higher pressure has to be applied to inject mercury into the pore. Thus a curve on pore size distribution is obtained. In soil hydraulics, the porous system is modeled and interpreted using soil water retention curves. Several different types of models have been used to describe experimentally measured soil water retention curves. The most frequent is derived from a bundle of parallel capillary tubes. The derivative curve to soil water retention curve with the pressure height h transformed to pore radius $r = a/h$ is then the pore size distribution. The model of lognormal pore size distribution $f(r)$ fits well for soils (Brutsaert, 1966; Pachepsky et al., 1992; Kosugi, 1994):

$$f(r) = \frac{\theta_S - \theta_R}{\sigma r \sqrt{2\pi}} \exp\left\{-\frac{[\ln(r/r_m)]^2}{2\sigma^2}\right\}$$

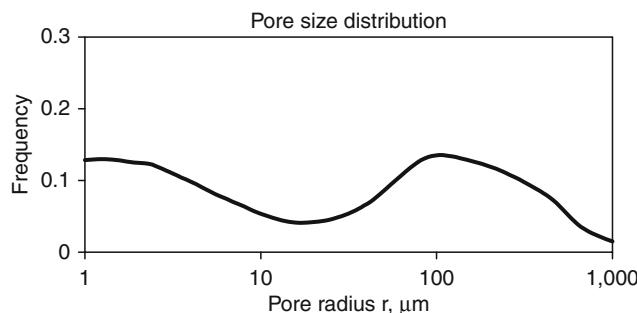

where r_m is the geometric mean radius, σ is the standard deviation, θ_S is the soil water content at full saturation of soil with water, and θ_R is the residual soil water content when the liquid flow is essentially zero. It is usually not measured but it is found as a fitting parameter of the retention curve. The detailed study of $h(\theta)$ of the porous system of majority of soils led to the discovery of bi- and multimodal porosity (Othmer et al., 1991; Durner, 1992; Pachepsky et al., 1992) due to the structural characteristics of soils, see the Figure 1. Then the pore size distribution equation is formulated for each domain separately

$$f(r)_i = \frac{\theta_{Si} - \theta_{Ri}}{\sigma_i r_i \sqrt{2\pi}} \exp\left\{-\frac{[\ln(r_i/r_{mi})]^2}{2\sigma_i^2}\right\}$$

where $i=1$ is for the matrix domain, and $i=2$ is for the structural domain. In spite of the generally lower value of the volume of structural pores, this domain influences mainly the transport processes and flow of water provided that the structural pores are at least partly saturated by water.

Summary

Pore size distribution is studied on the representative elementary volume and it depends upon the evolution and character of horizons and upon the soil structure and

Pore Size Distribution, Figure 1 Pore size distribution in a well-aggregated loamy soil. The peak on the right-hand side belongs to the structural domain and the peak on the left-hand side belongs to the matrix domain. The minimum at $r=27\text{ }\mu\text{m}$ denotes the boundary between the two domains.

texture. Soil pores belong to one of three basic categories: (1) submicroscopic pores, (2) capillary pores, and (3) macropores. The smooth function of pore size distribution in the capillary category is obtained from the derivative curve to the soil water retention curve.

POROSIMETRY

Mieczysław Hajnos

Institute of Agrophysics, Polish Academy of Sciences,
 Lublin, Poland

Definition

Porosimetry is an analytical technique used to determine various quantifiable aspects of a material's porous nature such as pore diameter, total pore volume, surface area, and bulk and absolute densities.

Introduction

Total porosity and specific surface area are two characteristics of soils that contribute in a significant way to the relationship between the observed properties and behavior of soils (Antilén et al., 2004). The soil porosity, critical for its aeration, is a parameter related to the storage and plant availability of water. Porosity and pore size are considered as structural factors related to the thermal properties of the soil.

Pore size, specified as the pore width (d_{pore}), is classified by IUPAC into three types: macropores ($d_{\text{pore}} > 50\text{ nm}$), mesopores ($2\text{ nm} < d_{\text{pore}} < 50\text{ nm}$) and micropores ($d_{\text{pore}} < 2\text{ nm}$). In the soil, micropores are important in the physisorption processes and the physical sequestration of chemical pollutants from the environment. Micropores are also important in the soil physicochemical processes, such as the K-Ca cation exchange selectivity of soils, where the size and shape of micropores are involved.

Mesopores act as a transport system, and the soil mesoporosity is of special interest because it regulates accessibility to the micropores.

The proportion of micro- and macropores affects the soil's water holding capacity, and the higher the microporosity, the higher the soil resistance to desiccation.

Soil macropores provide living space for the soil biota. Pores with a diameter smaller than 200 nm are inaccessible to soil microorganisms; those with diameter 800 to 6,000 nm are accessible to bacteria and protozoa; and pores larger than 30,000 nm of diameter are needed by nematodes.

The porous structure can be characterized by integral or differential curves of pore volume distribution vs. pore radius (porosimetric curves or porograms) (Volkovich et al., 2005).

The following methods for measuring porograms are well known:

- Mercury porosimetry – mercury intrusion into a non-wettable porous material
- Small-angle X-ray scattering
- Electron, atomic force and tunnel microscopy; centrifugal porosimetry
- Displacement of wetting liquids from the pore volume by gas pressure capillary condensation and others

Each of these methods has advantages and limitations.

For example, small-angle X-ray scattering can be used only for pore radii ranging from 2 to 50 nm and often leads to ambiguous results. Centrifugal porosimetry, optical microscopy, and displacement methods are practically useless for $r < 10^3$ nm. Measurements by electron microscopy are associated with difficulties in sample preparation and results interpretation. The method of capillary condensation can be used only in the pore size range from 0.3 to 50 nm. The method of mercury porosimetry (MMP) provides the widest range of measurable pore radii (from 2 to 10^5 nm). A great disadvantage of this method is the necessity to apply high pressure of mercury (up to thousands of atmospheres), which can lead to sample deformation or even destruction as well as the distortion of programs. The problem is also toxicity of mercury. All methods of microscopy practically give only half-quantitative information.

Methods of porosity determination

Following are the main methods used for determination of soil porosity and they are shown in [Figure 1](#).

Adsorption/desorption isotherm of nitrogen

Pores can be determined from adsorption/desorption isotherms of nitrogen in temperature -185.8°C . Pore size distribution can be calculated by various software methods accompanied by the measuring device. Usually these are the following methods: Dollimore/Heal, Horvath/Kawazoe, and B.J.H. (Barret–Joyner–Halenda).

Adsorption/desorption isotherm of water vapors

The pore size distribution can be calculated assuming that adsorbate molecules, by a given vapor pressure p , undergo capillary condensation in cylindrical pores of radii $r(p)$. Dependence of pore radii against pressure fulfil the Thomson (Kelvin) equation:

$$r(p) = \frac{-2\gamma V_m \cos \theta}{RT \ln \frac{p}{p_0}}, \quad (1)$$

where γ – surface tension of water, V_m – molar volume of water, θ – contact angle of water on the solid surface.

With relative pressures lower than inflection point of isotherm, adsorption occurs in monolayer and it cannot be interpret as the condensation process. Because of that the volume of monolayer calculated from the BET equation should be subtracted from the condensate volume.

The method from adsorption/desorption isotherms of nitrogen and water vapors enables pore size distribution in the range of lower pores than determined by mercury porosimetry ($r < 0.0039 \mu\text{m}$).

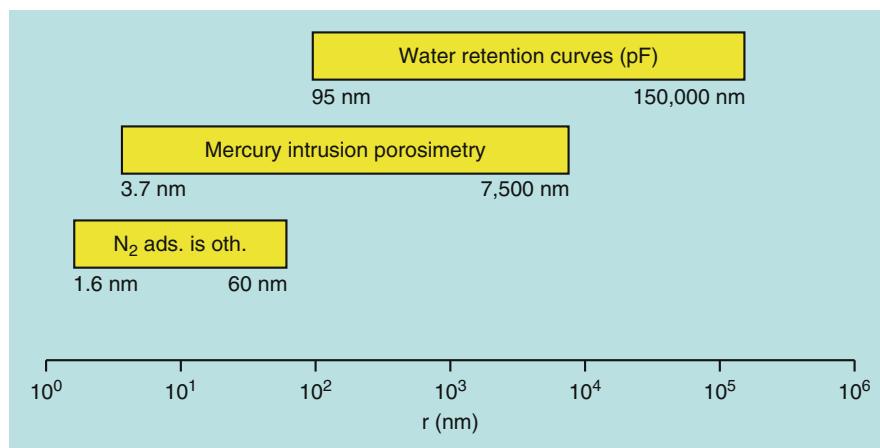

Mercury porosimetry

Mercury porosimetry and analysis of porosimetric curves is most often the method for determination of pore size distribution (Hajnos, 1998; Kozak, 1995). The basis of this method rests on the principle that a non-wetting fluid will not spontaneously intrude the pores of a solid, but will do so if sufficient pressure is applied. It is assumed that the sizes of pores intruded by mercury are inversely proportional to its pressure. The pressure indispensable for insertion of mercury to a capillary is the function of capillary radius according to the Washburn equation:

$$P = \frac{2\gamma_{\text{Hg}} \cos \theta}{r}, \quad (2)$$

where P – external pressure, γ_{Hg} – surface tension of mercury at 20°C (480 mN/m), θ – contact angle of mercury on soil material (average value 141.30°), r – determined pore radius.

Process of forcing of mercury into pores of investigated material under the influence of applied pressure underlies the basis of working of mercury porosimeter. It should be mentioned that determined pore radius r is not a real radius

Porosimetry, Figure 1 Ranges of porosity determined by various indirect methods. N_2 ads. isoth. – adsorption isotherm of nitrogen.

but so-called equivalent pore radius, depending on the mathematic model used for calculations.

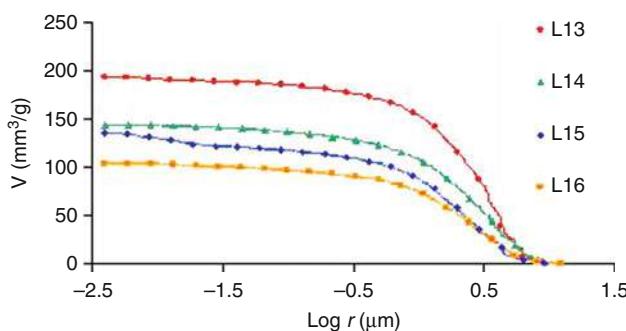

Usually pore size distribution is determined assuming cylindrical shape of pores. Because range of pores contains several orders of magnitude, cumulative distribution functions are often presented against logarithm of their radii:

$$f(\log r) = \frac{dV(\log r)}{d \log r}. \quad (3)$$

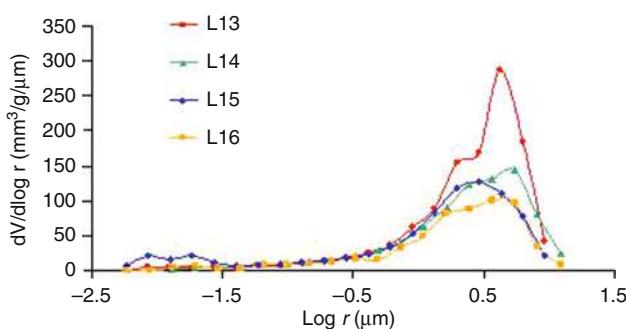

The modern mercury intrusion porosimeters allow usually for applying pressures up to 200 MPa, which corresponds to the equivalent pore size of 3.7 nm.

Range of pores measured by this method is from 0.0039 to about 12 μm .

Cumulative diagram of pore volume as a function of pore radius in logarithmic scale taking from the mercury porosimetry most often is presented as decreasing function, because total pore volume increases in the direction of low radii (Figure 2). The pore size distribution can be also presented by differential curves – $dV/d\log r = f(\log r)$ (Figure 3).

Porosimetry, Figure 2 Exemplary cumulative curves for orchard soils taken from the following horizons: L13 – 0–10 cm, L14 – 10–20 cm, L15 – 20–30 cm, L16 – 30–49 cm.

Porosimetry, Figure 3 Differential curves for orchard soils taken from the following horizons: L13 – 0–10 cm, L14 – 10–20 cm, L15 – 20–30 cm, L16 – 30–49 cm.

Soil water retention curves

In the unsaturated zone, the water is retained in the soil by capillary and molecular forces. As a result of these forces, the pressure in soil water is smaller than the atmospheric pressure. The atmospheric pressure is typically considered as the reference pressure in subsurface hydrology, and hence the pressure above the atmospheric pressure is positive, and similarly the pressure below the atmospheric level is negative. The negative pressure is also often called tension or suction.

The relationship between the volumetric water content and the soil water pressure can be described with a soil water retention curve (soil moisture characteristic curve) that plots the soil water pressure as a function of the soil water content. Often the soil water pressure is given as a pF value, which is the 10 base logarithm of the pressure in centimeters of water column h , i.e.,

$$\text{pF} = \log(-h). \quad (4)$$

Soil pore size can be determined on the basis of the water retention curve, because the given potential relates to definite pore radius, in which water is bonded. Relationship for the liquid perfectly wetting solid surface is given by the Laplace equation:

$$\Delta P = \frac{2\gamma}{r}. \quad (5)$$

Because the assumption of perfectly wetting soil samples, especially those with high content of organic matter (which means that water contact angle is equal zero), diverges from reality, the calculations performed on the basis of equation, taking into account measured contact angle (θ) (from the surface-free energy components):

$$r = \frac{2\gamma \cos \theta}{\Delta P} \quad (6)$$

Porosimetry is also applied to the structure determination of dried plant material (Rudko et al., 2004; Stawiński, 1976) and industrial plant products (Jamroz et al., 1999; Skiba et al., 2008).

Summary

Porosimetry is a technique used for the determination of pore diameter, total pore volume, surface area, and bulk and absolute densities. The following methods are applied for the determination of solid material porosity: mercury porosimetry – mercury intrusion into a non-wettable porous material, small-angle X-ray scattering, electron, atomic force, and tunnel microscopy, centrifugal porosimetry, and displacement of wetting liquids from the pore volume by gas pressure capillary condensation. The main methods used for the determination of soil and plant material porosity are the following: adsorption/desorption isotherm of nitrogen, adsorption/desorption isotherm of water vapors, mercury intrusion porosimetry, and water retention curves (pF).

Definitions

Precision agriculture: A management strategy that is based on information technologies implemented to optimize production agriculture.

Proximal soil sensing: Metering and data processing technology that allows *in situ* determination of physical, chemical, and other soil characteristics while placing sensor systems in close proximity to the soil being evaluated.

On-the-go soil sensing: Use of proximal soil sensing technologies while moving across a landscape.

Introduction

The concept of precision agriculture emerged from the belief that the variability of plant growing conditions is one of the major contributors to field-scale differences in yield, and that varying agricultural inputs according to local changes in soil properties could be beneficial. To engage in an effective decision-making process, it is important to obtain high-quality information about the spatial variability of different soil attributes that may limit yield in specific field areas ([Crop Responses to Soil Physical Conditions](#)). The inability to generate such information rapidly and at an acceptable cost using conventional means remains one of the biggest obstacles to the adoption of precision agriculture. Both proximal and remote sensing technologies have been implemented to provide high-density data layers relevant to the soil attributes of interest. Unlike remote sensing, which involves deployment of sensor systems using aerial platforms or space-crafts, proximal sensing requires placement of the sensor at a close range, contact, or it is even moved through the soil being measured. This allows real-time *in situ* determination of soil characteristics at or below the soil surface at specific locations.

Some proximal sensor systems can be operated in a stationary field position and can be used to: (1) make a single site measurement, (2) produce a set of measurements related to different depths at a given site, or (3) monitor changes in soil properties when installed at a site for a period of time. Although there are a variety of applications for which single site measurements can be beneficial, high-resolution thematic soil maps are typically obtained when measurements are conducted while the

sensor systems are moved across landscapes ([Online Measurement of Selected Soil Physical Properties](#)). Efforts to create these on-the-go proximal soil sensing technologies have become an interdisciplinary field of research and development with a goal of providing essential tools for precision agriculture and other areas of natural resources management (Hummel et al., 1996; Sudduth et al., 1997; Adamchuk et al., 2004; Shibusawa, 2006).

Proximal soil sensing concepts

Although the design concepts take a variety of forms, most on-the-go soil sensors being developed involve one of the following measurement methods: (1) electrical and electromagnetic sensors that measure electrical resistivity/conductivity or capacitance affected by the composition of the soil tested; (2) optical and radiometric sensors that use electromagnetic waves to detect the level of energy absorbed, reflected, or emitted by soil particles; (3) mechanical, acoustic, and pneumatic sensors that measure spatially variable interaction between a measuring tool and soil; and (4) electrochemical sensors that use ion-selective material, producing a voltage output in response to the activity of selected ions ([Figure 1](#)).

Usually, a sensor system based on one of these measurement principles is integrated with a global navigation satellite system (GNSS) receiver to locate and navigate a sensor carrier within a field. However, it is important to keep in mind that in addition to the geographic coordinates, high-accuracy GNSS receivers provide sufficiently accurate measurements of elevation (height above datum). In many instances, landscape relief as well as its derivatives (slope and aspect) can play key roles in forming the spatially variable crop growing environment. This means that frequently recorded field elevation data can also be useful when assessing soil variability. With optical

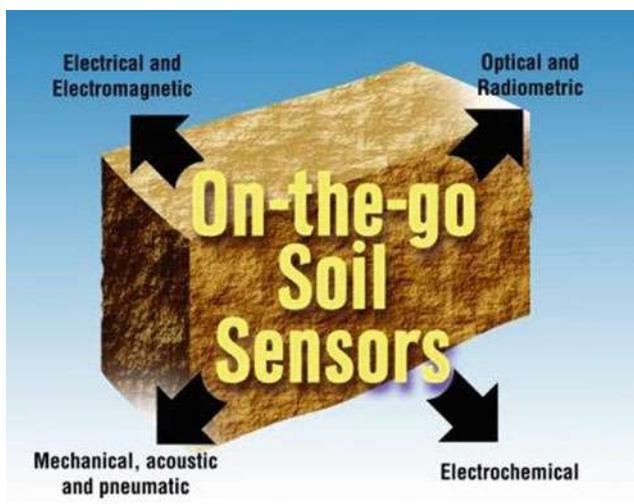

proximity distance sensors, researchers have also been able to study the micro-relief of the soil surface, which can be related to soil tilth and other attributes affecting soil resistance to erosion and other surface processes.

Electrical and electromagnetic sensors

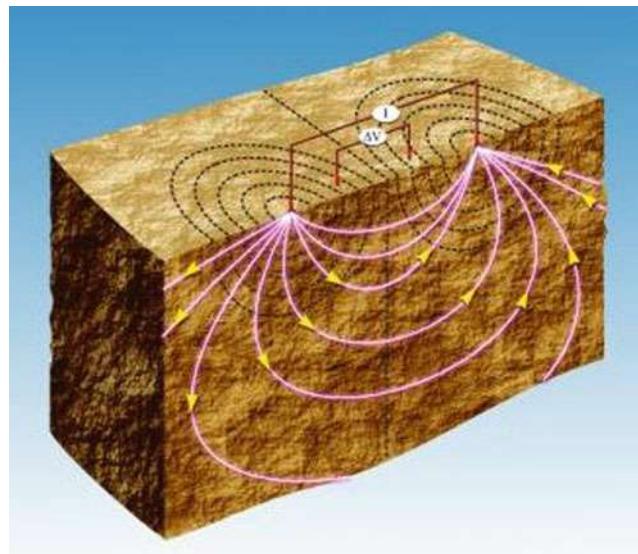

On-the-go proximal soil sensors that are based on electrical and electromagnetic principles use electric circuits to measure the capability of soil particles to conduct and/or accumulate electrical charge. When using these sensors, the soil becomes a part of an electromagnetic circuit, and the changing local conditions immediately affect the signal obtained ([Electrical Properties of Soils](#)).

To measure soil resistivity/conductivity ([Electrical Resistivity to Assess Soil Properties](#)), electrical current can be introduced using (1) galvanic contact, (2) capacitive coupling, or (3) electromagnetic induction methods. With the galvanic contact approach ([Figure 2](#)), at least two pairs of electrodes (typically in Wenner array configuration) must maintain stable contact with the soil surface (Allred et al., 2008). One pair of electrodes is used to create a low-frequency (<50 Hz) alternating current as other pairs measure the change of electrical potential, which is directly related to soil resistivity (the inverse of apparent electrical conductivity). By placing pairs of sensing electrodes at different distances from the current-injecting pair, it is possible to obtain multiple depths of investigation. Longer distance involves a deeper profile of soil affecting the signal.

Using the capacitively coupled resistivity method, current is injected into the soil using a coaxial cable serving as a large capacitor. The metal shield of the coaxial cable is one of the capacitor plates, the outer insulation of the cable is dielectric material, and the soil under the cable is the

Precision Agriculture: Proximal Soil Sensing,
Figure 1 On-the-go proximal soil sensing systems.

Precision Agriculture: Proximal Soil Sensing, Figure 2 A sensor based on the galvanic contact resistivity method.

other plate. The transmitter applies an alternating current to the coaxial cable, which causes an electrical current in the soil. At the receiver side, it is the current in the soil which causes current inside the coaxial cable. The difference in electric potential between the transmitter and the receiver is related to soil resistivity. As with the galvanic contact method, varying the distance between the transmitter and an array of receivers enables researchers to obtain measurements representing variable depths.

Popular in geophysical applications, the electromagnetic induction method is also used to determine soil apparent electrical conductivity (Daniels et al., 2008a). Unlike the sensor systems based on the galvanic contact and capacitively coupled resistivity methods, sensor systems based on electromagnetic induction do not require contact with soil. Instead, a transmitting inductor (a coil of wire with high-frequency (>1 kHz) alternating current) creates a magnetic field that causes a secondary (eddy) current in the soil (Figure 3). As with the capacitively coupled approach, electrical current in the receiving inductor is formed by the reverse process (current induced by the magnetic field from this secondary eddy current). From a number of parameters relating alternating current in the transmitting and receiving inductors (amplitude, time delay, and relative orientation), the measurements obtained can be used to quantify the apparent electrical conductivity as well as the magnetic susceptibility of the soil. Spacing between the transmitting and receiving inductors as well as their relative orientation affects the weight each layer of soil has when forming the output signal.

While using any of the on-the-go electrical resistivity/conductivity methods, measured electrical conductivity is

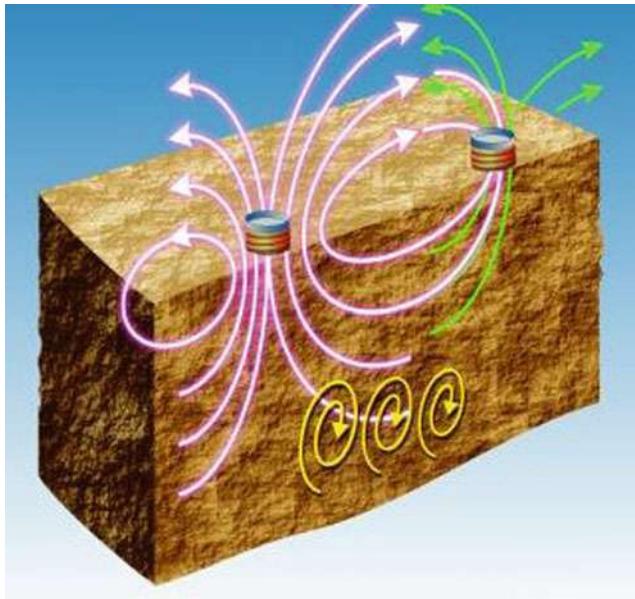

called “apparent” since it is different from a standardized solution-based test and is determined for a bulk media of soil containing different layers and inclusions. Various types of inverse modeling have been implemented attempting to predict the change of soil electrical conductivity with depth using measurements obtained with different geometrical parameters of an instrument.

In addition to electrical resistivity/conductivity sensing systems, capacitor-type sensors have been used to evaluate the soil dielectric properties. This differs from the capacitively coupled resistivity method in that the sensors use soil as a media between two capacitor plates. The direct relationship between the dielectric constant of soil and water content makes this type of sensor attractive for rapid measurement of volumetric soil moisture.

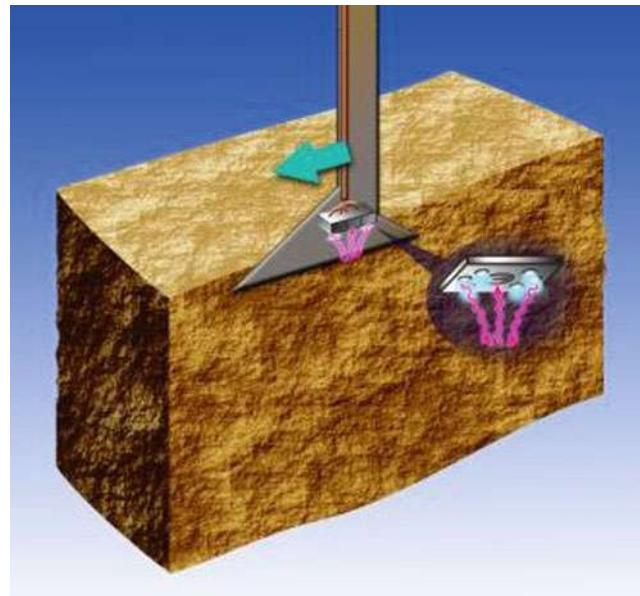

Optical and radiometric sensors

Proximal soil sensors that are used to measure the energy of electromagnetic waves can be active or passive. While optical sensor systems and ground-penetrating radars (GPR) detect energy provided by an artificial source (the active sensing approach), γ -radiometers used in agriculture detect radiation emitted by the soil (the passive sensing approach).

Optical sensors are used to determine soil’s ability to reflect light in different parts of the electromagnetic spectrum. Fundamentally, these can be similar to multispectral or hyperspectral remote sensing platforms but are deployed at the surface, or even below ground (Figure 4). Optical sensing systems can cover the visible (400–750 nm), near-infrared (750–2,500 nm), and/or mid-infrared (2,500–25,000 nm) wavelengths (Viscarra Rossel et al., 2006).

Precision Agriculture: Proximal Soil Sensing,
Figure 3 A sensor based on the electromagnetic induction method.

Precision Agriculture: Proximal Soil Sensing,
Figure 4 A subsurface optical reflectance sensor.

Typically, measurements are made using a combination of light-emitting diodes and photodiodes, or with spectrometers receiving the signal using fiber optics. Measurements obtained using optical sensors can be related (directly or indirectly) to a number of soil attributes such as soil mineral composition, clay content, soil color, moisture, organic carbon, pH, cation exchange capacity (CEC), etc. (Christy, 2008; Viscarra Rossel et al., 2009; Mouazen et al., 2010). Sensor calibration strategy ranges from simple linear regression to multivariate chemometrics and data mining methods. In any case, it appears that the relationship between soil characteristics of agronomic importance and soil reflectance may be limited to a particular set of conditions, and wider application of calibration models may not always be appropriate.

Ground-penetrating radars (GPR) have been used to investigate the behavior of 50–500 MHz electromagnetic waves directed toward the soil (Figure 5). A typical GPR output represents a sequence of amplitude traces with the depth of investigation related to the time of signal travel. Detectable changes in wave reflectance may indicate inconsistency in soil density or the existence of restricting soil layers (Daniels et al., 2008b). GPR has great potential for geophysics in general and agriculture in particular, especially to support water management.

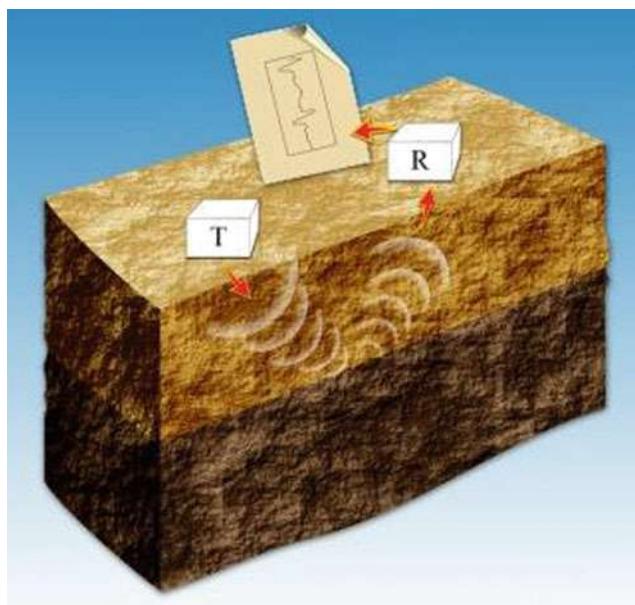

At the very short wavelength (i.e., high frequency) end of the electromagnetic spectrum, there is potential for the use of gamma (γ)-radiometric methods. All soils contain naturally occurring radioisotopes that can disintegrate to produce γ -rays. Gamma-rays are suited to spectroscopic detection because the energy of each photon is characteristic of the isotope from which it originates

(Hendriks et al., 2001). The attenuation of γ -rays through the soil varies with bulk density and water content. Also, γ -radiometrics has been used for field-scale mapping of some influential soil properties (Viscarra Rossel et al., 2007).

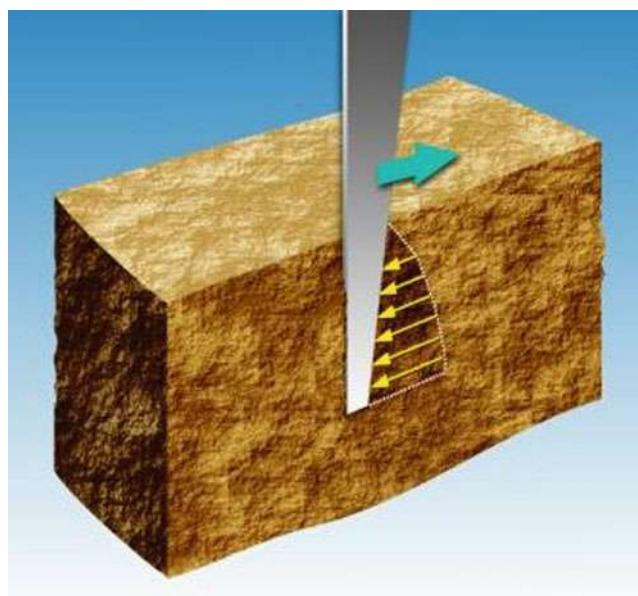

Mechanical, acoustic, and pneumatic sensors

Probably the most conceptually simple mechanical sensors are used to estimate soil mechanical impedance (resistance). By nature, these soil strength sensors measure resistance to soil failure (Hemmat and Adamchuk, 2008). As this type of sensor moves through the soil, it registers resistance forces arising from cutting, breakage, and displacement of soil, as well as from the parasitic (frictional and adhesive) forces that develop at an interface between the sensor surface and surrounding soil (Figure 6). Normally, soil mechanical resistance is expressed in units of pressure and represents the ratio of the force required to penetrate the soil media and the frontal (normal to the direction of penetration) area of the tool engaged with the soil.

A first step toward soil mechanical resistance sensing is to map the total horizontal (draft) and, sometimes, vertical force applied to a traditional fixed-depth implement engaged with the soil. Recorded measurements represent surrogate values affected by a variety of factors, including the type and shape of the tool working the soil, the speed and depth of the operation, and the surface conditions. Constructing a bulk soil strength sensor based on soil mechanics allows for better control of the type of soil failure and therefore produces more consistent measurements

Precision Agriculture: Proximal Soil Sensing, Figure 5 Ground penetrating radar.

Precision Agriculture: Proximal Soil Sensing, Figure 6 A mechanical resistance sensor.

in diverse soil conditions. In any case, bulk measurements can only reveal the spatial patterns of the overall soil strength. If a bulk soil strength sensor is actuated vertically (i.e., moved up and down) while mapping the field, the effective depth of engagement with the soil changes from location to location. Assuming a relatively strong spatial structure, this approach allows assessment of soil variability associated with the depth of operation in addition to the field location. On the other hand, adopted as a standard tool, a vertically actuated cone penetrometer is the most popular method for detecting changes in soil penetration resistance with depth at a given location. Traditionally, this tip-based sensor has been used manually; automated versions increase the number of simultaneous point measurements and/or labor efficiency. However, automated cone penetrometer sensors fail to provide economically justifiable mapping densities to determine spatial variability across large agricultural fields.

Single-tip horizontal sensors have been designed to generate high-resolution maps of horizontal soil penetration resistance obtained at a specific depth. Similar to the vertically actuated cone penetrometers, this method involves continuous logging of direct load measurements, which are frequently made using a load cell. Simultaneous deployment of multiple tips operated at different depths allows researchers to determine the spatial variability of soil mechanical resistance at any available depth as well as vertical variability in each location of the field. To avoid the expense of adding direct load sensing tips, a single-tip horizontal sensor can be actuated vertically in a way similar to a bulk soil strength sensor.

In addition to using a tip-based method, producers can measure the vertical distribution of soil mechanical resistance using an instrumented tine. This is done by measuring the direct load applied to the tine at discrete depths or by measuring the degree of bending using strain gauge technology (i.e., a cantilever beam approach). As with the inversion of apparent electrical conductivity, measurement arrays, the cantilever beam-like sensors, have been used to map the parameters of a modeled relationship between soil mechanical resistance and depth rather than using the discrete values at a given depth.

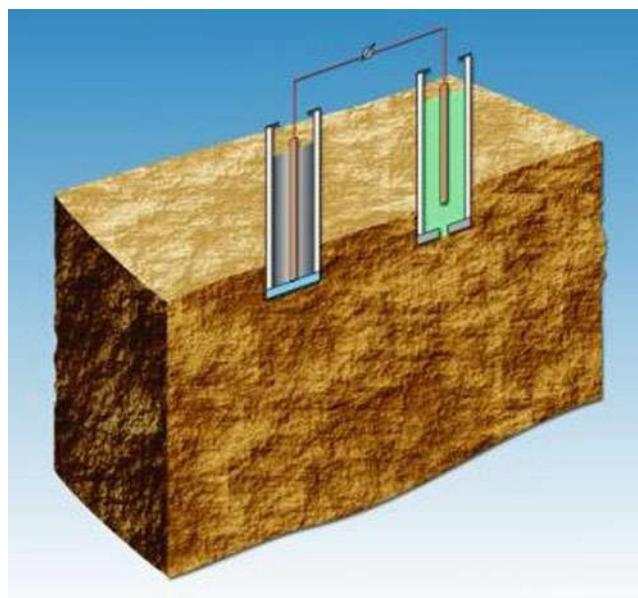

Acoustic and pneumatic sensors serve as alternatives to mechanical sensors when studying the interaction between the soil and an agricultural implement. Acoustic sensors have been investigated for determining soil texture and/or bulk density by measuring the change in the level of noise caused by the interaction of a tool with soil particles. Pneumatic sensors have been used for on-the-go sensing of air permeability in soil. The pressure required to force a given volume of air into the soil at a fixed depth was compared to several soil properties such as soil structure and compaction.

Electrochemical sensors

Finally, sensor systems that resemble a traditional wet-chemistry method to assess the content of certain chemical

compounds can provide the most important type of information needed for precision agriculture – soil nutrient availability and pH ([Electrochemical Measurements in Soils](#)). The measurements are conducted using either an ion-selective electrode (ISE) or an ion-selective field effect transistor (ISFET). These sensors detect the activity of specific ions at the interface between sensitive membranes and the aquatic part of either a soil solution or a naturally moist sample ([Figure 7](#)). A common ISE system consists of a membrane that is sensitive to specific ions and a reference electrode (Talibudeen, 1991). The difference in the potential between the sensitive membrane and the reference is measured and converted to the activity of specific ions in the tested solutions. The design of a combination ion-selective electrode allows both sensitive and reference parts to be assembled in one probe. Different electrode brands represent different designs of ion-selective membranes and reference junctions.

An ISFET integrates the ion selectivity of an ISE with the small size and robust nature of a field effect transistor (Artigas et al., 2001). In this case, the current between two semiconductor electrodes (source and drain) is controlled by a gate electrode represented by an ion-selective membrane. As ions of interest affect the gate, their charge impacts the source-drain current, providing an indication of ion activity. The main difference between an ISFET and an ISE is that an ISFET does not contain an internal solution, and the ion-selective membrane is affixed directly on the gate surface of the ISFET. Its compact size and theoretically high signal-to-noise ratio make ISFET technology attractive, especially when used to implement the flow injection analysis (FIA) method. However, the range of commercially available ISFETs

Precision Agriculture: Proximal Soil Sensing, Figure 7 An electrochemical sensor.

remains relatively narrow. In both the ISE and ISFET approaches, the sensitive membrane is made of glass (H^+ , Na^+), polyvinyl chloride (K^+ , NO_3^- , Ca^{2+} , Mg^{2+}), or metal (H^+).

The interface between an ISE or ISFET and a soil solution under investigation can involve a range of approaches, from methods involving soil processing to relatively simple methods. On one end of the spectrum, complete sample preparation with a prescribed controlled ratio between soil particles and extracting solution adds complexity to the measurement apparatus and may require a longer sampling and analysis cycle time. On the other end of the spectrum, a simple direct soil measurement (DSM) approach is relatively easy to implement (Adamchuk et al., 2005). However, real-time chemical extraction of the ions to be measured mimics conventional soil analysis procedures, while DSM-based measurements reveal specific ion content in a given soil state, which may not represent nutrient availability throughout the growing season.

Precision agriculture applications of proximal soil sensing

The decision-making process in precision agriculture requires knowledge and understanding of the soil's spatial variability in properties that are important for crop growth (e.g., nutrient availability, soil texture, organic matter, or water content). On the other hand, on-the-go proximal soil sensing systems provide high-density information on the spatial variability of specific measured quantities (e.g., field elevation, apparent electrical conductivity, optical reflectance, gamma radiation count). The relationships between sensor measurements and agronomic soil attributes are frequently specific to a certain agricultural environment.

For example, since clay particles are capable of transmitting more electrical charge than sand, popular maps of apparent electrical conductivity may be associated with the spatial distribution of different soil series in a given landscape. However, spatial and temporal variability in water content, salinity, and/or organic matter will affect electrical conductivity as well (sometimes even to a higher degree). Therefore, the same instrument can be used to identify localized patches of sand in one environment and sites with excessive salinity or manure deposition elsewhere. Although capacitive sensors have a more direct relationship with the amount of soil water stored, this relationship may also be affected by particle size distribution when predicting water content using either a volumetric or gravimetric basis.

Hyperspectral analysis of visual, near-infrared, and mid-infrared reflectance is an attractive approach for the prediction of various soil characteristics (both physical and chemical). Most reliable relationships have been found between light reflectance and soil carbon/organic matter content, soil moisture, clay content, mineral composition, and soil color. Significant secondary relationships have also been documented with CEC, calcium,

and magnesium as well as with soil pH, nitrate, and phosphate. In most of these cases, predictions require the development of multivariate calibrations, which may only generalize locally. Perhaps, some models currently under development could be applied to several geographic areas with similar soil mineralogy.

With ground-penetrating radars, it is possible to investigate soil layering without excavating the soil. Knowing the type of soil profile can help predict various physical processes that may have site-specific dynamics (e.g., water storage). Similarly, γ -radiometers have been used for surveying rather than for measuring. Like electrical conductivity sensing systems, these instruments are excellent tools for delineating soil spatial variability, with the goal of establishing management zones along with sampling or temporal monitoring sites.

Intuitively, measurements of soil strength are related to soil compaction (bulk density), which may be inappropriate if soil water content changes substantially at the time of mapping. However, when mapped at the beginning of a growing season, soil strength can reveal field areas with relatively high root penetration resistance (whether due to the dry soil or because of compaction). Measurement of soil strength at multiple depths allows researchers to detect variable depth hard pan, which suggests the use of variable depth tillage when appropriate ([Hardpan Soils: Management](#)).

It might seem that at least electrochemical measurements should have stable relationships with the content of important chemical elements. However, on-the-go measurements do not necessarily represent the same type of analysis as conventional laboratory tests. The differences may include sampling depth, preparation, and chemical extraction. Therefore, researchers have attempted to use prior information about soil buffering characteristics to define relationships between multiple proximal soil sensor measurements and chemical soil properties as well as the number of soil amendments needed.

Consequently, the integration of different proximal soil sensing technologies combined with the balanced use of different methods of sensor deployment has been the most promising strategy for successfully adopting soil sensing to support precision agriculture. Various innovative ideas and methods are on the horizon to unify different instruments and new geostatistical algorithms and make better use of the high-density data provided by the range of proximal soil sensing systems.

Summary

Information on the variability of different soil attributes within a field is essential to the decision-making process for precision agriculture. On-the-go proximal soil sensing is the most promising strategy to obtain much-needed high-density measurements of key soil properties. Proximal soil sensing systems are based on electrical and electromagnetic, optical and radiometric, mechanical, acoustic, pneumatic, and electrochemical measurement

concepts. The major benefit of on-the-go sensing is its ability to quantify the heterogeneity (nonuniformity) of soil within a field and to adjust other data collection and field management strategies accordingly. The integration of different sensing systems in multisensor platforms may allow better prediction of agronomic soil attributes.

PRESSURE POTENTIAL

The component of water potential due to the hydrostatic pressure that is exerted on water in a cell. In turgid plant

cells it usually has a positive value as the entry of water causes the protoplast to push against the cell wall (see *Turgor Pressure*). In xylem cells there is a negative pressure potential, or tension, as a result of transpiration.

PRIMING EFFECTS IN RELATION TO SOIL CONDITIONS – MECHANISMS

Evgenia Blagodatskaya^{1,2}, Yakov Kuzyakov¹

¹Department of Agroecosystem Research, University of Bayreuth, Bayreuth, Germany

²Institute of Physicochemical and Biological Problems in Soil Science, Russian Academy of Sciences, Pushchino, Russia

Definitions and terms

Priming effect is defined as a short-term change in the turnover of soil organic matter caused by treatments, usually addition of organic C to the soil (Kuzyakov et al., 2000) (Figure 1). Usually since the soil organic matter (SOM) turnover is not directly measured, but it is determined by changes in CO₂ efflux rates or N mineralization rates, the origin of extra CO₂-C (*primed carbon*) or N cannot be directly evaluated. Therefore, the *real priming effect* (RPE) cannot be assessed based only on extra CO₂. Other processes, such as accelerated microbial turnover may contribute to the changes in the CO₂ efflux rates or N mineralization rates (Dalenberg and Jager, 1981; Wu et al., 1993; De Nobili et al., 2001). Accelerated CO₂ evolution in response to the activation of microbial metabolism and higher microbial biomass turnover is not related to the SOM turnover and is termed as *apparent priming effect* (APE). Usually, the microbial succession initiated by the input of fresh organic matter is accompanied by activation of various, previously dormant microorganisms that respond specifically to the added substrate. Accelerated activity of such microorganisms may enhance the degradation of soil organic matter as a result of co-metabolism and higher enzyme production, i.e., RPE. Thus, both apparent and real priming actions are governed by microbial activity. Few studies, however, have evaluated PE as a function of abiotic factors such as temperature, moisture, pH, etc.

Jenkinson et al. (1985) suggested that RPE is an increase in the decomposition of recalcitrant SOM, whereas APE is an increase of microbial C turnover, which is not linked with changes of SOM decomposition. Usually the term “apparent” has been used in relation to primed CO₂-C originated from soil microorganisms (De Nobili et al., 2001; Gioacchini et al., 2002;

Bell et al., 2003; Fontaine et al., 2003; De Neve et al., 2004; Hamer and Marschner, 2005; Hopkins et al., 2006; Mondini et al., 2006). However, in a few cases, the term “apparent” priming has been also used to interpret extra CO₂ evolution derived from experimental errors due to the use of nonuniformly labeled substrate, incomplete trapping of evolved CO₂, addition of high amount of substrate to soil (Brookes et al., 1990; Conde et al., 2005), or enhanced decomposition of organic matter in response to improved soil moisture (Niklaus and Falloon, 2006). We suggest such PEs be termed as *artificial* to distinguish them from microbially originated apparent PE.

According to Jenkinson et al. (1985), most changes in N mineralization after addition of N to soil are to be considered as apparent effects caused by N displacement reactions (with fixed ammonium or with microbial N) or by pool substitution. They assumed that real acceleration of SOM mineralization requires an excess of fresh organic matter with a wide C/N ratio. We believe that this could be one cause, but not the sole one for real PE.

In recent years, new terms such as “signaling” and “triggering” (De Nobili et al., 2001; Mondini et al., 2006) have been proposed for some PEs but they were not clearly defined. Here we define the *triggering effect* as an acceleration of internal microbial metabolism with quick increase in the respiratory activity promoted by trace amounts of substrate. In many studies and under field conditions, the amount of C added to soil does not represent a significant source of energy but can promote changes whose energy demand can be much higher than the energy of the added substrate. This triggering effect can activate dormant soil microorganisms if promoted by the addition of available low molecular substrates such as glucose and amino acids to soil (De Nobili et al., 2001; Kuzyakov and Bol, 2006). The triggering effect induced by the input of external substrate should be distinguished from *quorum sensing*, which includes a wide range of signal exchanges *within* soil microbial community producing multiple cell–cell signaling molecules (Lazazzera, 2000; Burmolle et al., 2003; Wang and Leadbetter, 2005) and inducing gene expression, encoding a variety of both phenotypical and physiological responses upon reaching a critical threshold (Gray and Smith, 2005). Since the underlying molecular mechanisms of the triggering effect need to be investigated, we can hypothesize that permanent or occasional input of available low molecular weight substrates associated to plant residues, root exudates, excretes of soil animals etc., can act as *external inducer* and can *trigger* the mechanism of microbial communication similar to quorum sensing that can regulate the behavior of a group of organisms (Raffa et al., 2005). Thus, the triggering effect promoted by external compounds can represent the first step in a *signaling pathways cascade*, which alter the behavior on a population-wide scale by intra- and interspecies microbial interactions (Gray and Smith, 2005; Waters and Bassler, 2005; Little et al., 2008).

Introduction

The term priming effect (PE) was introduced to describe changes in the SOM turnover affected by the addition of organic or mineral substances (Jenkinson et al., 1985; Kuzyakov et al., 2000) (Figure 1). Depending on soil conditions, such changes can result in acceleration or retardation of SOM decomposition (positive or negative PE, respectively). The intensity of both processes is governed by physicochemical factors such as temperature, soil moisture, and pH, which act indirectly – mainly by affecting microbial activity that drives the mineralization of SOM and plant residues. Beyond these abiotic factors, however, many biotic factors directly affect C mineralization in soil. These changes are due to changes in the microbial activity as a response to altered amounts and availability of C. The increase in the number of investigations on priming effects during the last decade (see Blagodatskaya and Kuzyakov, 2008 for details) reflects the interest in biotic mechanisms of carbon (C) turnover in soil (Chander et al., 1997; Carreiro et al., 2000; Bell et al., 2003; Falchini et al., 2003; Fontaine et al., 2003; Cheng and Kuzyakov, 2005; Conde et al., 2005; Perelo and Munch, 2005; Zyakun and Dilly, 2005; Brant et al., 2006; Fontaine et al., 2007) (Figure 2). The indirect effect of abiotic factors, which are the main drivers of C turnover in soil, is not considered in most of these studies.

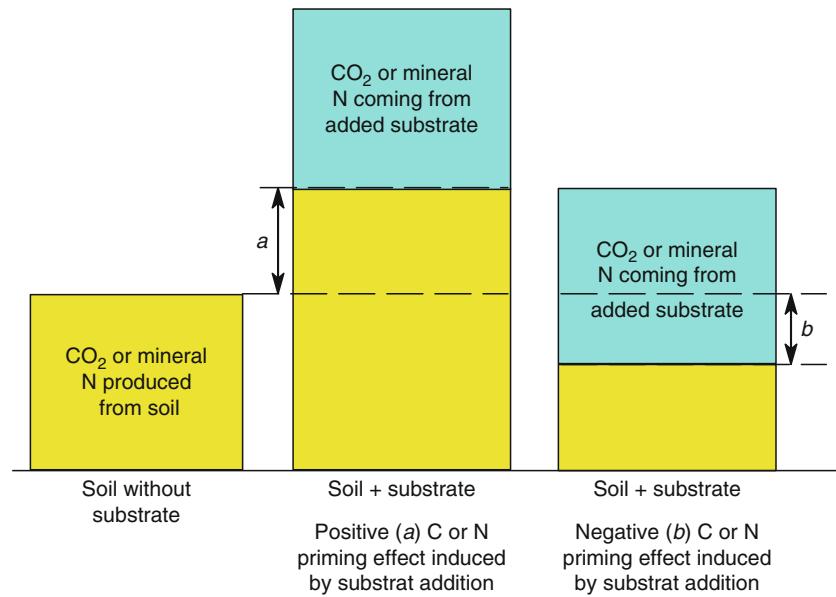

There might be various mechanisms for the changes in microbial activity in soil after adding organic or mineral substances (Jenkinson et al., 1985; Kuzyakov et al., 2000; De Nobili et al., 2001; Fontaine et al., 2003; Schimel and Weintraub, 2003). However, most studies failed to prove the suggested mechanisms because the

experiments were aimed at identifying priming effects (mainly by changes in CO₂ evolution) and not at identifying the mechanisms of these effects. This review will evaluate PE mechanisms based on CO₂ efflux data combined with other published data related to microbial biomass and activity. Therefore, we discuss the relationships linking the physicochemical soil conditions and the magnitude of priming effects observed in studies over the last decades. We distinguish real (SOM decomposition) and apparent (changes in microbial biomass turnover without effects on SOM decomposition) PE by considering the extra released C as affected by the amount of added C and microbial biomass C content (De Nobili et al., 2001; Luna-Guido et al., 2001; Hamer and Marschner, 2005; Mondini et al., 2006; Blagodatskaya et al., 2007). We also discuss the relationship between the phenomena of apparent or real priming effects and the role of soil properties, such as soil pH and aggregation, which were not considered earlier as affecting PE through their direct effect on biological activity.

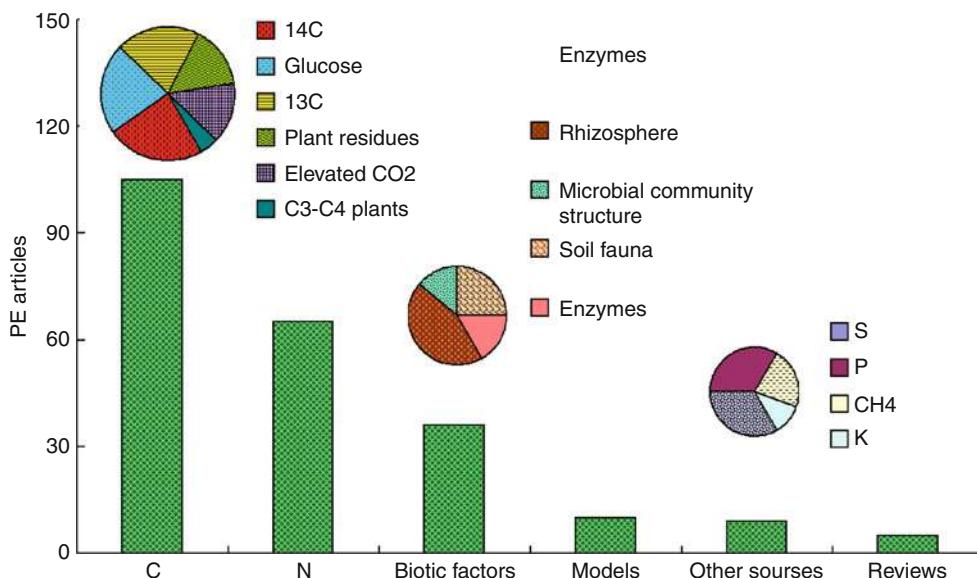

The amount of added substrate, the microbial biomass content, and priming effects

Adding easily available substances to soil provides C and energy sources to microorganisms. Depending on the amount of added C and energy, three types of changes can occur:

1. The amount of added substrate C is higher than the microbial biomass C content of soil and both microbial growth and changes in the community structure can occur.

Priming Effects in Relation to Soil Conditions – Mechanisms, Figure 1 Schema of the priming effect – nonadditive interactions between decomposition of the added substrate and of soil organic matter (SOM): (a) acceleration of SOM decomposition – positive priming effect, (b) retardation of SOM decomposition – negative priming effect.

Priming Effects in Relation to Soil Conditions – Mechanisms, Figure 2 Published papers to priming effects (PE) related to various questions: C and N mineralization, effect of biotic factors on PE, models simulating PE, release of S, P, CH₄, and K, and review articles from 1980 to late 2007. Web-of-Science citations with search options ("priming" AND "soil*") NOT "seed*" were evaluated.

2. The amount of added substrate C is similar or less than the microbial biomass C content of soil and changes in microbial activity and in turnover rate of the active microflora can occur, but the added substrate is not sufficient to induce microbial growth.
3. The amount of added C is much less than the microbial biomass C content of soil and the energy added is insufficient to directly accelerate microbial turnover. Either triggering or signaling effects can occur.

Here we discuss the threshold values for the three levels of substrate addition.

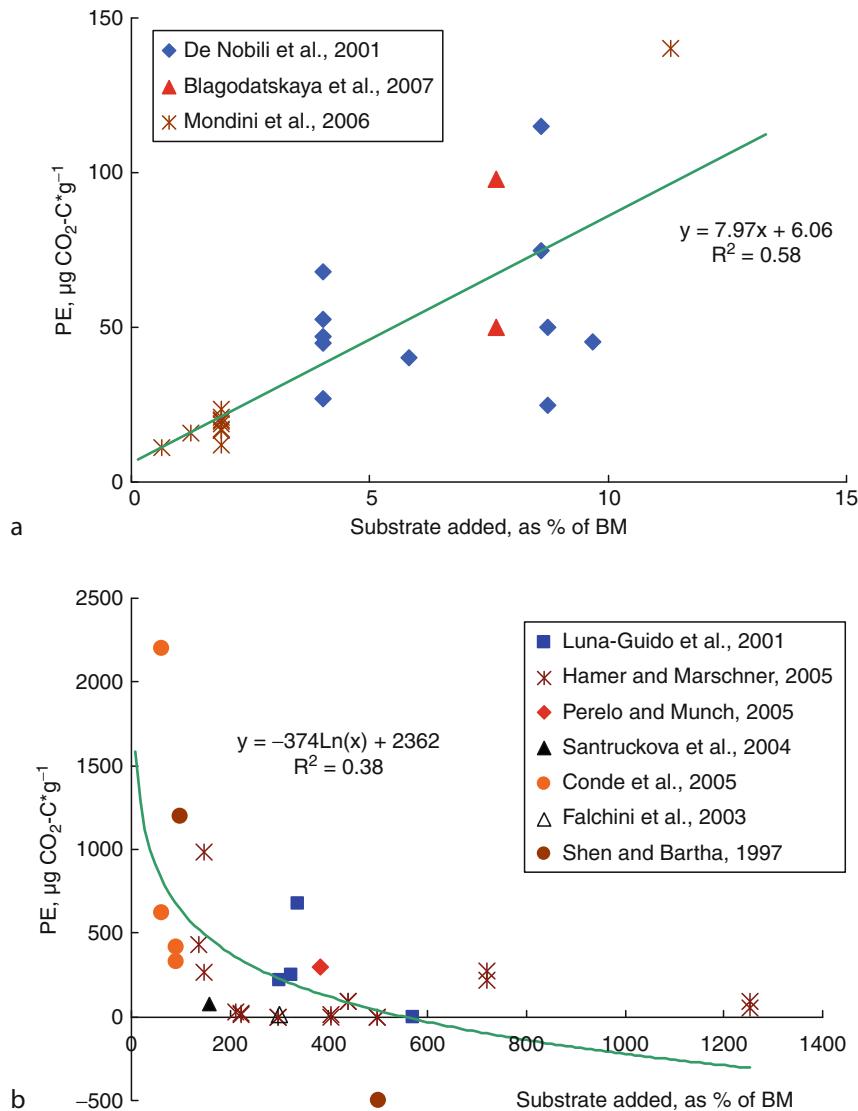

As the content of microbial biomass can differ in various soils, the amount of added substrate C should be expressed as the percentage of microbial biomass C (Figure 3). To find the threshold values for the three response possibilities mentioned above, we considered PE studies in which microbial biomass C was measured and a few studies (Shen and Bartha, 1997; Falchini et al., 2003; Fontaine et al., 2004; Conde et al., 2005), in which we calculated microbial biomass C considering that it represents 2% of the organic C content (Paul and Clark, 1989).

Surprisingly, two opposite relationships between the amount of added substrate and induced PE were found with different levels of added substrate C as related to microbial biomass C (Figure 3). When the amounts of added substrate C were lower than 15% of microbial biomass C, the magnitude of PE (here measured as extra CO₂) linearly increased with the amount of added C (Figure 3a). Therefore, for low levels of the added substrate, the PE is substrate limited and it confirms our hypothesis that priming effects are related to the energy

input to the soil microorganisms by easily available substrates such as glucose and amino acids (Figure 3). This means that microorganisms were able to utilize these substrates within a few hours or less, and thus, these inputs probably represent a pulse of available energy promoting the shift from dormant to active state.

When the amount of added substrates C exceeded 50% of the microbial biomass C value, the amount of primed CO₂-C decreased exponentially by increasing the added C (Figure 3b). At the rates of substrate C exceeding 200–500% of microbial biomass C, the priming effect tended to be zero or even negative. Thus, the amount of added substrates switches the direction of PE. If easily available substrates were added in sufficient amounts, soil microorganisms start growing within 4–10 h (Blagodatskaya et al., 2007) and end within 1–3 days, depending on the used substrate and available nutrients. The 1–3 day period coincides with the maximal intensity of the observed priming effects. We suggest that such short-term priming effects induced at high levels of added substrates (comparable or higher than microbial biomass C) are mainly related with changes in microbial community structure and also involves their demand for other nutrients, such as N.

With a level of added substrate C being 2–5 times higher than microbial biomass C, priming effects tended to be close to zero or even negative. We assume that preferential microbial substrate utilization (Kuzyakov, 2002; Cheng and Kuzyakov, 2005) is the main process occurring at these levels of added substrates with the switch of substrate conditions for soil microflora from low available SOM to easily available and highly accessible added substrate. This can cause a lower SOM decomposition

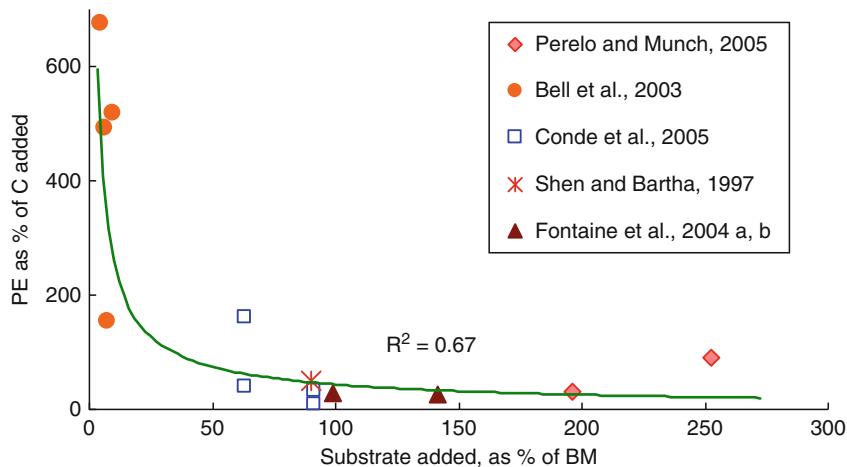

Priming Effects in Relation to Soil Conditions – Mechanisms, Figure 3 Primed $\text{CO}_2\text{-C}$ efflux as affected by the amount of easily available substrate C added and expressed as percent of microbial biomass C; added C is < 15% of microbial C (a); added C is > 50% of microbial C (b).

with a negative PE. It is important to underline that the magnitude of PE by high levels of the added substrate is about one order higher than the PE induced at levels of added organic C lower than 15% of microbial biomass C.

When plant residues were added to soil, the relationship between PE and the amount of added substrate was similar to that occurring when easily available substrates were added to soil (Figure 4). The highest PE (expressed as percent of added substrate from study of Bell et al., 2003) was observed when the amount of plant residue-C accounted for 4–9% of microbial biomass C. By increasing the amount of plant residues an exponential decrease in PE was observed.

Therefore, studies comparing priming effects in different soils or in different horizons, should consider the microbial biomass content that can differ among different soils, and among different soil horizons. By considering that microbial biomass C varied in the range of 0.2–1% of total organic C in the study of Hamer and Marschner (2005), the amount of organic C added to soil as 1.3% of the SOM C was 1.4–12.5 times higher than microbial biomass C. This caused the absence of PE in some soil horizons when microorganisms were oversaturated by the added substrate. Regrettably, many reports on PE did consider neither organic C nor microbial biomass C content in soil.

In conclusion, when the added substrate C accounted for less than 15% of microbial C, a linear increase of extra

Priming Effects in Relation to Soil Conditions – Mechanisms, Figure 4 Relationship between the input of less available substrate (plant residues) to soil expressed as percent of microbial biomass C and CO₂-C primed expressed as percent of added C.

CO₂ occurred by increasing amounts of added substrate C. When the amount of added substrate C was between 50% and 200% of microbial biomass C, an exponential decrease in primed CO₂-C was observed. When the amount of added substrate C accounted for more than 200% of microbial C, no PE or negative PE occurred. When the added substrate C was lower than 15% of microbial biomass C, the magnitude of PE was one order lower than PE induced by substrate C amounting to 50–200% of microbial biomass C.

Apparent and real priming effects

Until now, no clear-cut approach has been suggested to distinguish apparent from real priming effects and it is not clear if the source of primed CO₂-C is SOM or the endogenous microbial metabolism (Bell et al., 2003). At least two different kinds of *apparent PE* can be caused by microbial activity when fresh available substrates are added to soil:

1. A triggering effect that is an acceleration of internal microbial metabolism by trace amounts of substrate with an immediate (several minutes to several hours) increase in the respiratory activity.
2. A pool substitution with acceleration of microbial turnover revealed by a long-term (several days or weeks) increase in respiratory activity (Jenkinson et al., 1985).

The *real PE* depends on the composition of added substrate used by microorganisms. If some nutrients, mainly N, are lacking, this shortage can be supplemented by an accelerated SOM decomposition resulting in a real PE. When complex organic substrates are added, soil microorganisms can use the energy of most available compounds to synthesize enzymes hydrolyzing the low available compounds. Therefore, SOM can be co-metabolized by microorganisms. Thus, *real PE* can be due to:

1. Mineralization of soil organic N to supply available N
2. Co-metabolism of SOM

The difficulties in distinguishing real and apparent PE also reflect the fact that both effects may occur simultaneously (Mondini et al., 2006).

We suggest relating the response time with PE magnitude for a better interpretation of PE. The following situations can occur:

1. *Short-term response: the amount of the primed carbon (C_{primed}) exceeds the rate of substrate additions (C_{added}) but it is lower than microbial biomass C (C_{BM}): C_{added} < C_{primed} < C_{BM}.* This type of PE is usually observed from hours to days after applying trace amounts (5–50 µg C g⁻¹ soil) of substrate (De Nobili et al., 2001; Bell et al., 2003; Mondini et al., 2006; Blagodatskaya et al., 2007). It has been suggested that the quick short-term response with lower amount of primed CO₂-C versus microbial biomass C is a triggering effect that can be due to accelerated metabolism of soil microorganisms rather than to the decomposition of SOM. This hypothesis has been verified by adding unlabeled substrates to the ¹⁴C-labeled microbial pool (Dalenberg and Jager, 1981; Bell et al., 2003). The flush of microbial primed ¹⁴CO₂-C detected immediately after adding ¹²C derived from the increased turnover of microbial C. Therefore, if the amount of primed CO₂-C is much less than microbial biomass C, and if the additional CO₂ (or N_{min}) is released very shortly after substrate addition, then an apparent PE is probably observed.
2. *Long-term response: the amount of the primed carbon (C_{primed}) is higher than microbial biomass C: C_{primed} > C_{BM}.* This PE usually occurs during long-term incubation ranging from weeks to months (Shen and Bartha, 1997; Conde et al., 2005; Hamer and Marschner, 2005; Perelo and Munch, 2005) and can coincide

with a significant increase in microbial biomass. The presence of the apparent PE cannot be excluded even when the amount of extra CO_2 exceeds the initial microbial biomass C value since growing soil microorganisms can also contribute to the accelerated microbial turnover. Without applying isotopic labeled compounds, the real PE can only be evaluated if the amount of the primed carbon is higher than both microbial biomass C (C_{BM}) and the added C ($C_{\text{added}} < C_{\text{primed}} > C_{\text{BM}}$).

3. *Short and long-term responses.* Added substrate can accelerate both microbial turnover and decomposition of recalcitrant SOM. Thus, the observed PE may be the combination of both real and apparent PE. The triggering effect immediately after substrate addition is replaced by an apparent PE caused by pool substitution and occurring during the intensive substrate decomposition (Hamer and Marschner, 2005). Intensive mineralization results in a short-term increase in the active microbial biomass, which can also cause the real PE both during the intensive substrate mineralization and later at the beginning of microbial starvation. Thus, real PE can occur with apparent PE, as shown after the exhaustion of available ^{13}C -substrates added to soil (Perelo and Munch, 2005). It was shown that real PE occur as a significant increase in the incorporation of SOM-derived C in microbial biomass and this preceded the extra CO_2 evolution. Perelo and Munch (2005) suggested that substrate input increased the immobilization of soil organic C by soil microorganisms and then this microbial immobilized C was oxidized to CO_2 due to the accelerated microbial turnover.

To distinguish apparent from real PE in long-term incubation experiments, the amount of primed CO_2 -C should be related to changes in microbial biomass during the studied period. We suggest that the contribution of real and apparent PEs to the total PE can be estimated by distinguishing substrate-originated and SOM-originated pools in the newly formed microbial biomass (Schneckenberger et al., 2008). Further studies with different labeling of the three most important pools (added substrate, microbial biomass, and recalcitrant soil organic matter) are required to distinguish apparent from real PE (Kuzyakov and Bol, 2006) and to precisely estimate the real PE.

Priming effects as related to substrate and soil properties

Substrate properties

As already mentioned, the availability, composition, and amount of substrate determine the magnitude and the type (real or apparent) of PE. The decomposition of easily available C sources (glucose, fructose, alanine) led to a greater PE than the addition of less available substrates, such as catechol, oxalic acid, plant residues, manure, or slurry to soil (Conde et al., 2005; Hamer and Marschner, 2005). Among the easily available substrates, glucose

generally caused lower PE than L-glutamic acid (Mondini et al., 2006), a complex substrate mixture (root extract, rhizosphere soil extract; De Nobili et al., 2001), or an amino acid mixture (Mondini et al., 2006).

The amount of primed carbon is also dependent on the amount of available N in soil. Decrease in PE was observed when available N was applied to soil with organic C (Liljeroth et al., 1994; Cardon, 1996; van Ginkel et al., 1997; Martin-Olmedo et al., 2002; Blagodatskaya et al., 2007). This confirms the preferential substrate utilization (the added versus the SOM) if the main nutrients, such as N, are present. In the case of an input of C-rich substrates without N, soil microorganisms are activated to decompose SOM to acquire N with production of a real PE. However, it has been observed that N addition with glucose and plant residues can also produce a PE (Conde et al., 2005; Hamer and Marschner, 2005). Probably this depended on still high C-to-N ratio despite the N addition. The synthesis and the activity of various enzymes involved in C and N cycling are, respectively, controlled by N and C availability (Chander et al., 1997; Carreiro et al., 2000). Thus, N addition stimulated the activity of cellulases, while the activity of phenoloxidase, an important ligninolytic enzyme, was greatly reduced by the increased N availability (Carreiro et al., 2000). Similarly, the activity of amidohydrolases (Deng and Tabatabai, 1996) and other enzymes involved in N cycling (Skujins, 1976), was influenced by the organic C content of soils.

In conclusion, the addition of trace amounts of easily available substrates induces a short-term triggering effect, whereas the input of available substrate without nutrients in amounts sufficient for microbial growth leads to activation of SOM decomposition. If nutrients are present, no PE occurs or even preferential substrate utilization decreases SOM decomposition.

Soil physical properties

Since the effect of chemical (such as nutrient status and the C-to-N ratio of the active SOM pool) and physical soil properties on the PE were reviewed earlier (Kuzyakov et al., 2000; Kuzyakov, 2002), here we will focus on the effect of soil moisture, temperature, aggregation, and pH on PE as it is mediated by biological activity.

Soil moisture

Since soil moisture is the main driver of microbial activity, lower PE can be expected under limiting moisture conditions. The intensity of PE, however, can be also driven by the frequency and duration of drying–rewetting events. Rare rainfalls during long dry periods cause quick short-term activation of soil microorganisms metabolizing available substrates (microbial necromass, root exudates, plant residues). Quickly decreasing soil moisture is the main limiting factor of microbial activity under such conditions, so two types of PE can be expected before soil drying: (1) apparent PE caused by triggering microbial activity and by pool substitution mechanism or

(2) negative PE caused by preferential substrate utilization. Since SOM is not involved in such PE, carbon sequestration prevails under an arid climate. At high humidity the duration of decomposition processes can be relatively long, since microbial activity is not limited by soil moisture. So, other factors such as lack of nutrients become limiting at long-term wet periods. Microorganisms benefiting under such conditions can supply the lacking nutrients, degrading SOM and causing the real PE. Mineralization of SOM can occur under long-term high humidity resulting in accelerated SOM turnover. This mechanism can explain the relatively young age of humus in paleosoils formed during humid versus arid climatic periods (Alexandrovskiy and Chichagova, 1998). Thus, the alternation and duration of dry and wet periods are responsible for the type of PE prevailing in soil.

Soil temperature

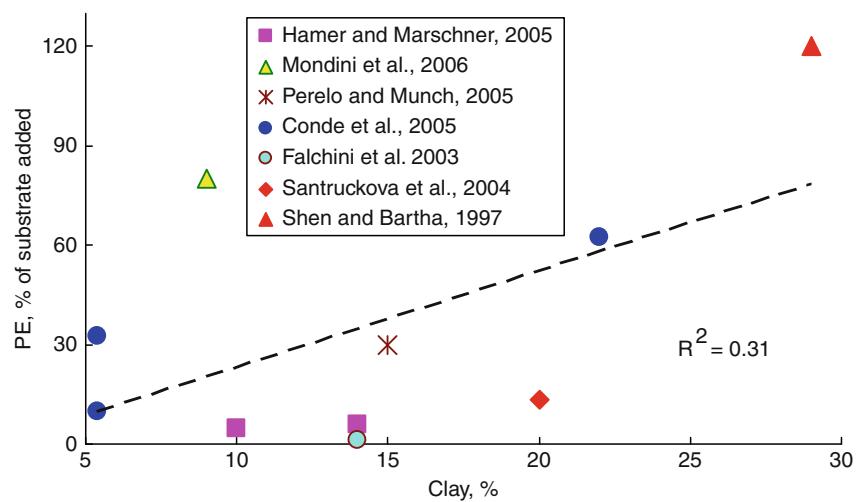

It is still unclear, what type of PE can prevail at global climate warming. On the one hand, greater amount and availability of substrate (e.g., from enhanced rhizodeposition), accelerated microbial and enzymatic activity caused by increasing temperature, can result in greater PE intensity. On the other hand, psychrophilic microorganisms benefiting at low temperatures have the enzyme system with higher affinity to low available substrates such as soil humus. Both increase and decrease in PE were observed in different studies at low versus high temperature. Such discrepancy can be explained by the interactive effect of temperature and substrate availability, which should be considered in PE studies at low amounts of substrate (S) (Davidson and Janssens, 2006). At high substrate amounts the decomposition rate does not depend on S and is only temperature dependent. Under substrate limitation, however, the rates of enzyme catalyzed reactions are mainly dependent on substrate affinity. Since psychrophilic

microorganisms have greater affinity to low available substrates, no changes or even increase in decomposition rate can occur at low versus high temperature in the interval of very low substrate amounts (Kuzyakov et al., 2007).

Aggregate and particle-size fractions

The accumulation and physical protection of SOM as well as its mineralization depends on soil-aggregate size (Denef et al., 2001; Six and Jastrow, 2002) and the mean residence time of C in macroaggregates is shorter than that of C in microaggregates (Six and Jastrow, 2002). This indicates that the PE due to the response of microorganisms to substrate addition may vary in aggregates with different size. Indeed, Degens and Sparling (1996) observed that only the middle-sized fraction (1–2 mm) showed a significant and positive PE as a quick response to glucose addition and this PE was apparently related to microbial biomass. Both larger (>2 mm) and smaller (<0.25 mm) particles showed PE, long (21 days) after glucose application and probably both PEs were real because they were not due to microbial turnover (Degens and Sparling, 1996). The intermediate-aggregate size fractions (0.25–1 mm) showed a negative PE. Probably the differences in response in various aggregates size classes was due to the different localization of soil microorganisms; generally fungi predominate in macroaggregates, whereas bacteria predominate in microaggregates (Guggenberger et al., 1999).

Silt mainly contributes to the formation of microaggregates, while sand particles are mostly associated with macroaggregates. According to Kandeler et al. (1999), invertase activity mainly due to intracellular activity, was abundant in the silt fraction, whereas extracellular enzyme activities were distributed among particle-size fractions; thus xylanase activity was associated with sand, alkaline phosphatase activity with silt and clay, and protease activity with sand and clay. It is important to underline

Priming Effects in Relation to Soil Conditions – Mechanisms, Figure 5 Relationship between primed CO_2 -C efflux expressed as percent of added C and clay content in soil.

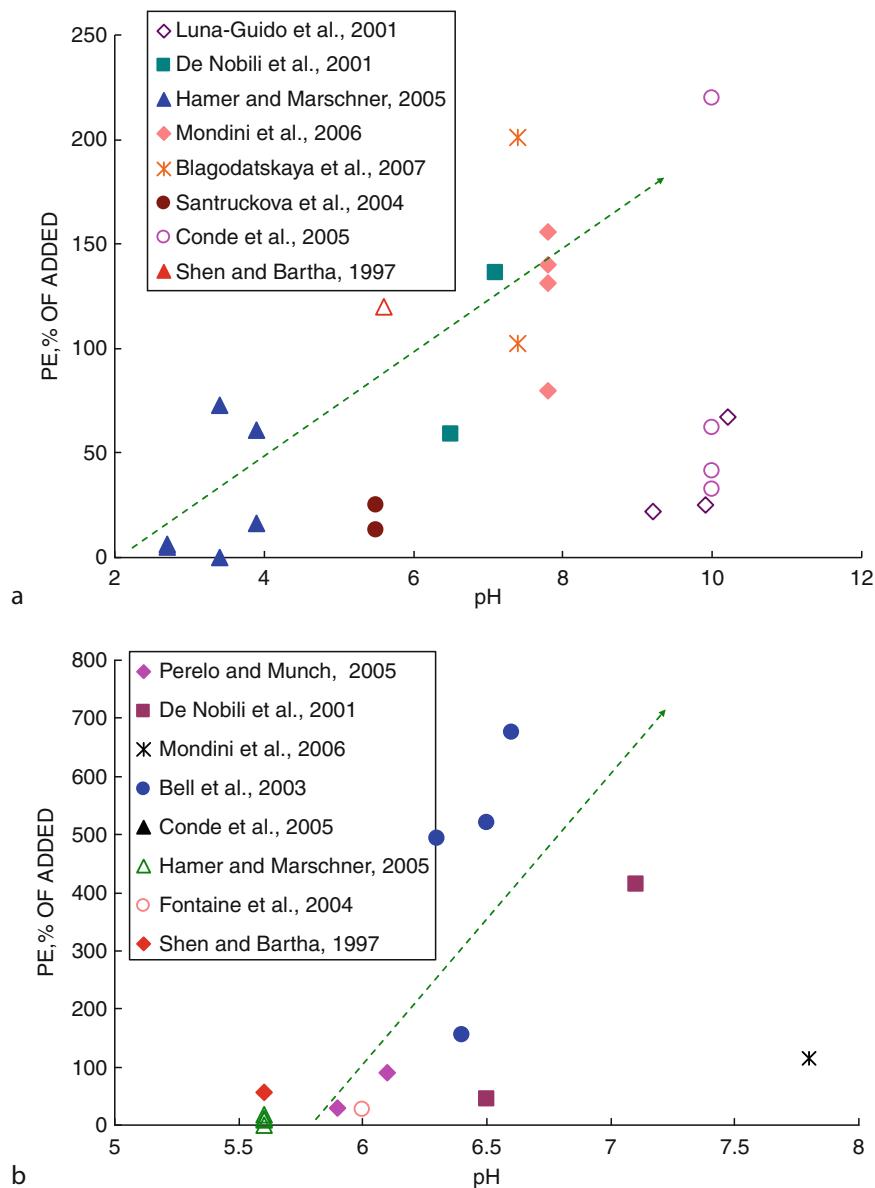

that since the present enzyme assays do not allow distinguishing the intracellular and extracellular enzyme activities, these are just hypotheses.

No differences in PE promoted by fructose and alanine were observed between soil fractions (sand, silt, and clay) obtained by mild sonication followed by wet sieving and sedimentation (Ohm et al., 2007). It is important to underline that available fractionation procedures can give artifacts. Sonication can promote not only disaggregation, but also desorption of microbial cells from soil particles and these desorbed microbial cells can redistribute during wet sieving to smaller size fractions. This

can smooth the differences in microbial activity between fractions. The dry sieving method used by Degens and Sparling (1996) seems to yield a more realistic distribution of microbial activity among the soil particles (Figure 5).

Soil acidity (pH)

The higher intensity of PE occurs in neutral soils – in the pH range between 6 and 8 – when both easily decomposable substances and plant residues are added to soil (Figure 6). The changes of microbial activity and community structure as well as the enzyme synthesis are higher in

Priming Effects in Relation to Soil Conditions – Mechanisms, Figure 6 Relationship between primed $\text{CO}_2\text{-C}$ efflux expressed as percent of added C and soil pH: easily available substrate (top) and plant residues (bottom).

soils with pH ranging from 5 to 8 than in acidic soils (Blagodatskaya and Anderson, 1998).

Most studies on priming effects are based on CO₂ measurements and artifacts can occur if the effect of soil pH on the solubility of CO₂ is neglected. Indeed, the equilibrium among H₂CO₃, CO₃²⁻, and HCO₃⁻, all derived from CO₂, in soil solution is pH dependent, and thus, the soil pH should be considered when interpreting results from CO₂ evolution. Possible misestimates of CO₂ evolution do not occur at pH values <5 because H₂CO₃ is the prevailing (about 98%) form that dissociates immediately into CO₂ and H₂O, and thus all CO₂ produced by soil microorganisms can be freely evolved as CO₂. At pH between 5 and 5.5, the contribution of H₂CO₃ decreases to 70% and some CO₂ can occur in soil solution as HCO₃⁻, and this can give a small underestimation of the produced CO₂. As the total amount of soluble CO₂ species is less than 0.03 mM l⁻¹ at pH 5–5.5, such underestimation does not exceed 0.1 µg CO₂-C g⁻¹ however, this value can be neglected considering that the CO₂ production rate in most unamended mineral soils is 1–2 µg CO₂-C g⁻¹ h⁻¹.

The prevailing forms of carbonate at pH values higher than 6.8 are HCO₃⁻ and CO₃²⁻. Therefore, CO₂ produced by microbial respiration will initially dissolve in soil water until the saturation capacity of the solution is reached. In such a case, CO₂ evolution depends on the volume of soil solution. Assuming the soil water content to be 30% of dry weight with a CO₂ evolution rate of about 30–40 µg CO₂-C g⁻¹ day⁻¹, the CO₂ evolution from soil can be underestimated by 10–100% at soil pH values of 8 and 9, respectively. This may explain the 1-day delay in the PE of alkaline soils (pH of 9.8–11.7) promoted by the addition of glucose or maize (Conde et al., 2005). Probably, CO₂ produced during the first day after treatment was accumulated as HCO₃⁻ and CO₃²⁻ in soil solution until the CO₂ saturation was reached; then the excess was evolved as CO₂. Therefore, the short-term PEs in soils at pH > 8, should be interpreted with caution. In soils with very high pH (9–11), the PE estimation is even more difficult because of carbonate recrystallization (Kuzyakov et al., 2006).

Summary

Priming effects are short-term changes in the turnover of soil organic matter caused by the addition of organic substances to the soil. Additions of easily available organic C up to 15% of microbial biomass C induce a linear increase of extra CO₂. When the added amount of easily available organic C is higher than 50% of the microbial biomass C, an exponential decrease of the PE or even a switch to negative values is often observed. PE increases with pH and clay content.

PROTON NUCLEAR MAGNETIC RESONANCE (NMR) RELAXOMETRY IN SOIL SCIENCE

Gabriele E. Schaumann

Department of Environmental and Soil Chemistry,
 Institute for Environmental Sciences, University
 Koblenz-Landau, Landau, Germany

Proton NMR relaxometry is a very powerful tool for investigating porous media and their interaction with water with organic molecules in solution. It is commonly used in material science or earth science and is increasingly applied in soil science as detailed in the review (Bayer et al., 2010). NMR relaxometry is sensitive and promising to study pore size distribution in soils (Jaeger et al., 2009), wetting (Schaumann et al., 2005; Todoruk et al., 2003), swelling (Jaeger et al., 2010; Schaumann et al., 2004), bio-film formation (Jaeger et al., 2006), or metal-NOM binding (Jaeger et al., 2008; Melton et al., 2007). It further helps to study interactions between molecules in soil organic matter (Schaumann and Bertmer, 2008). Relaxation times determined by NMR relaxometry are sensitive to various factors that play a role in soil–water interaction which is both an advantage and shortcoming of the method: NMR relaxometry is a versatile method, which can be applied to numerous investigations in soil science, but at the same time interpretation of the results in such complex and heterogeneous systems like soils requires expertise from both soil science and NMR.

PUDDLING: EFFECT ON SOIL PHYSICAL PROPERTIES AND CROPS

Gunnar Kirchhof¹, T. P. Tuong², H. B. So¹

¹School of Land, Crop and Food Sciences, The University of Queensland, Brisbane, QLD, Australia

²International Rice Research Institute, Metro Manila, Philippines

Definition

Soil puddling for paddy rice production is the process of working saturated or near-saturated soil into soft structureless mud.

Tillage in lowland rice production systems (paddy rice) is synonymous with puddling. Puddling is achieved by cultivating the soil under saturated condition using animal drawn or tractor driven implements. Mechanical breaking and dispersing of soil aggregates destroys the soil structure and forms the puddled zone. Puddling softens the soil and assists manual transplantation of rice seedling, minimizes water use through reduced percolation losses and effective weed control. Over time, soil puddling also creates a compacted layer below the puddled zone which further reduces percolation losses. The least permeable zone is usually found just below the puddled layer where tillage implements created a thin smeared layer. The reduction in permeability is mainly caused by blocking of macropores with fine dispersed particles translocated during puddling process, and the smearing effect of the tillage implements.

Although lowland rice does not require saturated conditions to produce high yields, it is traditionally kept under submerged conditions to maximize water supply, mobilize

nutrients, and to control weeds, which is generally not possible without puddling.

However, preferential flow or bypass flow through macropores, cracks, or large biopores contributes to water losses in paddy systems. This includes water losses through bunds which are not puddled. Water moves laterally into the bunds and then percolates down through the under-bund areas that are not puddled.

Despite the benefits of puddling for rice production, there are adverse effects, especially on post-rice crop production. Due to its structureless nature, puddled soils tend to harden and crack upon drying, with the rate and size of crack development depending on the rate of drying, type of clay, and clay content. These characteristics are the main constraint to the establishment and growth of post-rice crops. Irrigation of dried paddy soils can result in excessive losses from bypass flow, while severe cracking can result in root breakage and excessive strength impedes root growth.

Although soil puddling reduces the percolation rates, the puddling process itself requires large amounts of water. With increasing water scarcity, alternative tillage methods to reduce water use are needed. Dry tillage prior to flooding can reduce water requirements substantially by filling cracks and disrupting bypass flow pathways. It has become apparent that soils have often been puddled excessively. On clay soils, sufficient reduction in hydraulic conductivities can be achieved with only one pass of the

puddling implement, but coarser textured soils may require several passes. Landscapes with very shallow water tables may not need puddling at all, while broad cast planting of pre-germinated seed can save labor without sacrificing yield. In the context of rice and upland crop rotations, minimizing puddling to reduce soil structural degradation will benefit post-rice crops such as legumes or wheat.

Q

QUALITY OF AGRICULTURAL PRODUCTS IN RELATION TO PHYSICAL CONDITIONS

Guillermo P. Moreda, Margarita Ruiz-Alsent
Laboratorio de Propiedades Físicas y Tecnologías Avanzadas en Agro-Alimentación (LPF-TAGRALIA), Universidad Politécnica de Madrid, Madrid, Spain

Definition

Quality. Degree to which a set of inherent characteristics fulfills requirements (ISO 9000:2005).

Agricultural Products. In broad terms, food and fiber products. For more detail, see the Introduction section below.

Physical condition of agricultural products. In broad terms, everything related to the properties that can be observed or measured without changing the composition of the product matter. More specifically, the physical condition of, e.g., a fruit is related to textural aspects. Physical conditions determining agricultural products quality depend on the product considered.

Introduction

The quality of a commodity depends greatly on the intended use. As this entry deals with quality of agricultural products (see *Agophysical Objects (Soils, Plants, Agricultural Products, and Foods)*), it seems reasonable to start by identifying what commodities are included in the term *agricultural product*, and what their possible uses are. The United States Department of Agriculture (USDA) points out that agricultural products, sometimes also referred to as “food and fiber” products, cover a broad range of goods; specifically, all of the products found in Chapters 1–24 of the U.S. Harmonized Tariff Schedule – except for fishery products, manufactured tobacco

products like cigarettes and cigars, and spirits – are considered agricultural products. Agricultural products within these chapters generally fall into the following categories: grains, animal feeds, and grain products (like bread and pasta); oilseeds and oilseed products; livestock, poultry, and dairy products including live animals, meats, eggs, and feathers; horticultural products including all fresh and processed fruits, vegetables, tree nuts, as well as nursery products and wine; unmanufactured tobacco; and tropical products like sugar, cocoa, and coffee. Certain other products outside of Chapters 1–24, like raw rubber, raw animal hides and skins, and wool and cotton, are also considered agricultural products. To illustrate the wide variety of uses of agricultural products, let us take the corn grain as an example. While its main use is for livestock feed, corn grain is also used for human nourishment under the forms of corn cob, sweet tender canned corn, corn flakes, margarine elaborated from corn oil, etc., and through the industrial process of corn wet milling, to obtain starch and starch-derived chemicals. This corn-starch is then processed and used as food (e.g., as thickener in the food industry) and industrial products. It is routinely used as an adhesive, for manufacture of papers, and as an excipient or filler for pharmaceuticals. It can be converted into an enormous assortment of industrial chemicals now produced from petroleum sources. For example, new biodegradable plastic products are being made from corn, such as garbage bags, car parts, and packing “peanuts” (Olson and Warren, 2010).

Given the heterogeneity of agricultural products and their possible uses, to dissert on their quality it is convenient to focus on some agricultural products and specific uses. This article focuses on products obtained from cultivated plants for purposes of human nourishment, both in raw and processed form. More specifically, here we deal with grain and horticultural produce destined for human consumption. Other agricultural products as foods

obtained from animals (fish, meat, milk, eggs, etc.), or fibers of vegetal and animal origin (cotton, flax, wool, silk, etc.), are beyond the scope of this entry. Grains, and especially fruits and vegetables, are living, respiring, biologically active organisms that require optimal storage conditions (see *Physical Phenomena and Properties Important for Storage of Agricultural Products*) to maintain the quality that is present at harvest. A major difference between horticultural produce and grains is that horticultural products, mainly due to much higher water content, have to be stored under refrigeration, whereas grains do not.

According to Sloof et al., (1996), quality is a very elusive concept, which depends on several factors, the major of which are the product itself and its intended use. For instance, the required degree of ripeness of an olive depends on whether it will be seasoned for consumption as *table olive* or it will be processed for extracting olive oil. While most types of table olives are harvested before véraison, i.e., when they are green or immature, olives intended for oil extraction must be mature enough (véraison or purple turning to black). In both cases, the destination of olives is the food industry since these fruits, due to a glucoside in the flesh called *oleuropein*, are too bitter to be eaten raw. Olive is not the only horticultural produce that cannot be eaten raw; e.g., potatoes are never eaten raw, and quince flesh is so hard that all its production is processed. Another example of quality dependence on the intended use is in the fresh oranges we purchase for home consumption. Typically, there are two ways of using these oranges: one is eating the whole fruit – except the peel – and the other is making them juice. When a consumer buys *juice oranges*, he will normally expect a maximum content of juice, and the lesser fiber possible. But if he wants *table oranges*, i.e., oranges for being eaten whole, his preferences might differ. A third example can be mentioned for tomato. For fresh consumption, as in salads, a thick skin is a negative attribute, but if the tomato is to be processed, it should have a thick skin, in order to remain intact until it reaches the factory. The latter requirement arises because processing tomatoes are harvested mechanically, and this operation entails potential damage (see *Mechanical Impacts at Harvest and After Harvest Technologies*). If machine-harvested tomatoes had a thin skin, they would break easily, and the losses of juice would be considerable. In practice, processing tomato varieties are different from fresh-market varieties. Within fresh-market tomatoes, the quality desired by the consumer will vary depending on the intended use: ripe tomatoes for soup, hard tomatoes for salads. A last example can be addressed for peaches. Peach varieties can be classified as *freestone* or *clingstone*. Freestone peaches are destined for fresh consumption, whereas the peach canning industry demands exclusively clingstone peaches, since they have a harder flesh than their freestone counterparts. Apart from the product itself and the intended use, there are sociopsychological factors that play a role in defining the quality, since they affect the user's attitude toward

the product. For example, one person may be status conscious and prefer bananas from Spain's Canary Islands or plum tomatoes from Italy, another may be environmentally aware and prefer organically grown tomatoes. On the other hand, physical conditions determining the quality of grain and horticultural produce depend on the product under consideration.

Grain

Physiological maturity and maximum dry matter yield of winter cereals (wheat, barley, rye, oats) is reached when the grain moisture content is between 30% and 40%, but at this moisture content the grain is too soft to combine (see *Physical Properties of Raw Materials and Agricultural Products*). Grain is usually combine ready (sometimes referred to as "harvest ripe" or "grain ripe") when it has dried to about 15% moisture (Farrer et al., 2006). Besides, this is the moisture content limit required for safe storage. Harvest delay is not recommended, as it usually results in yield reduction due to hail damage, insects or birds attack, lodging, or shattering. Shattering occurs when the spikelets or grains fall from the plant. Moreover, when harvest is delayed the combine operation may be hindered by weeds infestation; weeds may even fructify, producing seeds that will be harvested together with the grain, contaminating it. In the case of rice, the drawbacks associated to harvest delay are the same as for winter cereals, plus the fact that rice will fissure while on the panicle if allowed to dry below certain levels and subsequently incur rapid moisture adsorption. Rain or exposure to high relative humidity could cause such adsorption. Therefore, in most countries, rice is not allowed to dry too much in the field after physiological maturity, but it is harvested with high moisture content (25–30%). Afterward, rice is dried down to safe storage conditions, about 15% moisture content, at dedicated facilities (see *Drying of Agricultural Products*).

The main cereals used for human nourishment internationally are wheat and rice. However, for the poorest rural people in the semiarid tropics of Asia and Africa, sorghum and millets are the most important staple foods, growing in harsh environments where other crops do not grow well (FAO, 1995). Barley is also important internationally insofar it constitutes the raw material for beer making (brewing). Rye is traditionally used for bread making in some European countries, competing with common bread made from wheat. Rye bread has the advantage over wheat bread of remaining tender during several days, while wheat bread soon dries and hardens (see *Water Effects on Physical Properties of Raw Materials and Foods*). Finally, white corn is of utmost importance in Spanish-American countries, such as Mexico or Peru, where it is used to produce *tortillas* and other traditional staple foods.

Wheat

Worldwide, the main use of wheat grain is for bread making. Species used in bread making is the *common wheat* or

bread wheat (*Triticum aestivum* L.), whereas *durum wheat* (*Triticum turgidum* ssp. *Durum*) is used to make pastas. Bread wheat mills to produce flour, whereas durum wheat mills to produce semolina, which has a coarser granulometry than flour. Depending on the variety, bread wheat can be soft or hard. Moreover, grain can be *white* or *red*. Attending to the duration of the vegetative cycle, there are winter wheat (long cycle) and spring wheat (short cycle) cultivars. Within bread wheat, soft wheat varieties are generally used to make biscuits and other bakery products, whereas hard cultivars are used to make loaf bread.

Wheat milling factories transform the grain into flour, which is then sold to bread-making facilities. According to the United Kingdom Home-Grown Cereals Authority (HGCA), the quality parameters analyzed by wheat millers for each grain delivery are: moisture content, specific weight (*test weight*), screenings and admixture, wheat variety, protein content, protein quality, Hagberg Falling Number, molds, damaged grain and odors, and

grain hardness. Grain moisture content does not directly affect grain quality, but can indirectly affect quality since grain will spoil at moisture contents above that recommended for storage (15%); this is because insects and molds, the causing agents of spoiling, require moisture to grow.

Thin, shriveled grain will not mill to produce adequate amounts of clean, white flour. Grain *test weight* is used as an indicator of general grain quality and is a measure of grain bulk density. The *test weight* measures the weight of wheat (in kg) that can be packed into a cylinder of fixed volume, normally 1 L. Wheat standards fix a minimum specific weight (Table 1). *Test weight* is composed of two components: the packing efficiency of the grain and the density of the individual kernels. Packing efficiency is dependent on genotype, while kernel density is primarily affected by environment (Farrer et al., 2006). Schuler et al. (1995) found that *test weight* did not predict flour yield in soft red winter wheat when shriveling was absent,

Quality of Agricultural Products in Relation to Physical Conditions, Table 1 Grades and grade requirements for all classes of wheat except Mixed wheat. Source: United States Standards for Wheat. Grain Inspection, Packers and Stockyards Administration. United States Department of Agriculture (2006)

Grading factors	Grades U.S. Nos.				
	1	2	3	4	5
Minimum pound limits of:

U.S. Sample grade is Wheat that:					
(a) Does not meet the requirements for U.S. Nos. 1, 2, 3, 4, or 5; or					
(b) Has a musty, sour, or commercially objectionable foreign odor (except smut or garlic odor) or					
(c) Is heating or of distinctly low quality.					

^aIncludes damaged kernels (total), foreign material, shrunken and broken kernels

^bUnclassed wheat of any grade may contain not more than 10.0% of wheat of other classes

^cIncludes contrasting classes

^dIncludes any combination of animal filth, castor beans, crotalaria seeds, glass, stones, or unknown foreign substance

but it was related to flour protein content, which is associated with bread-baking quality. Grain *test weight* normally increases as grain is dried ([Table 2](#)).

Screenings are undersized grains, and admixture comprises impurities, e.g., chaff, weed seeds and earth, which must be removed before milling marketable flour. Screenings and admixture represent a loss to the miller, so a maximum of 2% is normally allowed (HGCA). A synonym of admixture is *foreign matter*, and these terms should not be confused with the term *dockage*. The latter refers to any non-wheat material that can be easily removed from grain, and that must be removed in order that the grain can be assigned the highest grade for which it qualifies.

Protein content is specified for all bakery flours. For most bread-making flour, wheat with protein content above 13% dry matter is preferred (HGCA). When wetted, during dough making, some of the proteins in wheat flour form a viscoelastic (see [Rheology in Agricultural Products and Foods](#)) substance called gluten. This can hold gas produced during fermentation and supports the starch and bran producing well-risen loafs. For most biscuits and cakes, gluten formation is not required; hence, much lower protein flours may be used.

Visual examination assesses grain for molds, like *Fusarium* (pink grains) and particularly ergot. Ergot is a disease of cereal crops and grasses caused by the fungus *Claviceps purpurea*. It causes reduced yield and quality of grain. Although the crop loss caused by this disease is important, the effect of the ergot's alkaloid toxins on man and animals is of much greater significance. Most of the sclerotia (ergot bodies) can be removed from ergoty grain with modern cleaning machinery, unless broken pieces are present or the sclerotia are similar in size to the grain (Mc Mullen and Stoltenow, [2002](#)). Ergot is a particular problem in durum wheat because semolina is not sifted, as flour is for bread, and ergot shows up as dark spots in the pasta. Apart from visual examination for molds, checks are made for live insects and grain damaged by insects. Grain is also assessed for unusual odors; "mustiness" or "chemical" odors indicate storage problems.

Quality of Agricultural Products in Relation to Physical Conditions, Table 2 Test weight variation due to moisture content (Hellevang, [\[1995\]](#))

Grain	Moisture content (%)	Test weight (kg/hL) ^a

The Hagberg Falling Number (HFN) is an internationally recognized measure that allows the indirect determination of α -amylase activity (α -amylases are enzymes that decompose starch). This activity may become excessive if germinated grains are present. The laboratory measurement of HFN aims to measure the viscosity of a mixture of ground wheat and water, placed in a bain-marie at 100°C. Low values for HFN (below 120 s) mean excessive levels of α -amylase, hence excessive activity, causing loaves to be discolored, sticky, and of poor resilience and texture (see [Rheology in Agricultural Products and Foods](#)). The ideal level of activity is between 180 s and 250 s (GeotraceAgri project, [2003](#)). Wheat grains whose α -amylase activity is too high do not suit bakery use and rather should be used for animal feeding.

In regards to durum wheat, Jiménez González ([1995](#)) pointed out the following quality criteria:

- Grain moisture content must be the lowest possible.
- Small grains are not valid for milling, due to the low endosperm/seed coat ratio.
- Grain size must be uniform.
- Germinated grains can yield pasta of bad cooking quality.

Rice

Rice, unlike most other cereals, is consumed as a whole grain. Therefore physical properties such as size, shape, uniformity, and general appearance are of utmost importance. A whole grain of rice, i.e., a grain of rice as it comes from the field after harvest (*paddy rice* or *rough rice*) has several constituent layers. More precisely defined, paddy rice is rice which has retained its husk after threshing (Codex Standard for Rice, [1995](#)). Only the outermost layer, the hull or husk, is removed to produce *husked rice*, more commonly known as *brown rice* or *cargo rice*. This process is the least damaging to the nutritional value of the rice and avoids the loss of nutrients that accompanies further processing. If brown rice is further milled to remove the bran and most of the germ, the result is a white rice, but also a rice that has lost many more nutrients. At this point, however, the rice is still unpolished, and it takes polishing to produce the white rice we are used to seeing. Polishing removes the aleurone layer of the grain, a layer filled with essential fats, to extend the shelf life of the product; polishing is important because fats in the aleurone layer, once exposed to air as a consequence of the previous stage in the refining process, are highly susceptible to oxidation. The drawback of the refining-polishing process is that the resulting white rice is largely bereft of its original nutrients (The George Mateljan Foundation, [2010](#)). To compensate the loss of nutrients, vitamins, minerals and specific amino acids may be added in conformity with the legislation of the country in which the rice is sold (Codex Standard for Rice, [1995](#)).

Because most rice is milled, the important physical properties are determined primarily by the milled endosperm. Several components of rice quality largely

determine market price and consumer acceptance. Milling yield is one of the most important criteria of rice quality. Two values of rice milling yield are *whole-grain yield* and *total* (whole plus broken) *milling yield*. Broken rice is generally valued at only 30–50% of whole grain (Mutters, 2003). Physical characteristics of rice considered important by the quality standards for rice in force in Japan include:

- The number of whole grains (damaged, opaque, immature, foreign matter)
- The number of damaged grains (germinated, diseased, insect-damaged, cracked grains, malformed)
- Morphology parameters (periderm thickness, filling status, softness, uniformity of grain size, shape, luster, abrasion, white core, white belly)

The second major criterion of quality in Japanese standards for rice is taste. Good eating quality relates to high stickiness, sweet flavor, gloss of cooked rice, and palatability.

Barley

There are two main types of barley: six-row and two-row. Generally, two-row barley has lower enzyme content, less protein, more starch, and a thinner husk than six-row barley (Goldammer, 2008). These characteristics make two-row barley the preferred one for brewing in most countries. However, six-row barley outperforms its two-row counterpart as to enzymes content. In those breweries or elaborations where *adjuncts* – corn and rice – are used in the elaboration process, six-row barley is preferred, since in this case a highest amount of enzymes is required. Brewing exclusively from barley produces strong-flavored beers, whereas blending with some percentage of rice or corn makes beer “lighter,” but more refreshing.

The brewing process begins at the malthouse. In these facilities, after cleaning the grain, the kernels are steeped to make them germinate. At a certain moment, germination is stopped by drying the grains (*kilning*), then the tiny sprouts developed at germination are removed. The produce obtained, *malted barley*, is the raw material for the breweries and differs from raw barley in that the original starch in the barley grain has suffered some amount of degradation by enzymes; in technical language it is said that the starch has been *modified*.

Correct harvesting of barley is critical to maximize both yield and quality. Grain that is overthreshed causing cracking and *skinning* will have poor viability and result in low malt extract as well as increased risk of microbial infection when malted. Maltsters and brewers require grain that is free from skinning. The presence of a complete husk on barley protects the embryo during handling (the embryo must be protected because it is the agent in charge of converting the barley into malt), retains the modified starch within a parcel, and is used as a filtration aid during brewing (Department of Agriculture and Food, Government of Western Australia, 2006).

The maltster wants little nitrogen in the barley because excessive proteins in the grain prolong the process of malting, making it more difficult and more expensive. Not only that, but excessive of protein in beer reduces both the quality and shelf life of the beer (Holder, 2002). For example, chill haze in beer is partly caused by excessive protein content. The brewer has to adopt a trade-off between reducing protein content to improve colloidal stability, i.e., preventing haze development, and affecting fermentation and beer quality (if the protein content is too low, the yeasts in charge of the alcoholic fermentation will not work well, and on the other hand, the “mouthfeel” of the beer will negatively be affected). Barley growers know that fertilizing the crop too much nitrogen can increase protein beyond levels acceptable to the malting industry’s standards.

The maltster wants barley varieties characterized by rapid and synchronous germination of the grains. An important quality test undertaken by maltsters upon reception of a lot of barley is the germinative capacity test. A highest germination capacity is crucial since only germinated grain will produce malted grain. The ideal germination capacity is of 100%. In practice, a minimum germination capacity of 95% is required for a grain delivery to be accepted.

Grain size is a term used to describe a morphological character (see *Grains, Aerodynamic and Geometric Features*) of barley grain. Large grain will usually provide a higher level of starch with a decreased level of protein (Fox et al., 2006). On the other hand, although barley varieties with small grains can provide satisfactory malting quality, these varieties risk producing commercially unacceptable levels of small grain and thereby reduce the chance for barley growers to meet malt barley specifications (Fox et al., 2006). Finally, varieties exhibiting varying grain size within a delivery can cause uneven malt modification.

Fruits and vegetables

Fruits and vegetables are irreplaceable in a wholesome diet. They constitute a fabulous source of vitamins, minerals, and dietary fiber (non-starch polysaccharides). The assortment of horticultural produce is enormous. There are green leafy vegetables as lettuce, spinach, and kale; bulb vegetables as onion, garlic and leek, root vegetables as carrot and turnip, flower vegetables as cauliflower and broccoli; stem vegetables as celery and asparagus; fruit vegetables as pepper, melon, watermelon, zucchini (courgette, marrow), cucumber, pumpkin, and aubergine (eggplant); tropical fruits as mango and papaya; sweet fruits of temperate areas like plums and apricots; berries, etc. There are also tree nuts and mushrooms – strictly speaking the latter are not plants – they belong to the Kingdom Fungi. In the last decade, some sweet fruits of temperate areas like kiwifruit or persimmon have experimented notable production increase. From a worldwide economic point of view, some of the more relevant fruits and

vegetables are apples, peaches, citrus fruits (orange, tangerine, lemon, grapefruit), potato, and tomato, and in following sections we focus on them.

Fruits and vegetables marketing standards establish the main quality criteria that fresh-market products have to meet. The European Communities (EC) Commission Regulation 1221/2008 provides a *general marketing standard* for 26 products, namely, apricots, artichokes, asparagus, aubergines, avocadoes, beans, Brussels sprouts, carrots, cauliflowers, cherries, zucchini, cucumbers, cultivated mushrooms, garlic, hazelnuts in shell, headed cabbage, leeks, melons, onions, peas, plums, ribbed celery, spinach, walnuts in shell, watermelons, and chicory. The foregoing Regulation also provides specific marketing standards for the ten most traded products in the European Union, namely, citruses, apples, pears, kiwifruits, lettuces, peaches and nectarines, tomatoes, strawberries, sweet peppers, and table grapes.

Now let us take one of the specific quality standards, e.g., that for kiwifruit, for examining some aspect of it. The marketing standard for kiwifruits (EC Commission Regulation 1221/2008) includes *minimum maturity requirements* consisting of that the fruit must have attained a degree of ripeness:

- At packing stage within the region of production and the subsequent delivery by the packer, as well as at import and export stage, of at least 6.2°Brix or an average dry matter content of 15%
- At all other marketing stages (e.g., at the sale point), of at least 9.5°Brix

The unit °Brix is a measure of sugar or soluble-solids content very much used for internal quality assessment of fruits. In the last few years, some packers have installed near-infrared spectrophotometers for online determination of fruit sugar content in their packinghouses (see [Nondestructive Measurements in Fruits](#)). This new capability is advertised by packers as *brix sensing*.

Apart from the minimum maturity requirements above-mentioned, the marketing standard for kiwifruits provides shape requirements for the fruits to be classified as *Extra class* or *Class I*. For qualifying *Extra class*, the ratio of the minimum/maximum diameter of the fruit, measured at the equatorial section, must be 0.8 or greater, while for qualifying *Class I*, the ratio must be 0.7 or greater. This means that a kiwifruit of *Extra class* has to present a rather round cross section. Three dimensionally considered kiwifruits feature a maximum length axis, called polar axis, plus an intermediate and a minimum length axis, the two latter contained in the fruit cross section. In the ideal case of a fruit featuring a perfect circular section, the major and minor axis of the equatorial section would coincide. If a kiwifruit has a ratio smaller than 0.7, it means that its cross section is rather elliptical or flattened, i.e., the fruit has an “ugly” shape. Finally, the marketing standard for kiwifruits includes provisions concerning the sizing of the fruits. Sizing means sorting by size, and the size of kiwifruits is determined by the

fruit weight. Likewise, for some other produce, e.g., lettuce, the size is determined by the weight of one unit; nevertheless, for other products such as citrus fruits, size is determined by the maximum diameter of the equatorial section.

The *minimum quality requirements* of the EC *general marketing standard* establish that the products shall be:

- Intact
- Sound; products affected by rotting or deterioration such as to make them unfit for consumption are excluded
- Clean, practically free of any visible foreign matter
- Practically free from pests
- Practically free from damage caused by pests affecting the flesh
- Free of abnormal external moisture
- Free of any foreign smell and/or taste

In each batch the standard allows a tolerance of 10% by number or weight of product not satisfying the foregoing *minimum quality requirements*. This tolerance does not, however, cover product affected by rotting or any other deterioration rendering it unfit for consumption. Unlike the specific marketing standards for the above-mentioned group of ten products, the EC *general marketing standard* does not include provisions concerning sizing or shape. It seems that this decision pursues that *off-size* and *off-shape* fruits can be dispatched to fresh market instead of being classified as culls and destined for processing or animal feeding. The advantage of diverting these “ugly” fruits to the fresh market is that their price should accordingly be lower, and this is good in the present world economic conjuncture of crisis.

Apparently trivial physical properties may have a definite effect on the quality of the end product. For example, from the wine-making point of view, grape berry has three major types of tissue: flesh, skin, and seed, with the sheer bulk of wine being derived from the flesh. These tissues vary considerably in composition, and therefore by extension, they contribute differently to overall wine composition. Because of this, the composition of wine can be manipulated by simply changing berry size. As a general rule, wines made from smaller berries will have a higher proportion of skin and seed derived compounds (Kennedy, 2002).

Most consumers prefer seedless fruits. Throughout the years, plant breeders have selected seedless tangerines, grapes, and watermelons. To meet consumer expectations, it is important that fruit labeled as *seedless* is effectively free of seeds. Nowadays, there is X-ray and magnetic resonance imaging (MRI)-based methods (see [Nondestructive Measurements in Fruits](#)) that allow detecting if a tangerine contains seeds. Sometimes, the production of a seedless variety carries problematic “side effects.” This has occurred with seedless watermelons, where some fruits develop an internal void, while this defect is less frequent in the traditional seeded watermelon.

Apples and peaches

Physiological disorders are abnormalities of the fruit that are not associated with diseases or insect pests. They can appear during the growing season or after harvest during storage, and affect the appearance and usability of the fruit. Some physiological disorders affecting apples are watercore, sunburn (sunscald), scald (common scald or superficial scald), bitter pit, internal browning (brown heart), and mealiness. Among them, bitter pit and mealiness are probably the best known by most consumers. Bitter pit reduces the fresh-market quality of fruit. It is recognized as an abiotic disorder found in all areas of the world where apples are grown. Bitter pit is influenced by climate and orchard cultural practices. Symptoms consist of small brown lesions of 2–10 mm in diameter in the flesh of the fruit. The tissue below the skin becomes dark and corky. Cultural practices that reduce the incidence of bitter pit are annual bearing, moderate tree vigor, smaller fruit size, calcium sprays, summer pruning, and harvesting mature fruit (Andris et al., 2002).

Horticultural produce must be stored under refrigeration to maintain freshness and reduce decay development. However, low-temperature disorders, chilling injury classified as internal breakdown, limit the storage life of produce under refrigeration. According to Lurie and Crisosto, (2005), chilling injury in peaches and nectarines manifests itself as fruit that are dry and have a mealy or woolly texture (mealiness or woolliness), or hard-textured fruit with no juice (leatheriness), fruit with flesh or pit cavity browning (internal browning), or with flesh bleeding (internal reddening). These authors mentioned a “killing temperature zone” comprehended between 2.2°C and 7.6°C, which must be avoided. Peach maximum storage life can be achieved near or below 0°C, depending on the soluble solids content of the fruit.

Two well-known textural disorders, mealiness in apples and wooliness in peaches and nectarines, diminish the quality of affected fruit in the fresh market. Both disorders share a lack of juiciness that is perceived when the fruit is chewed, and both of them are negative textural attributes because consumers systematically dislike them. According to Arana et al. (2004), there is a correlation between firmness and juiciness in apple, and this explains why firm apples are usually not mealy. The foregoing correlation makes mealiness detection based on firmness measurement feasible. Firmness (see *Fruits, Mechanical Properties and Bruise Susceptibility*) is one of the aspects of vegetable tissue texture. When a consumer bites a firm apple, the pressure of his teeth breaks cell walls, releasing juice. Nevertheless, when a soft apple is chewed, the pressure exerted by the teeth deforms instead of breaking the cell walls of the apple flesh tissue, and no juice is released, implying that it is a mealy apple.

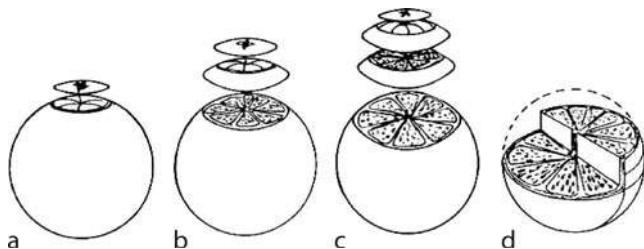

Citrus fruits

We can highlight three physiological disorders affecting citrus fruits: freeze damage as a potential accident in all

citrus species, puffiness in tangerines, and sheepnosing in grapefruit.

The symptoms of freeze injury are principally due to membrane damage. This applies to both the tough carpillary membranes around the individual segments, to the very frail vesicular membranes of the juice sacs, and of the individual cells within the juice sacs (Miller et al., 2006). Initially, frozen areas within the fruit tend to be wet and mushy with the normal radial arrangement of the segment membranes distorted by the action of the formation of ice crystals. At this stage, frozen fruit cannot be mechanically separated from sound fruit. The injured portions dry out within 4–5 weeks. A completely frozen fruit never shrivels because there is no membrane to be pulled inward (see *Shrinkage and Swelling Phenomena in Agricultural Products*). The water diffuses to the outside leaving hollow dried up areas within apparently sound fruit (see *Water Effects on Physical Properties of Raw Materials and Foods*). The severity of the freeze damage is determined by the total volume of desiccated or mushy tissue, following the procedure shown in Figure 1. Lorena Falcone Ferreyra et al. (2006) studied the effect of freeze injury on carbohydrate metabolism and fruit quality in Valencia oranges. They suggested that freezing temperatures provoke a notable metabolic switch in citrus fruit toward a fermentative stage, resulting in low-quality fruits.

Puffiness, also known as “floating skin” or “floating peel,” is a weakening and disintegration of the albedo tissues which is characteristic of mature tangerines. The rind becomes thick and separates from the pulp (segments), creating an air gap between the peel and the segments. Floating skin makes the fruit very susceptible to damage during picking and packing, due to punctures and fissures around the calyx. This can cause severe harvest and

Quality of Agricultural Products in Relation to Physical Conditions, Figure 1 To evaluate freeze damage in oranges, first cut a thin slice off the stem to expose the flesh (a). Then remove a 0.64 cm slice and examine the orange (b). If damage does not extend below this 0.64 cm slice, the fruit automatically grades No. 1 as far as internal quality is concerned. If some damage is noted, make another 0.64 cm cut (c), and depending on the extent of the damage noted, the fruit is graded No. 1 or No. 2. Additional cuts may be made as needed to determine the full extent of damage-down to the middle of the orange (d) and, in some cases, even lower. Inspectors must balance the area of damage with its depth. A 10% tolerance is allowed on fruit graded for the fresh market. Oranges for concentrate must be “wholesome.” (Miller et al., [2006]).

postharvest losses. Moreover, there are some markets, paradigmatically in Japan, where puffy tangerines are not acceptable. In these markets, the detection of a single puffy tangerine usually carries the rejection of the whole carton, and even of the whole pallet. Nowadays, it is technically feasible to detect puffy tangerines using techniques such as X-ray computer vision, MRI, or mechanical firmness assessment (see *Nondestructive Measurements in Fruits*). Occurrence of puffiness in some tangerine varieties is a usual phenomenon; in fact, this peel alteration can affect up to 50% of harvested fruit under the worst conditions (Gutiérrez et al., 1999).

Misshapen, sheepnosed fruit is consistently among the top five causes of fruit elimination at the packinghouse (Ritenour et al., 2003). Sheepnosing, or stem-end taper, is often associated with thick, puffy, or coarse rinds of relatively large fruit. Figure 2 shows some typical sheepnosed or pear-shaped grapefruits. Online detection of misshapen grapefruit at the packinghouse is possible using machine vision technology, i.e., with one or more video cameras that inspect the fruits (see *Image Analysis in Agrophysics*).

Finally, it is important to remark that consumers consider “easy-to-peel” as a quality attribute of utmost importance for tangerines.

Tomato

Tomatoes are consumed both fresh and in various processed foods, with more than 65% of the world tomato production being processed (Moraru et al., 2004). The most relevant quality attributes of tomatoes vary depending on their intended use: taste, appearance, color, and handling characteristics are crucial for fresh-market

Quality of Agricultural Products in Relation to Physical Conditions, Figure 2 Picture taken in a citrus packinghouse in Florida (USA), in 2003. The fruit handled on the date was red grapefruit. Note the defect known as “sheepnosing” or pear-shaped grapefruit in the fruits picked off the roller conveyor. Only the far-right grapefruit is of correct shape.

tomatoes; viscosity and soluble solids content are the most important attributes for triturated or sauce-processing tomatoes (Schuch and Bird, 1994); firmness and skin resistance are the most relevant properties in quality characterization of whole-peeled canned tomatoes (Arazuri et al., 2007). Depending on their industrial use, tomato varieties are classified into two groups: peeled and concentrated varieties. Peeled tomato requires oblong-shape varieties and high quality tomatoes with total absence of mechanical damages. Tomato processing companies are interested in developing varieties which carry oblong, almost square-shaped fruit, in order to pack them more efficiently. For example, some companies might be interested in developing extremely elongated tomatoes shaped like cucumbers. These fruits would be very advantageous when preparing sliced tomatoes for hamburgers, as less ends would have to be thrown away. For the larger fresh-market slicing tomatoes, the ideal is a high locule number (van der Knaap and Tanksley, 2003).

Potato

Physiologically mature potato tubers have high starch and protein levels and low respiration, water content, and sugar levels. Carbohydrates content of tubers can reach 85% of dry matter. Starch content represents usually over 95% of carbohydrates. At harvest, the content of reducing sugars (glucose, fructose) is usually very low (about 0.5%), but it increases during storage, depending on temperature conditions and mechanical damage (impacts, injuries, etc.) suffered by the tuber.

French fries manufacturers prefer long-oval or long tuber with a length of at least 50 mm. For the production of crisps (chips), round tubers are required with a diameter range of 40–60 mm. Potato varieties for frying must absorb little oil, show golden color, and have a crisp and firm texture. If the dry matter content (Table 3) is too low, the French fries or crisps will be too soft or too wet, whereas if it is too high, the French fries will be too hard and dry and the crisps too brittle. Chip color is a very important factor in determining consumer acceptability of potato chips or crisps. The browning of chips is primarily the result of the Maillard reaction which occurs between reducing sugars and amino compounds during

Quality of Agricultural Products in Relation to Physical Conditions, Table 3 Quality requirements for processing potatoes (Netherlands Potato Consultative Foundation [NIVAP Holland])

End product	Dry matter content (%)	Maximum reducing sugars content (% of fresh weight)
French fries	20–24	0.5
Potato chips or crisps	22–24	0.3
Dehydrated potato products (flakes, granules, flour)	>21	0.3

the frying operation at high oil temperature, with the amount of reducing sugars being the limiting factor.

The sugar content in potato tubers depend on many factors, both hereditary and environmental. Tubers of most chipping cultivars stored at temperatures below 9°C for sprouting control accumulate appreciable amounts of reducing sugars. These sugars are the result of starch hydrolysis. Due to the low respiration rate associated to the low storage temperature, sugars are not oxidized ("burned"), resulting in potatoes with a sweet taste. High sugar concentrations in the tubers result in an objectionable sweet flavor in baked or boiled potatoes and result in dark colored chips and French fries. The dark product in fried products is also bitter-tasting. Potatoes that are destined for use as chips or fries are usually taken from cold storage and reconditioned at 12–16°C for a period of 1–2 weeks to reduce the sugar level and make the potatoes satisfactory for processing. The effect of a warmer storage temperature is that sugars are oxidized at a higher rate compared to cold storage conditions.

Potatoes can present several internal defects, like hollow heart, internal discoloration, and "greening." Hollow heart (an irregular hole at the center of the tuber) is caused by excessively rapid growth. Internal discoloration may be caused by improper field or storage conditions, freezing or disease; each causes a different type of discoloration. Potatoes with severe internal discoloration should not be eaten. After harvest, potatoes should be kept away from natural or artificial light because exposure to light causes a green coloring – "greening" – to the tubers. Sometimes only the skin is affected, but greening may penetrate the flesh. The green portions contain the alkaloid *solanin*, which causes a bitter flavor and may have a poisonous effect when consumed in great quantities.

Summary

Grain and horticultural produce are irreplaceable in human nourishment. According to the opinion of some scientists, for a reasonable utilization of the planet resources we should be as vegetarian as possible. Eating beef is little efficient, as a bovid transforms into protein only the 5% of the protein it consumes. Chickens are more efficient, since their protein conversion rate is of 25%. From this point of view, it seems more reasonable to consume the vegetables directly. This does not imply that livestock industry should disappear since livestock provides us with products such as wool, milk, eggs, etc., which are of great nutritional interest and cannot be obtained from plants.

Although crucial vegetal foods in human nourishment as legumes and oilseeds have not been addressed here, some ideas have been presented on quality of emblematic grain and horticultural produce. An interesting reflection is that the quality of a product depends on the intended use. With the purpose of protecting public health and guaranteeing trade transparency, official organisms dictate quality or marketing standards for agricultural products.

RAINFALL INTERCEPTION BY CULTIVATED PLANTS

Józef Kołodziej

Department of Agrometeorology, University of Life Sciences, Lublin, Poland

Definition

Rainfall interception is a process of retention of rainwater by the plant cover. It is expressed in millimeters of water layer, similar to atmospheric precipitation, or as a percentage value in comparison to precipitation measured over open space. Water retention by abiotic objects (buildings, roots, etc.) is named *wetting*.

Introduction

The interception process is one of the phenomena of the hydrological-meteorological sequence in which permanent and periodically cultivated vegetation takes part. The vegetation affects the process of retention of rainwater that is mostly directly returned to the atmosphere through evaporation, and partly absorbed by plants, or flows along plant stems down to the ground. Rainfall interception investigations were concentrated mainly on tree and grass stands, ignoring seasonal crops, because of the significantly longer duration of tree and grass canopies during the annual hydrologic cycle (Savabi and Stott, 1994).

Rainfall interception

Methods of measurements

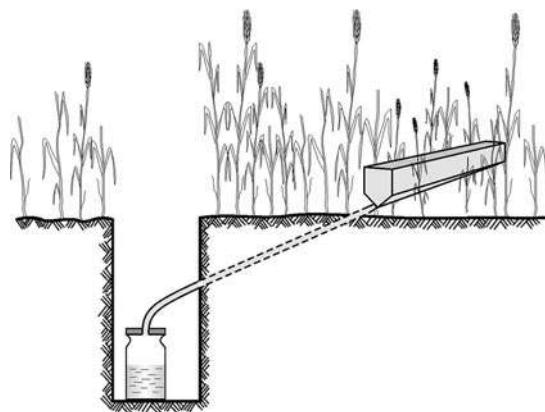

At the beginning of studies on rainfall interception by cultivated plants, measurements were carried out with the use of commonly used rain gauges placed among plants. Later, Stoltenberg and Wilson (1950) cut plants, weighed them, and then moistened and weighed them again. The difference in weight was a measure of water retention by plants. From the knowledge of the amount of plants on a given area, the retained rainfall was calculated. Kontorshchikov and Eremina (1963) cut plants in different growth stages and placed them in a vessel with a known amount of water. A decrease of water in the vessel, after removing the plants, was a measure of the amount of interception. In turn, Burg and Pomeroy (1958) measured the loss of water in a portable frame with grass, which was weighed before and after rain simulation.

Kołodziej and Orzeł (1978) used for interception investigations a drainpipe rain gauge of their own design, with dimensions 5 cm × 40 cm, matching the collecting surface of Hellmann's rain gauge (Figure 1). It enables the comparison of interception results with rainfall data made in open space. Its additional advantage is the possibility of making measurements during the whole vegetation period. Another type of device placed on soil with cultivated plants (Figure 2) was elaborated by Kołodziej and Orzeł (1978) for measuring the total amount of rain water coming to the surface of the ground.

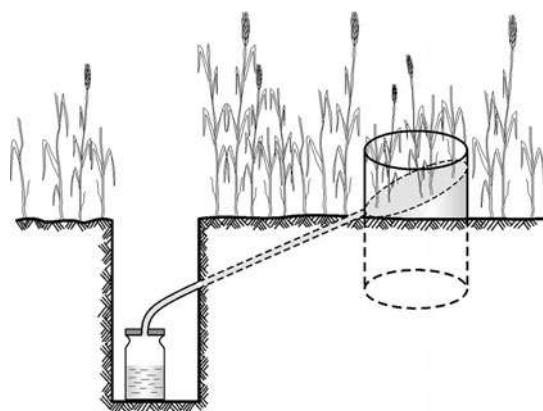

Results

An example of results of rainfall interception and the amount of water retained by various cereal plants during 8-year measurements is shown in Table 1.

The numbers of observations were different in the successive years of the study. They depended, among other

Rainfall Interception by Cultivated Plants, Figure 1 Drainpipe rain gauge for direct measurement of rainfall reaching ground surface inside plant canopy (Kołodziej and Orzeł, 1978).

Rainfall Interception by Cultivated Plants, Figure 2 Rain gauge for direct measurement of rainfall and water flowing down the stems to the surface of the ground (Kołodziej and Orzeł, 1978).

things, on the frequency of atmospheric precipitation and were characterized by the following values: under spring barley – from 51 to 77 days, under winter wheat – from 92 to 97 days, and under winter rye – from 91 to 97 days.

The rate of rainfall interception in the canopy of cultivated plants depends on the level of precipitation, its intensity and duration, on the kind of vegetation, its height, development stage, and its ground coverage. The rate of interception is negatively correlated with precipitation measured on the open space. During the most intensive growth and foliation of plants precipitation from 0.1 to 5.0 mm undergoes nearly total interception, but at higher levels the precipitation is intercepted only partly. A positive correlation is observed between the rate of interception and the height of vegetation. The dependence curve between chosen meteorological elements (amount, duration and intensity of precipitation, and also wind speed and evaporation) and the amount of interception has a logarithmic form and tends asymptotically to the final value of interception.

Among the cereals, the highest dependence of interception on the precipitation duration was found for spring barley. Leaf area and area of whole plant and also condensation on the unit surface affect the highest interception. At leaf area index (LAI) equal to 20, the mean value of rainfall interception during the whole vegetation seasons of 1977–2005 is directed to 33% for winter rye, 38% for winter wheat, and 36% for spring barley. How plant development stage affects rainfall interception by two different cereals is shown on the example of winter rye, where it is the highest from shooting to heading, and of spring barley – from heading to dough maturity. Such differences are due to differences in their morphological structure, canopy density, position of leaf angle, length of internodes, and time of drying up of the lowest leaf blades. A part (about 7%) of retained water is absorbed through plant stomata or flows down along the stems to soil surface, and the rest evaporates back to the atmosphere (Kołodziej et al., 1979, 1992, 2005; Kołodziej and Liniewicz, 1992, 1994; Bednarek et al., 2000).

Rainfall Interception by Cultivated Plants, Table 1 Mean values of rainfall interception and amount of water retained by various cereal plants during 8-year (1987–1995) measurements. Felin Agrometeorological Observatory, Lublin, Poland (Kołodziej et al., 2005)

Years	Spring barley		Winter wheat		Winter rye	
	Interception (%)	Amount of water (mm)	Interception (%)	Amount of water (mm)	Interception (%)	Amount of water (mm)
1987	45.6	39.3	37.4	65.2	30.1	48.7
1988	30.6	59.0	31.8	73.3	35.4	81.6
1989	34.4	54.1	35.3	74.4	38.6	81.2
1990	29.4	43.1	33.9	53.4	22.4	35.3
1991	41.0	51.2	37.7	74.5	23.8	48.6
1992	39.3	32.1	26.6	30.0	17.7	20.0
1993	30.2	48.0	26.4	42.2	29.9	53.1
1994	36.5	46.1	19.7	5.2	12.2	10.8
1995	17.8	19.6	42.1	58.0	34.6	47.7
Mean	33.1	43.6	33.8	52.9	28.9	47.5

On the basis of results from field experiments, prognostic mathematical models of rainfall interception for various cultivated plants in their stages of growth and development were elaborated (Wigneron et al., 1996; Kozak et al., 2007; Lorens and Domingo, 2007; Muzylo et al., 2009).

Conclusion

Rainfall interception is one of the most important elements in water budget of cultivated field. During the vegetative season, it can be in the range of 30–40%.

REMOTE SENSING OF SOILS AND PLANTS IMAGERY

Ramsis B. Salama
Managed Water Resources, Ocean Reef, Australia

Definitions

Remote sensing can be defined as the study of make observations, take measurements, and produce images of phenomena that are beyond the limits of our own senses and capabilities without making actual contact with the object of study. It can also be defined as: Any of the technical disciplines for observing and measuring the Earth from a distance, “The acquisition and measurement of data/information on some property(ies) of a phenomenon, object, or material by a recording device including satellite imaging, Global Positioning Systems, Radar, Sonar and aerial photography which is not in physical or close contact with the feature(s) under surveillance” and generate digital or hard copy image data (Jensen, 2007, 2008; http://en.wikipedia.org/wiki/Remote_sensing).

Introduction

Remote sensing data are indispensable for measurement and evaluation of regional-to-global processes. Remote sensing is now widely used for collecting data, monitoring and studying the natural resources and environment conditions of the universe. Tens of new Earth-observing satellites and a larger number of airborne instruments are available for research. Instruments are better calibrated, more stable, and produce more channels of spectral data. An increasing number of instruments have capabilities that include imaging spectroscopy, multiple-view-angle, and/or multipolarization bands that can simultaneously capture information about the plants, soils, biochemistry of surface materials, and their structures. Use of remote sensing data is advancing from correlative studies to fundamental understanding of the physical variables and their interactions with electromagnetic radiation. This information is used in increasingly complex models to plan most of the activities of politicians, scientists, and human resources in all areas of agriculture and related environmental processes to assess ecosystem goods and services, and to evaluate sustainability of land use activities (Figure 1).

Remote sensing

Optical remote sensing makes use of visible, near-infrared, and shortwave infrared sensors to form images of the Earth's surface by detecting the solar radiation reflected from targets on the ground. Different materials reflect and absorb differently at variable wavelengths. Therefore, the targets can be differentiated by their spectral reflectance signatures in the remotely sensed

images. Remote sensing systems offer four basic components to measure and record data about an area from a distance.

- Energy source; electromagnetic energy is required to transmit information from the target to the sensor.
- As the energy travels from its source to the target, it will come in contact with and interact with the atmosphere it passes through.
- Once the energy makes its way to the target through the atmosphere, it interacts with the target depending on the properties of both the target and the radiation.
- After the energy has been scattered by, or emitted from the target, the energy is recorded by the sensor and transmitted electronically to a receiving and processing station where the data are processed into a hardcopy or digital image.

Quality of remote sensing data

The quality of remote sensing data consists of its spatial, spectral, radiometric, and temporal resolutions.

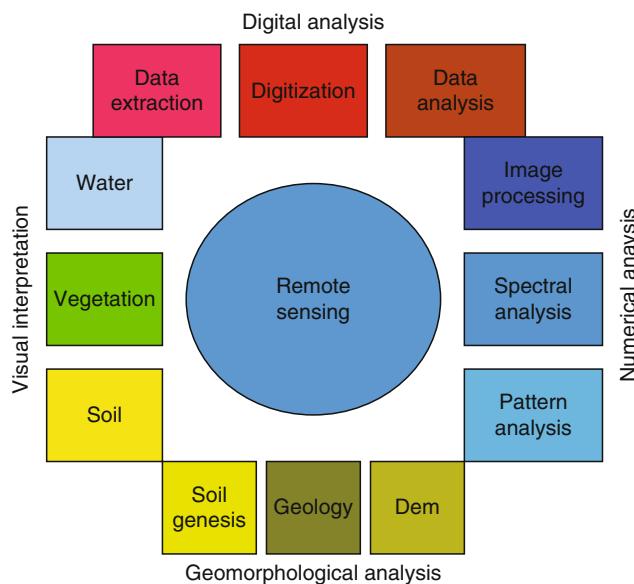

Spatial resolution

The size of a pixel that is recorded in a raster image – typically pixels may correspond to square areas ranging in side length from 1 to 1,000 m.

Spectral resolution

The number of different frequency bands recorded, this is equivalent to the number of sensors carried by the platform. Optical remote sensing systems are classified into the following types, depending on the number of spectral bands used in the imaging process: <http://www.crisp.nus.edu.sg/~research/tutorial/optical.htm>.

- Panchromatic imaging system:** Sensor is a single channel detector sensitive to radiation within a broad wavelength range. Examples of panchromatic imaging systems are: IKONOS PAN, SPOT HRV-PAN
- Multispectral imaging system:** Sensor is a multichannel detector with a few spectral bands. Each channel is sensitive to radiation within a narrow wavelength band. The resulting image is a multilayer image which contains both the brightness and spectral (color) information of the targets being observed. Examples of multispectral systems are: LANDSAT MSS, LANDSAT TM, SPOT HRV-XS, IKONOS MS
- Superspectral Imaging Systems:** A superspectral imaging sensor has many more spectral channels (typically >10) than a multispectral sensor. The bands have narrower bandwidths, enabling the finer spectral characteristics of the targets to be captured by the sensor. Examples of superspectral systems are: MODIS, MERIS
- Hyperspectral Imaging Systems:** Hyperspectral imaging system is also known as an “imaging spectrometer.” It acquires images in about a hundred or more contiguous spectral bands. The precise spectral information contained in a hyperspectral image enables better

Remote Sensing of Soils and Plants Imagery,
Figure 1 Remote sensing key components and inter-related areas (DEM = Digital Elevation Model).

characterization and identification of targets. Hyperspectral images have potential applications in such fields as precision agriculture (e.g., monitoring the types, health, moisture status, and maturity of crops), coastal management (e.g., monitoring of phytoplanktons, pollution, bathymetry changes). An example of a hyperspectral system is: Hyperion on EO1 satellite.

<http://www.crisp.nus.edu.sg/~research/tutorial/optical.htm>

Radiometric resolution

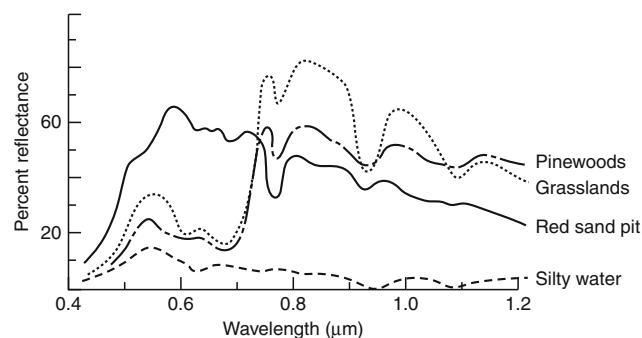

The number of different intensities of radiation the sensor is able to distinguish. Typically, this ranges from 8 to 14 bits, corresponding to 256 levels of the gray scale and up to 16,384 intensities or “shades” of color, in each band.

Temporal resolution

The frequency of flyovers by the satellite or plane, and is only relevant in time-series studies or those requiring an averaged or mosaic image as in deforesting monitoring. This was first used by the intelligence community where repeated coverage revealed changes in infrastructure, the deployment of units, or the modification/introduction of equipment. Cloud cover over a given area or object makes it necessary to repeat the collection of said location. http://en.wikipedia.org/wiki/Remote_sensing.

Electromagnetic spectrum: spectral signatures

For any given material, the amount of solar radiation that it reflects, absorbs, transmits, or emits varies with wavelength. When that amount (usually intensity, as a percent of maximum) coming from the material is plotted over a range of wavelengths, the connected points produce a curve called the material’s *spectral signature* (spectral response curve) http://en.wikipedia.org/wiki/Spectral_signature. This important property of matter makes it possible to identify different substances or classes and to separate them by their individual spectral signatures, as shown in Figure 2.

Remote Sensing of Soils and Plants Imagery, Figure 2 Spectral curves for Pine Wood, Grassland, Red Sand Pit, and Silty Water. (NASA remote sensing tutorial available at <http://rst.gsfc.nasa.gov> [accessed September 2009]).

Processing and classification of remotely sensed data; pattern recognition; approaches to data/image interpretation

Processing and classification of remote sensing system are to detect radiation signals, determine their spectral character, derive appropriate signatures, and inter-relate the spatial positions of the classes they represent. This ultimately leads to some type of interpretable display product, be it an image, a map, or a numerical data set, that mirrors the reality of the surface (affected by some atmospheric property [ies]) in terms of the nature and distribution of the features present in the field of view. The determination of these classes requires that either hard copy, i.e., images, or numerical data sets be available and capable of visual or automated analysis. http://rst.gsfc.nasa.gov/Intro/Part2_5a.html; http://rst.gsfc.nasa.gov/Intro/Part2_6.html.

There are several image processing techniques. Data from the several bands that are set up from spectral data in the visible and near-IR tend to be varyingly correlated for some classes. This correlation can be minimized by a reprocessing technique known as *Principal Components Analysis (PCA)*. New color images can be made from sets of three band ratios or three Principal Components. The color patterns will be different from natural or false color versions. Interpretation can be conducted either by visual means, using the viewer’s experience, and/or aided by automated interpretation programs, such as the many available in a computer-based Pattern Recognition procedure. A chief use of remote sensing data is the *classification* of the numerous features in a scene (usually presented as an image) into meaningful categories or classes. The image then becomes a *thematic map* (the theme is selectable, e.g., land use; geology; vegetation types; rainfall). This is done by creating an *unsupervised* classification when features are separated solely on their spectral properties and a *supervised* classification when we use some prior or acquired knowledge of the classes in a scene in setting up *training sites* to estimate and identify the spectral characteristics of each class http://rst.gsfc.nasa.gov/Intro/Part2_6.html.

Remote sensing for soils

Soil is a fundamental natural resource; it is the basis of human agriculture. Civilizations rise in regions blessed with fertile soil; they fall when humans fail to treat soil with respect. Further, soil plays an essential role in the biophysical and biogeochemical functioning of the planet. On continents, soil forms a porous boundary where the biosphere, hydrosphere, lithosphere, and atmosphere interact (Scull et al., 2003). Understanding the spatial distribution and management of soil is critical to maintain a productive society and to understand the complex balance of chemical and physical processes that make life possible on Earth.

Soil characteristics

Soil has properties that cause the ratio of near-infrared and visible red reflectance to plot in a linear fashion. This

Remote Sensing of Soils and Plants Imagery, Figure 3 Soil line, line of a bare field plot in a straight line when looking at the reflectance values of NIR vs. Red.

means that as light energy comes into contact with the individual soil particles, each particle will reflect a proportionately similar amount of near-infrared and red wavelengths. For very homogenous soils, this line may be very short and for soils that vary in type and moisture content, this line may be stretched significantly more. The soil line of the soil reflectance spectra characterizes the soil type, defines vegetation indices, and corrects the plant canopy reflectance from the optical soil property effects (Figure 3).

The line can be established by locating two or more patches of bare soil in the image having different reflectivities and finding the best fit line in spectral space. The soil line can also be calculated by the least-square regression method:

$$\text{NIR}(\text{soil}) = \alpha \text{RED}(\text{soil}) + \beta \quad (1)$$

where RED (Soil) = soil reflectance in the red band, NIR (soil) = soil reflectance in the near-infrared band, α , β = parameters of the soil line estimated by the least-square regression method. Other visible bands, such as green or blue ones, can be used instead of red ones.

Factors that influence soil reflectance in remote sensing

The properties of soils that govern their spectral reflectance are biogeochemical (mineral and organic) constituents, optical geometric scattering (particle size, aspect, roughness), and moisture conditions of the surface (Baumgardner et al., 1985; Irons et al., 1989; Ben-Dor et al., 1999).

(a) The mineral composition of soils affects the reflectance spectrum. Most soils exhibit increasing reflectance with wave length over the visible to NIR portion of the spectrum, since iron is fairly omnipresent (Mulders, 1987). Minerals with OH, CO_3 (Calcite), and SO_4 (gypsum) exhibit vibrational features

in the 1.8–2.5 μm region, while silicates with OH absorb near 1.4 and 2.2 μm (Baumgardner et al., 1985; Mulders, 1987).

- (b) Soil moisture has a strong influence on the amount and composition of reflected and emitted energies from a soil surface, and thus information about soil moisture condition can be derived from measurements in all parts of the electromagnetic spectrum. In the shortwave region, the major effect of adsorbed water on soil reflectance is a decrease in reflected energy, making soils darker when moistened, particularly in the water absorption bands centered at 1.45 and 1.9 μm (Reginato et al., 1977). The decrease in reflectance is proportional to the thickness of the water film around the soil particles and can be related to gravimetric water content as well as the energy status of the adsorbed water (Idso et al., 1975). Moisture of soil has an equal effect over the entire spectrum and the ratios between spectral bands such as red and near-infrared bands are independent of the soil moisture.
- (c) The presence of organic matter in the soil has been found to decrease the overall reflectance and result in decrease in the spectral contrast. Organic matter has a lower effect in the bands beyond 1.8 μm . Organic matter absorbs strongly in shorter wavelength as well as in the infrared region due to the presence of various functional groups and conjugate bonds (Hoffer, 1978; Hunt, 1980). High organic matter in soil may produce spectral interferences for band characteristics of minerals like Mn and Fe. This factor has an indirect spectral influence through its effect on soil structure and on water retention capacity.
- (d) Soil texture, which is the relative proportion of sand, silt, and clay, affects the spectral reflectance of the soils due to its influence on water-holding capacity and the size of soil particles. Large grain size exhibits numerous well-developed absorption features at wavelengths less than 1,600 nm, and smaller grains exhibit fewer less developed features in this region and well-developed features at wave lengths more than >1,600 nm. In smaller grains, the soil surface becomes smoother and more incoming solar energy is reflected. An increase in particle size causes a decrease in reflectance as light is trapped in the rough surfaces of the coarse soil particles. However, silt content of soil is considered as major controlling factor for spectral reflectance. The reflectance becomes lower as the silt content decreases (Hoffer, 1978). On the other hand, it is commonly observed that sandy soil exhibits higher reflectance than that of clayey soil, which is due to abundance of macro pores and air–soil interface that cause multiple reflection/scattering. For example, if iron and lime are present, a stronger reflectance is received than if the soil material was fine textured and dry. Variations in soil reflectance occur where there is a change in distribution of light and shadow areas with surface roughness areas. This factor is important in the thermal infrared and microwave spectral domains.

Plant characteristics

Vegetation has distinct properties when exposed to light energy. The reflective and absorptive properties of vegetation with respect to red and near-infrared radiation are much different than that of soil. Active vegetation uses light energy available in the atmosphere as an ingredient in the photosynthesis process. The plant uses water from the soil, CO₂ from the air, and light energy to produce sugar molecules used by the plant. The by-product is oxygen molecules, which are released into the air. For this process to take place, certain wavelengths of light are absorbed by the plant and used as fuel for the process. As light strikes the leafy surfaces of the plant, three things can occur. The light may either be reflected back into the atmosphere, it may be absorbed by the plant, or it may be transmitted through the plant onto other lower lying surfaces. In most cases, a combination of all three things happens. The light that is transmitted through the leaf will then come into contact with whatever lies beneath it. If it is another leaf, a combination of the above three circumstances will again occur. This explains how light energy that is not reflected but transmitted by the first leaf layer may eventually be reflected back into the atmosphere by lower leaf levels. In the same manner, some wavelengths that are transmitted through the first layer may eventually be absorbed by lower leaf layers. As the biomass of the vegetation increases over the soil, the amount of light reaching the soil decreases. Intense radiation can be harmful to vegetation, and therefore plants have adapted to absorb only what is necessary, and reflect the longer more harmful rays (Jensen, 2007). As the vegetation biomass increases, more and more visible red light is absorbed by the plants for photosynthetic purposes, while more and more near-infrared energy that can be damaging to the plant is reflected.

Vegetation indexes

The visible portion of the leaf reflectance spectrum is characterized by high absorption of pigments. The chlorophyll pigments absorb violet, blue, and red but green, so most vegetation has green appearance. The reflectance spectrum of green vegetation has maximum absorption at 420, 490, and 660 nm bands; all by chlorophyll. The electromagnetic absorption mechanism in the pigments of green vegetation is by atomic excitation. Pigments, such as chlorophyll and carotenes, absorb light in particular wavelength, causing an electron jump in the pigment molecular structures. The energy produced by de-excitation will be consumed for electrochemical reaction.

Numerous indices have been developed to quantify how vegetation responds to light energy as it grows. In fact, over 50 vegetation indices exist (Huete et al., 1994; Ray, 1994; Jensen, 2007).

Ratio vegetation index (RVI)

The first developed of these indices is the ratio vegetation index (RVI), which is simply the near-infrared reflectance values divided by the visible red reflectance values.

$$\text{The RVI is defined as : } RVI = \frac{NIR}{Red} \quad (2)$$

NIR=near infra-red reflectance, *Red*=visible red reflectance.

Red simple ratio

The near-infrared (NIR) to red simple ratio (SR) is the first true vegetation index:

$$SR = \frac{\rho Red}{\rho NIR} \quad (3)$$

(*ρRed* = reflectance in the red spectral range. *ρNIR* = reflectance in near-infrared range).

It takes advantage of the inverse relationship between chlorophyll absorption of red radiant energy and increased reflectance of near-infrared energy for healthy plant canopies (Cohen, 1991).

The generic normalized difference vegetation index (NDVI)

$$NDVI = \frac{(NIR - RED)}{(NIR + RED)} \quad (4)$$

(RED and NIR stand for the spectral reflectance measurements acquired in the red and near-infrared regions, respectively).

NDVI measures of the overall amount and quality of photosynthetic material in vegetation and provided a method of estimating net primary production over varying biome types (Tucker, 1979; Lenney et al., 1996) (Biomes are defined by factors such as plant structures (such as trees, shrubs, and grasses), leaf types (such as broadleaf and needleleaf), plant spacing (forest, woodland, savanna), and climate), identifying ecoregions (Ramsey et al., 1995) (Ecoregion is geographic area characterized by distinctive environmental characteristics including climate, geomorphology, vegetation, soil, water, fauna, and land use), monitoring phenological patterns (Phenology is the study of periodic plant and animal life cycle events) of the earth's vegetative surface, and of assessing the length of the growing season and dry-down periods (Huete and Liu, 1994).

Normalized difference moisture or water index (NDMI or MDWI)

Vegetation water content has widespread use in agriculture, forestry, and hydrology. Gao (1996) found that the normalized difference moisture or water index (NDMI or MDWI) based on Landsat TM near- and middle-infrared bands was highly correlated with canopy water content and more closely tracked changes in plant biomass than did the NDVI.

$$NDMI = \frac{NIR_{TM_4} - MidIR_{TM_5}}{NIR_{TM_4} + MidIR_{TM_5}} \quad (5)$$

Soil-adjusted vegetation index (SAVI)

Improved vegetation indices that may take advantage of calibrated hyperspectral sensor systems such as the moderate resolution imaging spectrometer – MODIS has been developed (Running et al., 1994; Zarco-Tejada et al., 2003). The improved indices incorporate a *soil adjustment factor* and/or a *blue band for atmospheric normalization*. The *soil-adjusted vegetation index* (SAVI) introduces a soil calibration factor, L , to the NDVI equation to minimize soil background influences resulting from first order soil–plant spectral interactions (Huete et al., 1994):

$$SAVI = \frac{(1+L)(\rho_{nir} - \rho_{red})}{\rho_{nir} + \rho_{red} + L} \quad (6)$$

An L value of 0.5 minimizes soil brightness variations and eliminates the need for additional calibration for different soils (Huete and Liu, 1994).

Atmospherically resistant vegetation index (ARVI)

SAVI was made less sensitive to atmospheric effects by normalizing the radiance in the blue, red, and near-infrared bands by the *atmospherically resistant vegetation index*:

$$ARVI = \frac{\rho^{*nir} - \rho^{*rb}}{\rho^{*nir} + \rho^{*rb}} \quad (7)$$

where

$$\rho^{*rb} = \rho^{*red} - \gamma(\rho^{*blue} - \rho^{*red}) \quad (8)$$

The technique requires prior correction for molecular scattering and ozone absorption of the blue, red, and near-infrared remote sensor data, hence the term ρ^* .

Aerosol free vegetation index (AFRI)

Karnieli et al. (2001) found that under clear sky conditions, the spectral bands centered on 1.6 and 2.1 μm are highly correlated with visible spectral bands centered on blue (0.469 μm), green (0.555 μm), and red (0.645 μm). Empirical linear relationships such as $\rho_{0.469\mu\text{m}} = 0.25\rho_{2.1\mu\text{m}}$; $\rho_{0.555\mu\text{m}} = 0.33\rho_{2.1\mu\text{m}}$, and $\rho_{0.645\mu\text{m}} = 0.66\rho_{1.6\mu\text{m}}$ were found to be statistically significant. Therefore, based on these and other relationships, two *Aerosol Free Vegetation Indices* were developed:

$$AFRI_{1.6\mu\text{m}} = \frac{(\rho_{nir} - 0.66\rho_{1.6\mu\text{m}})}{(\rho_{nir} + 0.66\rho_{1.6\mu\text{m}})} \quad (9)$$

$$AFRI_{2.1\mu\text{m}} = \frac{(\rho_{nir} - 0.5\rho_{2.1\mu\text{m}})}{(\rho_{nir} + 0.5\rho_{2.1\mu\text{m}})} \quad (10)$$

Enhanced vegetation index (EVI)

The MODIS Land Discipline Group proposed the *enhanced vegetation index* (EVI) for use with MODIS Data:

$$EVI = G \frac{\rho_{nir}^* - \rho_{red}^*}{\rho_{nir}^* + \rho_{red}^* - C_2 \rho_{blue}^* + L} \quad (11)$$

The EVI is a modified NDVI with a soil adjustment factor, L , and two coefficients, C_1 and C_2 , which describe the use of the blue band in correction of the red band for atmospheric aerosol scattering. The coefficients, C_1 , C_2 , and L , are empirically determined as 6.0, 7.5, and 1.0, respectively. This algorithm has improved sensitivity to high biomass regions and improved vegetation monitoring through a de-coupling of the canopy background signal and a reduction in atmospheric influences. G is a gain factor set to 2.5.

Triangular vegetation index

Broge and Leblanc (2000) developed a *triangular vegetation index* (TVI), which describes the radiative energy absorbed by pigments as a function of the relative difference between red and near-infrared reflectance in conjunction with the magnitude of reflectance in the green region, where the light absorption by chlorophyll *a* and *b* is relatively insignificant. The index is calculated as the area of the triangle defined by the green peak, the chlorophyll absorption minimum, and the near-infrared shoulder in spectral space. It is based on the fact that both chlorophyll absorption causing a decrease of red reflectance and leaf tissue abundance causing increased near-infrared reflectance will increase the total area of the triangle. The TVI index encompasses the area spanned by the triangle ABC with the coordinates given in spectral space:

$$TVI = \frac{1}{2} [120(\rho_{nir} - \rho_{green})] - 200(\rho_{red} - \rho_{green}) \quad (12)$$

where ρ_{green} , ρ_{red} , and ρ_{nir} are the reflectances centered at 0.55, 0.67, and 0.75 μm , respectively.

Visible atmospherically resistant index (VARI)

The index is minimally sensitive to atmospheric effects, allowing estimation of vegetation fraction with an error of <10% in a wide range of atmospheric optical thickness (Gitelson et al., 2002):

$$VARI_{green} = \frac{\rho_{green} - \rho_{red}}{\rho_{green} + \rho_{red} - \rho_{blue}} \quad (13)$$

The generic normalized difference vegetation index (NDVI) may be not be adequate for assessing crop vegetation due to confounding soil background effects in imagery and indices such as the *soil-adjusted vegetation index* was suggested (SAVI; Huete, 1988), *optimized soil-digital adjusted vegetation index* (OSAVI; Rondeaux et al., 1996), and *transformed soil-adjusted vegetation index* (TSAVI; Baret et al., 1989). On the other hand, Gitelson et al. (1996) proposed use of the *green normalized difference vegetation index* (GNDVI) (where the

green band substituted for the red band in the NDVI equation), which may prove to be more useful for assessing canopy variation in green crop biomass.

$$GNDVI = \frac{(NIR - Green)}{(NIR + Green)} \quad (14)$$

$$TSAVI = a \left[\frac{NIR - (ax Red) - b}{Red + (ax NIR) - (ax b)} \right] \quad (15)$$

where the a and b values represent the slope and intercept, respectively, of an equation fitted through a plot of red vs. NIR reflectance data for a variety of bare soil conditions (dry, wet, smooth, and rough).

Red edge

The abrupt change in the 680–800 nm region of reflectance spectra of leaves caused by the combined effects of strong chlorophyll absorption and leaf internal scattering is called the *red edge*. The *red edge position* (REP) is the point of maximum slope on a vegetation reflectance spectrum between the red and near-IR wavelengths. The red edge was first described by Collins (1978). The REP is highly correlated with foliar chlorophyll content and can be a sensitive indicator of vegetation stress.

A linear method proposed by Clevers (1994) can be used to compute the REP that makes use of four narrow bands and is computed as:

$$REP = 700 + 40 \left[\frac{\rho_{(red_edge)} - \rho_{(700\text{nm})}}{\rho_{(740\text{nm})} + \rho_{(700\text{nm})}} \right] \quad (16)$$

where

$$\rho(red_edge) = \frac{\rho_{670\text{nm}} + \rho_{780\text{nm}}}{2} \quad (17)$$

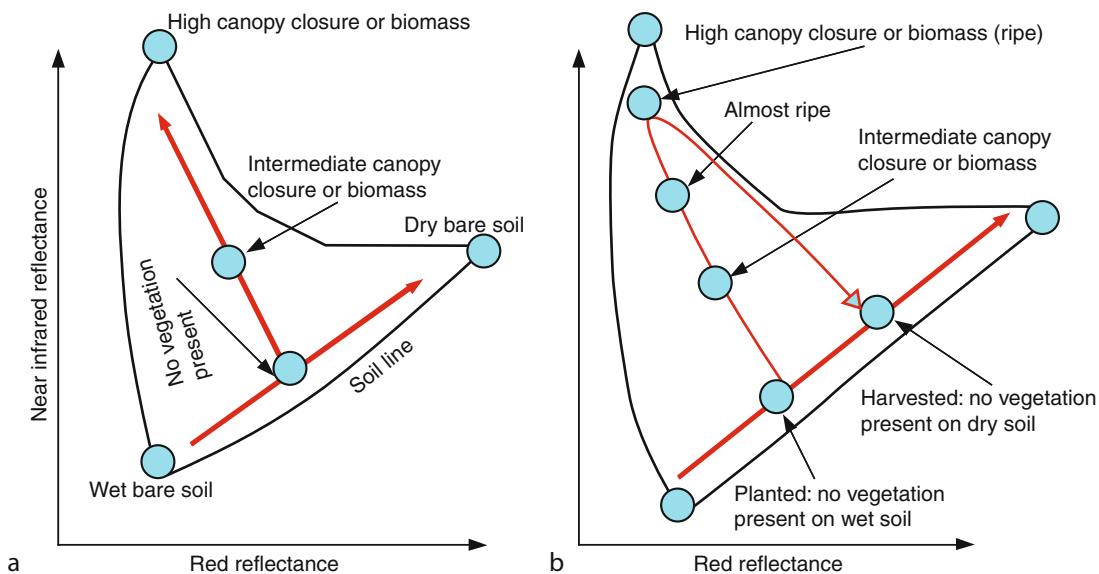

The red-infrared triangle (vegetation boater)

If we plot the red against the near-infrared reflectance for an entire image, we generally see a triangular shaped distribution as shown in Figure 4. The soil line represents areas on the ground that do not have significant vegetation cover but vary in reflectance based upon whether the soil is wet or dry. Areas where vegetation is present will be found somewhere above the soil line.

Pixels falling at the peak of the curve indicate the densest canopy, while pixels near the soil line indicate little to no vegetation. All areas between indicate a combination of soil and vegetation. Using a ratio such as this puts the data in a format that is easier to view and also removes factors that affect both bandwidths equally. Ideally the soil and vegetation in the index should be easily distinguishable.

Development of absorption and reflectance from active vegetation to senescence

Actively growing plants show a strong contrast between strong absorption in the red and high reflectance in the

Remote Sensing of Soils and Plants Imagery, Figure 4 (a) Distribution of reflectance values in a remote sensing image in the red and near-infrared regions of the electromagnetic spectrum is found inside the triangle. The greater the amount of photosynthetically active vegetation present, the greater the near-infrared reflectance and the lower the red reflectance. This condition moves a pixel's spectral location in a perpendicular direction away from the soil line. (b) The migration of a single vegetated agricultural pixel in red and near-infrared multispectral space during a growing season is shown. After the crop emerges, it departs from the soil line, eventually reaching complete canopy closure. After harvesting, the pixel will be found on the soil line, but perhaps in a drier soil condition. (Modified from Jensen, J. R., (2007) *Remote Sensing of the Environment: An Earth Resource Perspective*. New Jersey: Prentice-Hall, Figure 11.8 on p. 364.)

near-infrared regions of the spectrum. The amount of absorption in the red and reflectance in the near-infrared varies with both the type of vegetation and the vigor of the plants. Pigments such as chlorophyll and carotenes absorb light in particular wave length, causing an electron jump in the pigment molecular structures. The energy produced by de-excitation will be consumed for electrochemical reaction. The chlorophyll pigments absorb violet, blue, and red but green, so most vegetation has green appearance. The reflectance spectrum of green vegetation has maximum absorption at 420, 490, and 660 nm bands, all by chlorophyll. The natural change of a green leaf as it senesces is shown in Figure 5. We see that the healthy green leaf has very low reflectance values in the red (600–700 nm) due to chlorophyll absorption and very high reflectance values in the near-infrared (700–1,000 nm). However, as the plant begins to senesce, reflectance begins to decrease in the near-infrared and increase in the red regions. The electromagnetic absorption mechanism in the pigments of green vegetation is by atomic excitation (Ray, 1994; Jensen, 2007; Jensen, 2008).

In the period of senescence, faster degradation of chlorophylls compared to carotenes causes significant increase in the red wavelength due to the great decrease in the chlorophyll pigment density. In this case, carotenes absorb blue and reflect green and red, hence leaves will have yellow appearance. By death of brown pigments (tannins), leaf reflectance and transmittance in 400–700 nm decrease (Fourty et al., 1996); the decline in reflectance in the near-infrared is due to the spongy-mesophyll layer collapsing as the leaf comes under stress and the increase in reflectance in the red is caused by the die-off of chlorophyll and therefore a decrease in absorption. This

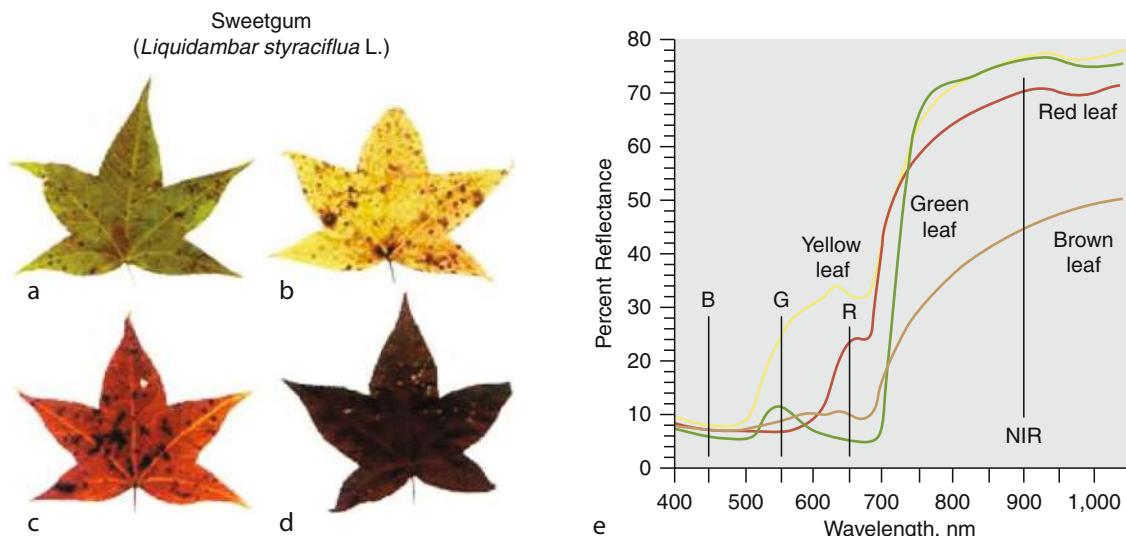

information can be used to evaluate vegetation type, condition, or density. One way of characterizing this relationship with a single variable is by dividing the near-infrared reflectance by the red reflectance (NIR/Red). The larger this ratio, the more photosynthetically active vegetation is present; the lower the ratio, the less photosynthetically active vegetation is present (Figure 5).

Remote sensing and grain yield

The goal of estimating green leaf or crop biomass has been to arrive eventually at some estimate of harvestable crop yield. Yield models that are related to remotely sensed data: reflectance-based and thermal-based models. Tucker et al. (1980) proposed a relationship between spectral reflectance and crop yield. This was similar to the approach suggested by Idso et al. (1978), Aase and Siddoway (1981), and Pinter et al. (1981). The general class of these models can be characterized as some form of a relationship between rate of change in the vegetation index (VI) and crop growth rate. The faster the rate of growth, the higher the harvestable crop yield.

Using a physiological approach, Hatfield (1983) developed a method using the maximum NIR/red ratio during the growing season as an indication of the maximum leaf area attained by the crop. He found that at 0.5 of the maximum ratio, 90% of the reproductive dry matter was attained. Spectral reflectance was coupled with thermal measurements as a combined approach to estimate stress and growth for both wheat and grain sorghum.

Idso et al. (1980) had found that grain yields in wheat were related to the rate of crop senescence. Recent observations by Shanahan et al. (2001) using TSAVI, NDVI, and a GNDVI, where the red reflectance is replaced by

Remote Sensing of Soils and Plants Imagery, Figure 5 (a) Healthy green sweet gum leaf obtained from a tree on November 11, 1998. (b–c) Senescing yellow and red sweet gum leaves obtained from the tree. (d) Senesced sweet gum leaf that was on the ground. (e) Reflectance measurements of the four leaves. (Jensen, J. R. (2007) *Remote Sensing of the Environment: An Earth Resource Perspective*. Prentice-Hall, New Jersey, Color Plate 11.1.)

green reflectance, showed a slight improvement in yield estimates for four corn hybrids grown with varying nitrogen and water levels. Usually, NDVI is useful as a tool for estimating net primary production over various biomes (Huete and Liu, 1994), but has a number of deficiencies. GNDVI acquired during midgrain filling could be used to produce relative yield maps depicting spatial variability in fields, offering a potentially attractive alternative to use of a combine yield monitor (Shanahan et al., 2001). Eldaw Elwadie et al. (2005) find that corn grain yield was strongly related to canopy reflectance for either individual wavelengths or for SVIs (spectral vegetation index), reaching an optimum ($R^2 > 0.9$) at R5 dent stage. Green reflectance based on simple ratio (green simple ratio index, GSRI) had the highest R^2 , lowest RMSE, and most consistent slope and intercept. In contrast, LAI was best predicted by NDVI (RMSE = 0.426) while GNDVI performed poorly (RMSE = 0.604).

Radar remote sensing for estimation of surface soil moisture at the watershed scale

A great deal of progress has been made in the use of spectral images from satellite sensors for surface soil moisture mapping, where surface soil moisture (SM) is the average moisture ($\text{cm}^3 \text{ cm}^{-3}$) in the top few centimeters of soil over a heterogeneous volume (Moran et al., 2004). The greatest progress has been made with passive microwave sensors. These sensors measure the intensity of microwave emission (at wavelengths $1=1 - 30 \text{ cm}$) from the soil, which is related to its moisture content because of the large differences in dielectric constant of dry soil (~ 3.5) and water (~ 80). This emission is proportional to the product of surface temperature and surface emissivity, which is commonly referred to as the microwave brightness temperature (BT). The relation between BT and SM varies with differences in surface roughness and vegetation biomass and is further affected by the changes in dielectric constant related to soil texture. The efficacy of the measurement is a function of wavelength, where longer wavelengths ($1 > 10 \text{ cm}$) probe deeper into the soil and have the ability to penetrate a vegetated canopy.

Moran et al. (1994) also developed the water deficit index (WDI), utilizing surface minus air temperatures and a spectral vegetation index to estimate the relative soil moistures. The WDI takes into account surface temperature variations resulting from plant water stress in partial canopies.

Remote sensing and precision farming

Precision farming is an integrated agricultural management system incorporating several technologies. The technological tools often include the *global positioning system*, *geographical information system*, *yield monitor*, *variable rate technology*, and *remote sensing*. Remote sensing provides practical insights into crop growth and vigor, stress presence, and moisture status. Crop growth and vigor determining plant "greenness" or nitrogen

content, plant cell density and biomass, and seedling emergence. Hyperspectral analysis has the ability of improving best practices in the field of precision farming. This technique allows the characterization of agri-environmental indicators and notably the estimation of certain terms of the nitrogen balance through the study of the soil organic matter content and the chlorophyll content in plants. These two parameters, linked to the soil nitrogen concentration, intervene in the plant answer to fertilizer applications and are essential in the establishment of the nitrogen balance within the framework of precision farming. Stress presence is useful to identify disease or weed effects. Moisture status is useful for irrigation scheduling. Remote sensing fits neatly within a management system that utilizes precision farming technologies (Moran et al., 1997).

Remote sensing's functional role in studies of land-use/land-cover change

The problem of identifying the causes and consequences of land-use/land-cover change requires that the functional aspects of ecosystems be examined (Golubiewski et al., 2007). This involves the incorporation of land-use change into models that can couple land use with biogeochemical, biophysical, and atmospheric dynamics. New techniques in quantitative data retrieval allow the application of remote sensing to expand from a role of mostly spatial description to one where functional relationships can be examined. The basic concept is to use the structural attributes that can be pulled from satellite imagery to relate directly to functional variables. These ecological variables can then be incorporated into models instead of literature values in order to make more realistic assessments of linkages between changes in canopy structure and biogeochemical processes (Golubiewski et al., 2007).

Use of remote sensing for detecting weeds and stress

Remote sensing techniques offer the advantage of rapid acquisition of data with generally short turnaround time and considerably less cost. Everitt et al., 1995 used remote sensing techniques to detect leafy spurge in an active phenological stage, which had higher visible (0.63- to 0.69- μm) reflectance than several associated plant species. Quantitative data obtained from digitized video images showed that leafy spurge had statistically different digital values from those of associated vegetation and soil.

Alterations in the chlorophyll absorption feature are also indicative of phenological and stress-induced changes in chlorophyll activity. Research suggests that other canopy biochemical constituents, such as cellulose and lignin, influence reflectance in the shortwave infrared and can potentially be quantified using imaging spectrometry. Capability to estimate biochemical properties in terrestrial ecosystems would aid in the assessment of carbon fixation/allocation patterns, metabolic processes,

and nutrient availability altered by a changing environment (Wessman, 2003).

Predictive soil mapping

All approaches to soil mapping rest on our ability to use knowledge of the process of soil genesis to predict the properties of soils at any point in the landscape. Predictive soil mapping (PSM) can be defined as the development of a numerical or statistical model of the relationship among environmental variables and soil properties, which is then applied to a geographic database to create a predictive map. PSM is made possible by geocomputational technologies developed over the past few decades. For example, advances in geographic information science, digital terrain modeling, remote sensing, and fuzzy logic have created a tremendous potential for improvement in the way that soil maps are produced. PSM research is being driven by a need to understand the role soil plays in the biophysical and biogeochemical functioning of the planet. (Scull et al., 2003).

Identification of soil heterogeneity

- (a) Combining ground measurements of morphological crop parameters collected from representative soil sites with multispectral information at visible, infrared, and thermal wavebands recorded from the airborne scanner Daedalus AADS 1268 using bioindicative transfer functions, based on cause and effect relationships of the soil–plant system, enabled the spatial detection and the quantification of soil properties. The available water capacity of the rooting zone accounted predominantly for the heterogeneity of crop stands and yield formation of winter wheat. The thermal emission and its relationship to the transpiration of crops was recognized as most suitable to detect quantitatively soil properties via crop stand conditions of winter wheat. Soil maps derived from remote sensing and bioindicative transfer functions explained the pattern of nitrogen uptake and yield information (Seliger and Schmidhalter, 2006).
- (b) Soil erosion, an important soil degradation process, can influence soil spectra. Soil erosion influences indirectly by influencing soil surface roughness and iron content in top soils. So the more is the erosion, the more will be soil reflectance in the longer wavelength of visible and NIR regions (Latz et al., 1984). Direct spectral measures indicative of soil erosion include changes in organic matter content, mineral composition, albedo, roughness, and soil structure (Mulders, 1987; Irons et al., 1989).
- (c) Ground radar can be used in combination with remote sensing, to detect changes of diagnostic soil horizons such as albic, spodic, and argillic horizons or soil/rock boundaries. Limitations with ground radar include soils with high salt content/clay/silt/moisture amounts. <http://www.ucalgary.ca/geog/Virtual/Remote%20Sensing/rssoils.html>.

Predicting types of soil processes from remote sensing data

Predicting the types of soil processes and their rates from remote sensing data will depend on strong correlations between canopy variables and the process of interest (Wessman, 2003). Soil plays an integral role in almost all remote observations of the land surface either because the vegetation cover is discontinuous or because multiple scattering of the radiation occurs between vegetation and the underlying soil surface. However, since vegetation covers most of the land surface, plant canopy can be considered as a primary interface to soil processes. In many ways, the canopy is an integrated expression of (and is mutually linked to) below-ground processes and can, as such, be used to infer ecosystem properties. Classifications of satellite imagery into vegetation communities in which soil processes have been characterized can be used to extrapolate those processes across the landscape based on the areal extent of the associated cover type. Ratios of reflectance values measured in the region of chlorophyll absorption to those in the highly reflected near-infrared region are sensitive to biomass quantity and, when integrated over time, strongly correlate with primary productivity. High spectral resolution measurements of the absorption characteristics of major foliar chemical constituents may permit assessment of canopy-level concentrations and related processes such as decomposition and nitrogen mineralization (Wessman, 2003).

Remote sensing for salinity studies

Remote sensing was extensively used for salinity studies in many parts of the world. Several remote sensing studies used MMS and TM and SPOT data for salinity studies (Szilágyi and Baumgardner, 1991; Dwivedi, 1992; Dwivedi and Rao, 1992). It has been found that saline soils give lower reflectance than non-saline throughout the range between 0.5 and 2.38 μm (Baumgardner et al., 1985). In the case of salt-affected soils, the white crust that forms on the surface tends to have higher reflectance in the visible and near-infrared part of the spectrum (Barnes et al., 2003).

Dutkiewicz et al. (2009) used hyperspectral images from three sensors (Airborne HyMap, satellite Hyperion imagery and airborne Compact Airborne Spectrographic Imager (CASI) imagery) to discriminate and map selected symptoms of salinity in a dry-land agricultural area in southern Australia. The evaluation of imagery included comparisons of spectral resolution, spectral range, spatial resolution, and landscape seasonality. Salinity symptoms were also characterized using field spectra collected with an ASD FieldSpecPro spectrometer. Saltpans were discriminated using the gypsum 1,750 nm absorption feature, whereas full-wavelength image spectra were necessary to map the halophytic plants. HyMap imagery produced the most accurate maps of samphire and saltpans, identifying substantial saline areas covered with samphire that had not been delineated in previous aerial photo-interpretation.

Salama et al., 1997 used combination of vegetation, soils, and geology from remote sensing imagery with digital elevation models to classify catchments to hydrogeomorphic units, which recognize and classify salinity hazard zones.

Outlook

With increasing population pressure throughout the world and the need for increased agricultural production there is a critical need for improved management of the world's agricultural resources which is the most important renewable, dynamic natural resources. Comprehensive, reliable and timely information on the quality, quantity and location of these resources must be acquired at the required frequency. Remote Sensing technology has been and will continue to be the best system for acquiring and generating agricultural and resources data. This is mainly due to easy data acquisition over inaccessible areas at different scales and resolutions and acquired data are analyzed in the laboratory, thus reducing the amount of fieldwork. One of the most successful applications of multispectral space imagery is monitoring the state of the world's agricultural production including detection, identification, measurement and monitoring of agricultural phenomena including crop identification, acreage, vigor, density, maturity, growth rates and yield forecasting as well as plant health, insect and disease infestation. Remote sensing is also used for land surveys including mapping of soil physical properties, soil types, fertility, toxicity, moisture content, and erosion and for irrigation requirements, water quality, water availability, and plant drought stress.

The science of remote sensing is rapidly developing and new areas are continuously emerging which makes it the most important and indispensable tool in monitoring all routine agricultural activities.

RHEOLOGY IN AGRICULTURAL PRODUCTS AND FOODS

Jiří Blahovec
 Department of Physics, Czech University of Life Sciences, Prague 6-Suchdol, Czech Republic

Synonyms

Deformation in agricultural products and foods; Flowing in agricultural products and foods

Definition

Rheology is the part of science dealing with the flow of matter; mainly liquids but also soft solids or solids in states where they flow rather than deform elastically. It applies to substance aggregates of different properties (see [Agrophysical Objects \(Soils, Plants, Agricultural Products, and Foods\)](#)), including biological materials (see [Physical Properties of Raw Materials and Agricultural Products](#)). Complex materials of this type cannot be characterized by a single parameter like viscosity – in fact viscosity changes due to other factors. The experimental characterization of the rheological properties of a material is termed “rheometry.”

Shortly speaking, rheology is an extension of the “classical” disciplines of elasticity and (Newtonian) fluid mechanics (see [Stress–Strain Relations](#)) to materials whose mechanical behavior cannot be described by the classical theories.

Continuum Mechanics	Solid Mechanics	Elasticity	Rheology
	Viscoelasticity	Non-Newtonian Fluids	
Fluid mechanics		Newtonian Fluids	

One of the tasks of rheology is to empirically establish the relationships between deformations and stresses (*Stress–Strain Relations*), and their derivatives by adequate measurements. These experimental techniques are concerned with the determination of well-defined rheological material functions. Such relationships are then amenable to mathematical treatment by the established methods of continuum mechanics.

Introduction

Agricultural products and foods (see [Agrophysical Properties and Processes](#)) belong to a wide group of non-crystalline substances that can be included in the so-called “soft matter” (Jones, 2002) characterized by weak interaction between structural units, large thermal fluctuations, large numbers of internal degrees of freedom, macroscopic softness indicative of a weak modulus of elasticity, and sensitivity of their phase diagrams to external constraints. The physical properties are strongly dependent on temperature and pressure. Matter stability plays an important role in the multi-phase state.

Processed foods represent a typical example of soft matter of biological origin (see [Thermal Technologies in Food Processing](#)). Agricultural products before processing (see [Quality of Agricultural Products in Relation to Physical Conditions](#)) contain information on their biological content, mainly on structural character (organs, tissues, and cells). The cellular structure is a source of the special mechanical properties of the agricultural products. The soft matter can be divided into two groups: quasi-liquids described by means of liquid rheology, including the rheology of non-Newtonian liquids (not given here, for details see Steffe (1996), Steffe and Daubert (2006)), and quasi-solids described by theories and models presented here.

The real quasi-solid represents mixing of elastic (solid) and inelastic (fluid) properties. Crude assessment of participation of both properties in the resulting properties of a real product leads to determination of the degree of elasticity (DE) and/or hysteresis losses (HL) in a loading/unloading test or analysis of the corresponding tests: by stress relaxation, or in creep test. Results of the tests depend on many test parameters like temperature, strain rate, and type and level of deformation.

The first attempts to describe real rheological, i.e., inelastic, behavior of quasi-solid matter in macroscopic deformation tests were based on simple models combining serial (Maxwellian) and parallel (Kelvinian)

connection of ideal elastic and viscous elements. The rheological models of this type were not able to describe all details of deformation in real materials for which special functions (relaxation and creep) were developed. Their application to low level deformations of bodies is termed (linear) viscoelasticity. The deformation behavior is strongly influenced by strain rate-temperature scenario that can be unified in a complex theory. Temperature influences also the state of the deformed matter being the basis for the so-called thermomechanical analysis. Information on the polymer rheology is given by Ward (1983) and Ferry (1980).

Irreversibility in deformation of quasi-solid materials

The viscous-like processes represent irreversible part of the whole deformation process. They can be assessed using results of special tests (loading/unloading t., stress relaxation t., and creep t.).

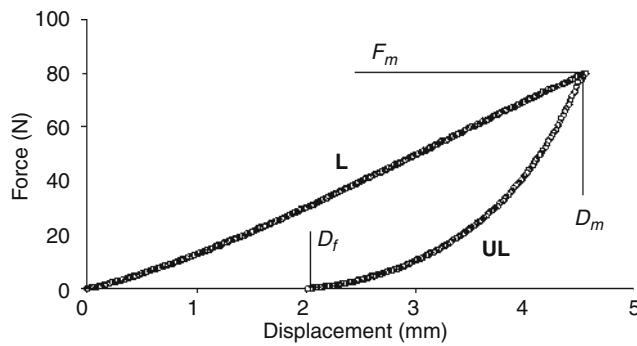

Loading/Unloading test

The loading/unloading test is presented by a Force–Displacement plot in Figure 1. From the figure it is clear that after reaching a displacement 4.55 mm, the compression loading was reversed and two branches of the test were obtained: the loading branch (L) and the unloading branch (UL). The participation of the irreversible inelastic deformation can be assessed by two ways (Blahovec, 2008) in this case.

Using characteristic deformations the “degree of elasticity” (DE) can be calculated as follows:

$$DE = 1 - \frac{D_f}{D_m} \quad (1)$$

where D_m is the maximum displacement (i.e., the displacement corresponding to the reversion of loading) and D_f

Rheology in Agricultural Products and Foods, Figure 1 Force-displacement curve in Loading/Unloading test. L denotes loading part, UL is unloading part, D_m is maximum displacement, D_f final displacement. Result of deformation of potato specimen in compression. Maximum displacement 4.55 mm, maximum force 80.08 N.

final (resulting) permanent displacement. Degree of elasticity varies between 0 ($D_f = D_m$) and 1 ($D_f = 0$). In our case (Figure 1) $DE \approx 0.553$.

The “hysteresis loss” (HL) is based on deformation work during loading (W_L) and unloading (W_{UL}). The deformation work is proportional to the area between the corresponding curve and the displacement axis. The area of the loop between L and UL curves represents the energy dissipated during the whole process. The hysteresis loss is expressed by its relative value as follows:

$$HL = \frac{W_L - W_{UL}}{W_L} = 1 - \frac{W_{UL}}{W_L} = 1 - \frac{\frac{D_m}{D_f} \int_0^{D_m} F_{UL} dD}{\int_0^{D_m} F_L dD} \quad (2)$$

where F_L denotes the loading force and F_{UL} the unloading force. The hysteresis loss varies between 1 for $W_{UL} = 0$ (inelastic, i.e., plastic deformation) and 0 for $W_{UL} = W_L$ (elastic deformation). In our case (Figure 1), $HL \approx 0.640$.

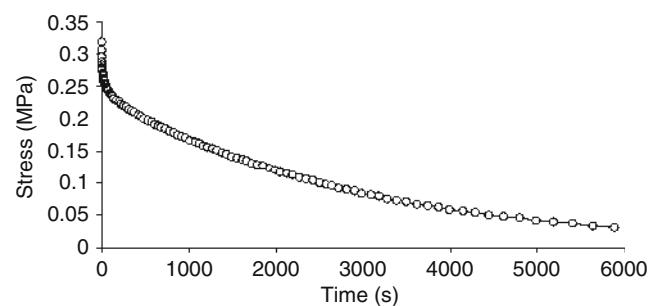

Stress relaxation

The stress relaxation test consists of a quick pre-strain that is followed by the proper relaxation step during which the strain is kept at constant value. The internal stresses in the tested specimen relax in this step and the stage is characterized by the falling down of the external stress value (see Figure 2). More detailed analysis of the individual stages is obtained by a slope analysis of the relaxation curve, calculating the so-called source f -function:

$$f = -\frac{d\sigma}{dt} \quad (3)$$

where σ is the stress. The source f -function serves to calculate of the activation volume v :

$$v = k_B T \frac{d \ln f}{d \sigma} \quad (4)$$

Rheology in Agricultural Products and Foods, Figure 2 Stress relaxation curve obtained at potato cylindrical specimen (diameter 15 mm, height 20 mm) deformed in compression (pre-strain 10%), time of relaxation 100 min.

where k_B is Boltzmann constant and T absolute temperature. For more information on this problem see Blahovec (2002).

In an elastic body, the stress is constant during the stress relaxation test so that the source f -function is constant and the activation volume v is constant, too. It means that the increasing values of the source f -function and the activation volume as well, indicate increasing participation of the inelastic deformations in the tested specimen.

Creep test

The creep test aims in the detection of inelastic deformation in the tested specimen at its constant loading in longer time interval (see, e.g., Ward 1983).

Rheological models

The simplest way in rheological models is based on models with springs and dampers. The springs are characterized by spring constants (elasticity modulus E) whereas the dampers are characterized by their viscosities (η). The serial connection of a spring and of a dumper represents the Maxwell's model, suitable for the description of stress relaxation in a body, i.e., time development of the stress (σ) in the body at constant strain ε_0 . This process is described by a simple differential equation:

$$\frac{d\varepsilon}{dt} = \frac{1}{E} \frac{d\sigma}{dt} + \frac{\sigma}{\eta} \quad (5a)$$

with solution:

$$\sigma = \sigma_0 e^{-\frac{Et}{\eta}} = \sigma_0 e^{-\frac{t}{T_{rel}}} \quad (5b)$$

where $\sigma_0 = E/\varepsilon_0$ is the initial stress and $T_{rel} = \eta/E$ is the relaxation time.

The parallel connection of a spring and a dumper represents the Kelvin's body that is suitable for description of creep. The creep determines the increase of strain (ε) during specimen constant loading by stress σ_0 as follows:

$$\varepsilon = \varepsilon_0 e^{-\frac{Et}{\eta}} = \varepsilon_0 e^{-\frac{t}{T_{ret}}} \quad (6)$$

where $\varepsilon_0 = \sigma_0/E$ is the initial strain and $T_{ret} = \eta/E$ retardation time. Equations 5b and 6 show that the exponential functions describe the development of the simple stress relaxation and creep processes.

The parallel connection of different Maxwell's models (of different parameters E_i and η_i) is termed Generalized Maxwell's model with the following expression for stress:

$$\sigma = \sum_{i=1}^n \left(\sigma_{0i} e^{-\frac{t}{T_i}} \right) \quad (7a)$$

where $\sigma_{0i} = E_i/\varepsilon_0$ and $T_i = \eta_i/E_i$. For $i=2$ and $\eta_2 \rightarrow \infty$ the model is termed standard linear body. The serial connection of different Kelvin's models (of different parameters E_i and η_i) is termed Generalized Kelvin's model with the following expression for strain:

$$\varepsilon = \sum_{i=1}^n \left(\varepsilon_{0i} e^{-\frac{t}{T_i}} \right) \quad (7b)$$

where $\varepsilon_{0i} = \sigma_0/E_i$ and $T_i = \eta_i/E_i$. The serial connection of a Maxwell's and a Kelvin's model is termed Burgers' model. More information on rheological models can be found in Gross (1953).

The rheological models were used for description rheology of agricultural materials mainly in 1950s and 1960s and they are widely described by Mohsenin (1986).

Rheological functions

Rheological functions are easily applicable to stress relaxation and creep of the viscoelastic bodies (Ferry, 1980; Ward, 1983). They are based on time dependent modulus of elasticity in tension $E(t)$ or in shear $G(t)$, so-called relaxation functions, or the corresponding time dependent creep compliances $D(t)$ and $J(t)$. The sense of the rheological functions is given by their application in the calculation of the strain and the stress (Ferry, 1980):

$$\varepsilon(t) = \int_{-\infty}^t D(t-\tau) \frac{d\sigma(\tau)}{d\tau} d\tau \quad (8a)$$

$$\sigma(t) = \int_{-\infty}^t E(t-\tau) \frac{d\varepsilon(\tau)}{d\tau} d\tau \quad (8b)$$

The shapes of rheological functions are sensitively dependent on deformation temperature and deformation rate. In some special cases, like at some polymers, it is possible to find some unifying principle for rheological functions determined at different conditions. The concept of rheological functions can be extended to the study of dynamic loading either by the initial harmonic periodic strain (ε) or by the initial harmonic periodic stress (σ). Both strain and stress are understood as complex functions as well as the rheological functions $E(\omega)$, $D(\omega)$, $G(\omega)$, $J(\omega)$, where the bold symbol denotes complex character of the function and ω angular frequency of the loading. In the frame of linear viscoelasticity, the rheological functions are interdependent as follows:

$$\begin{aligned} D(\omega)E(\omega) &= 1 \\ J(\omega)G(\omega) &= 1 \end{aligned} \quad (8c)$$

The rheological functions can be analyzed using spectral analysis of the relaxation and retardation times (Ferry, 1980).

The usual way of unifying the rheological functions is by using a "master curve" at reference temperature T_0 that is built using Williams-Landel-Ferry (WLF) transformation of data obtained at different temperatures. Two steps are used in this process:

- The time is multiplied by time-factor a_T :

$$a_T = \exp\left(\frac{-C_1(T - T_0)}{C_2 + T - T_0}\right) \quad (9a)$$

- The following parameter is defined:

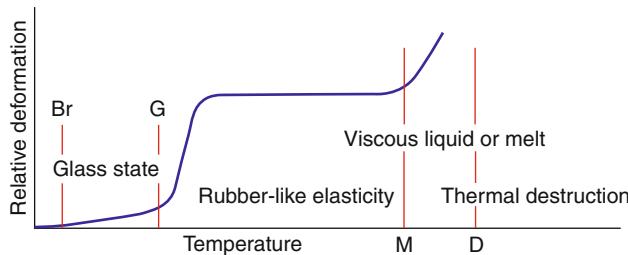

$$x(T, T_0) = \frac{T_0 \rho_0}{T \rho} \quad (9b)$$

where T and ρ are the experimental absolute temperature and density, respectively, and T_0 and ρ_0 are the same quantities at the reference state. The transformed rheological function is either multiplied by the factor $x(T, T_0)$ in the case of the functions E , G , their complex parts and the corresponding spectral functions or divided by the factor in all other cases.

Thermomechanics of biopolymers

(See also Tolstoguzov, 2000)

Quasi-solids of agricultural products and their ingredients are in different physical states: amorphous (liquid, rubber-like, solid) and crystalline. Whereas in crystalline solids the solid state is changed at the melting point into the liquid state, in amorphous solids the change from solid to liquid state is more complicated (Jones, 2002) and a new change, termed glass transition (T_g), is observed (Wunderlich, 2005). A typical temperature plot of the deformation of an amorphous polymeric material is given in Figure 3. The arbitrary temperature scale in Figure 3 is strain rate dependent: when strain rate increases, the

Rheology in Agricultural Products and Foods,

Figure 3 Thermomechanical curve of the amorphous polymeric material at the same stress plotted versus temperature. The temperature scale depends on deformation rate: at higher deformation rates the temperature scale is shifted to higher temperatures (Jones, 2002). At lowest temperatures the material is brittle; at brittle transition (Br) is changed into the brittle state changing at glass transition (G) into rubbery state characterized by relatively high but temperature sensitive deformation. M denotes melting of the polymer with transition to the viscous and/or viscoelastic state with temperature sensitive flow. In some cases the temperature corresponding to thermal destruction (D) can be observed.

temperature scale with the characteristic points is shifted to higher temperatures and vice versa (see *Rheology in Agricultural Products and Foods* and *Rheology in Soils*). The flow is temperature sensitive mainly in glassy and viscous states.

Therefore, the states of matter are distinguished by the energy ratio between the thermal movement and the intermolecular interaction, and by the mutual arrangement of individual macromolecules relative to one another (Strick et al. 2003). In the solid state, the energy of intermolecular interaction exceeds the energy of thermal motion, while in the liquid state, these values are comparable and macromolecules are in thermal motion. Accordingly, in the absence of external forces a solid body has a preferred shape, while a liquid has a definite volume but not shape. The liquid state is characterized by a relative molecular disorder. An external force, e.g., the weight of a liquid, directs the molecular movement. This corresponds to flow, i.e., an irreversible deformation of the liquid. Due to its extremely high viscosity, a glassy system behaves like a solid, and has both a definite shape and a definite volume. An amorphous glassy system exhibits the mechanical properties of a solid material and a structural arrangement typical for liquids. This reflects an increase in inter- and intramolecular interactions and a loss of molecular mobility (Rubinstein and Colby, 2003).

The glassy state of a macromolecular system only requires a mutual fixation of a certain proportion of the chain segments. The higher the rigidity of the chains, the lower the number of the chain segments which has to be fixed during change to glassy state. Mechanical stress can help to re-activate the motion of the fixed segments and makes possible longer deformation of glassy material. The stress necessary for this effect can reach the strength of the material as the temperature decreases from the glass transition to the temperatures of brittleness (crispness – see also *Physical Properties as Indicators of Food Quality*). The glassy state of a loaded viscoelastic system results in an accumulation of mechanical energy, which can be released above the glass transition temperature due to heating and/or addition of a plasticizer.

Unlike the amorphous state, the crystalline state is very rigid. The rate of crystallization (nucleation and crystal growth) increases as the temperature approaches the melting temperature (T_m). Since the probability of crystallization increases with time, crystallization can be avoided by cooling of a macromolecular liquid rapidly to below the melting point, where this liquid becomes super-cooled. On further cooling this liquid changes to glassy state, i.e., is converted into a solid-like system at around T_g . In the vicinity of T_g , the system's viscosity greatly rises with a decrease in temperature. Formation of a glass is accompanied by a gradual change in temperature dependencies of the mechanical properties, specific volume, and heat capacity. Normally, the specific heat capacity of a glass is close to that of the crystal, i.e., well below that of the liquid. The absolute values of the changes in thermodynamic

variables are quite comparable to those of crystallization/melting. Accordingly, T_g in both polymers and food systems can be measured by various techniques termed thermal analysis (Haines, 2002). The glass transition is a kinetically controlled structure formation process. Unlike T_m , which is well defined by an abrupt change in the temperature dependence of thermodynamic variables, the glass transition usually covers quite a wide region (up to 10–30°C around T_g) on the temperature scale. The size of this region depends on the rate of cooling/heating and loading.

Molecular parameters influencing T_g and T_m are chain stiffness, intermolecular interactions, and molecular weight. Other factors are the presence of other macromolecules, water, and other plasticizers. These parameters simultaneously and differently affect both T_g and T_m values. Figure 3 schematically shows a thermomechanical curve typical of both low moisture food systems and polymer materials. The thermomechanical curve characterizes a change in deformability of a material during heating at a constant rate (Jones, 2002). It presents the relative deformation-temperature (D-T) dependence at a constant value of periodically applied stress and constant loading-unloading times. The thermomechanical curve shows that during heating the deformability of a glassy material is greatly increased in the vicinity of T_g and T_m . These two jumps in deformability correspond to the transitions from the solid glassy state to the rubber-like elastic state at T_g and then to the viscous liquid state at T_m . Above T_g deformability increases (i.e., the elastic modulus sharply drops), becomes nearly constant and reversible, i.e., forms a so-called “rubbery plateau.” Deformability change with temperature is relatively small between the two transition temperatures, T_g and T_m , and below T_g . Both changes are reversible. Upon cooling, the viscoelastic melt and the rubber-like system are again glassy. Above T_m the deformation is partly irreversible. Figure 3 presents three sub-states of the amorphous solid state distinguishable on a temperature scale. These sub-states represent brittle, non-brittle glassy, and rubber-like materials. Many food systems can exist in each of these sub-states of matter. It should be noted the term “rubbery-like,” which is widely used in food science, is quite arbitrary.

The dynamics of polymer chains is different above, below and in the vicinity of T_g . The glass transition can be determined as the temperature range at which segment motion of macromolecules becomes thermally activated. The physical cross-links are labile above T_g and “frozen” below T_g . The cross-linking density decreases the distance between the cross-links. Movement of more flexible chains leads to a denser packaging of macromolecules in the glassy state.

We can distinguish materials with rigid (a) and flexible (b) macromolecular chains. Normally, biopolymer chains are rigid due to large side groups, high degree of conformation and presence of groups forming hydrogen bonds, i.e., strong inter- and intramolecular attractive forces. An increase in intermolecular attractive forces, i.e., in the

cohesive energy density, reduces chain flexibility and increases the T_g . Usually biopolymers exhibit high T_g values and form rigid dry materials, which are more similar to plastics than rubbers. Some biopolymers are more flexible and this property leads to higher deformability in rubbery and melted states.

Plasticizers and water

Water is the main solvent and plasticizer in biological and food systems (Jones, 2002). The effect of a plasticizer consists in decreasing the critical transitions temperatures T_g and T_m and increasing the deformability of the basic polymer above the glass transition temperatures. Addition of a plasticizer to a rigid chain material can transform the system to a highly viscous liquid or a rubber-like solid. The absence of rubber-like elasticity is typical for highly rigid macromolecules. A plasticizer decreases and brings closer both T_g and T_m , and reduces the viscosity and the elastic modulus of the system.

Plasticization is due to several factors. The first is an affinity of the plasticizer, water, to the macromolecular compound, and its interactions with charged and polar groups. The second factor is an increase in the distance between macromolecules (see *Shrinkage and Swelling Phenomena in Agricultural Products*) and a decrease in intermolecular interaction due to dilution with water. These plasticizing mechanisms, together with factors such as the lowest molecular weight of water, its low density, high dielectric constant, highly pronounced ability of forming H-bonds, and low T_g (see *Water in Forming Agricultural Products*), make water the most effective plasticizer for macromolecular structures of biological origin (see *Water Effects on Physical Properties of Raw Materials and Foods*) and the best solvent for polar and charged biopolymers. Relatively small amount of adsorbed water, which is not available as a solvent, is the most efficient plasticizer. Molecular mobility of a plasticizer usually results in its loss, by either evaporation or extraction by the medium (see *Drying of Agricultural Products*).

Aggregated bio-materials

(See also Blahovec, 2007)

The most biological structures are aggregated structures in which the substances of different state participate one with another. This is typical also for the other structures based on structure units of complicated properties. Generally, we can wait that all the basic matter states could participate at the aggregate architecture that could be crudely described in the three state diagrams (see *Water in Forming Agricultural Products*) based on participation of dry matter, water, and air in the product.

The three state diagram describes all the possible participations of the basic state components in the material. We can speculate about the state property of the aggregate and we have to take into account the main properties laying in basis of the state classification of the aggregate: its compressibility and shape change ability.

Analysis of the properties of many cellular (Gibson and Ashby, 1988) and particular materials (see [Soil Aggregates, Structure, and Stability](#)) shows that participation of the basic state components in the volume of the aggregated material is not important for the resultant state character of the aggregate. The concentration of the gaseous components is usually meaningless for the gaseous character of the aggregate. The aggregates with high gas concentration are usually unstable in the gravitational field and they form the real gas-like aggregates only in the special cases in which the gaseous state is stabilized by motion of the gaseous component to overcome gravitational sedimentation due to different densities of different state components. This is very frequent in dusts, fogs, boils, droplets, etc. The aggregates of this type then can be classified really as fluids during the permanent stabilization process.

The solid-like aggregates and liquid-like aggregates are more stable than the aggregates previously described. Most of them are built on the solid and/or liquid basis like solutions, colloids, gels, suspensions, emulsions, etc. The most frequent are the multi-state aggregates with relatively big structural units being in contact at their external surfaces. When the contact forces between the structural units are low, e.g., of the frictional character, then the structural units are relatively free and movable one from the other, and we speak about particles forming the particular materials. The particular materials easily change their shape in flowing processes, classifying them as fluids even in cases in which the important part of the material volume is formed by solids (see [Aeration of Soils and Plants](#)). The sands are a good example of this kind of material (see [Soil Aggregates, Structure, and Stability](#)); in sands about half of their volume is occupied by stony particles and the other volume, the inter-particle spaces, is occupied either by water or by air. It is well known that sands are fluid-like despite the high content of solids.

In other aggregates, the contact forces among the structural units are high, i.e., they are formed by chemical bonds of the soft character at least, and the connections among the structural units cover a big part of their surface. We speak then about cellular structures that behave rather as solid materials even in cases where big amounts of the cellular volume is represented by fluids (Fung, 1993). We use this method to classify some agricultural aggregates. Soil (see [Soil Aggregates, Structure, and Stability](#)) is a material that can be classified in many cases as a particular one: really, sands and light not-compressed soils are easy movable. Other aggregates, in which the bonding forces among particles is high (e.g., clay), are classified as the cellular structure. It is clear that the final decision about the state character of soils depends mainly on the level of the cohesion forces rather than on the dry matter content. Water and air contents in wood are very variable but the state character of the wood is not changed by their ratio and the wood is classified as solid.

The relative independence of the aggregates of biological origin on the relative participation of substances of different state is clearly demonstrated by fruit or vegetable tissues. The moisture content (see [Water in Forming Agricultural Products; Fruits, Mechanical Properties and Bruise Susceptibility, Microstructure of Plant Tissue](#)) in many of those aggregates is higher than 90% but these aggregates behave as solids (see [Physical Properties of Raw Materials and Agricultural Products](#))! These rather surprising results are based on tough cellular walls connected one to another by many bonds of medium strength and filled by quasi-liquid sap of high turgor pressure (see [Microstructure of Plant Tissue](#)). The solid properties of the cellular aggregates are determined by the complex properties of the cellular walls.

Role of water in cellular structure

(See also [Water Effects on Physical Properties of Raw Materials and Foods](#))

Moisture content in every material is not an independent value; storing the material in a box with some definite air humidity results in moisture content changes depending on the difference between water activity in the material and humidity of the surrounding air (see [Adsorption Energy of Water on Biological Materials](#)). These changes are drying or adsorption depending on the water activity and humidity difference (see [Drying of Agricultural Products](#)). The final spontaneous end of the process is the equilibrium – the state in which the air relative humidity has the same value as the water activity of the material (Oertli, 1976). It means that there exists some equilibrium moisture content for a given temperature and water activity. The plot of the equilibrium moisture content (usually based on dry basis – see [Water in Forming Agricultural Products](#)) versus water activity (e.g., different air humidity) at the same temperature is termed sorption isotherm (see [Adsorption Energy of Water on Biological Materials](#)). In many cases the details of sorption isotherms depend on the procedure leading to its values (drying or adsorption – see [Drying of Agricultural Products](#)) forming the so-called sorption hysteresis ([Hysteresis in Foods](#)). Water activity is a very important parameter because its value predetermines the rate of many biochemical and biological processes in the materials including the rate of microbial growth (see [Adsorption Energy of Water on Biological Materials; Physical Phenomena and Properties Important for Storage of Agricultural Products](#)).

At the same moisture content water activity increases with increasing temperature.

In the cellular structures, water is adsorbed on solid surfaces, in pores and forms solute solutions (see [Shrinkage and Swelling Phenomena in Agricultural Products](#)). The part of water bound in cell solute solutions is a source of cell wall “turgor pressure” as a result of selective cell permeability for water and solutes.

Cellular rheology

(See also *Microstructure of Plant Tissue* and *Plant Biomechanics*)

A crucial role in cell rheology is played by cell walls (Boal, 2002). Cell walls are formed by many biopolymers (Heimburg, 2007). Water serves as a plasticizer also in this case and the strength of the cell walls materials increases with increasing moisture content significantly. This trend is typical also for cellular materials with moisture content below 10% w.b. at the beginning of the corresponding sorption isotherm. The cell wall materials that form substantial part of the cellular material at these conditions can be classified as brittle and water as a plasticizer only reduces the probability of the brittle fracture. At higher moisture contents, the water plays more complicated role that affects mainly cell wall properties. Removing of water from the tissue structure can lead to substantial increase of the yield strain (for apples in order of hundreds% - Lin and Pitt, 1986) and also stress. In wet conditions, the moisture content in cells increases causing an increase of the turgor pressure and then also of the modulus of elasticity.

Rheology of cellular materials can be then divided into three different regions:

1. *Rheology of turbid cellular materials (turgor pressure is higher than zero).* Water penetrates cell walls and causes an increase of the internal (turgor) pressure on the cellular walls and thus it acts as a source of the product toughness. This process is influenced by the cellular solutions and the solutes concentration in the solutions depending on the cell wall properties. There are important differences among different products. Sources of the differences should be found not only in the cellular walls but also in the concentrations and properties of the cellular solutions. The role of water as plasticizer is limited. The toughness of the structure decreases with decreasing turgor pressure but the yield stress increases at the same conditions. The region in plants is well limited by the point of wilting at water potential approximately -1.5 MPa (Richter, 1976). The turbid state is typical for soft fruits and vegetables, with bigger cells and thin cell walls (Fung, 1993). Flowing of the materials included into this region increases with increasing level of loading (Blahovec, 2007).
2. *Rheology of flaccid cellular materials.* Turgor pressure does not play the previous most important role (there is zero in the basic state) but the yield stress increases with decreasing water activity as a result of the formation of the nonzero intercellular stress due to deformation. Water plays its role of the polymer plasticizer. The lower water potential, the lower the moisture content and then the yield point and the strength points are higher (Lin and Pitt, 1986). This group is formed by very wide spectrum of materials starting with soft flaccid products like wilted vegetable and fruits or soft animal organs and finishing with products like moist wood or moist cereals. Flowing in this group is very

variable and depends on the type of material, temperature, strain rate, and plasticizing in a similar way as it was described in thermomechanics of biopolymers.

3. *Rheology of cellular structure in brittle state.* At moisture content lower than 10%, water in the cellular structure is close to monomolecular state of water (Van den Berg and Bruin, 1981; Blahovec, 2007). Water plays its role of the polymer plasticizer. In this state, crack formation is so frequent that this process is an important source of strength decrease with decreasing moisture content. The brittle state in cellular structures does not differ from the same state of the other polymeric materials. All dry or dried products are included into this group, moreover all brittle components, like bones or shells, are included. Flowing of the materials of this group is observed sporadically.

Conclusion

Agricultural products and foods form very wide spectrum of materials with properties that vary with temperature and strain rate. At low temperatures and high deformation rates, the products are deformed as brittle solids. With increasing temperature, the deformability of the products increases but the changes are rather of step-wise character with characteristic temperatures. The first step is the glassing state with permanent increase of deformability with increasing temperature. At glass transition temperature, the state of the crucial components of the product is changed substantially and deformability strongly increases. In the rubbery state the deformability is approximately constant. This state is finished by “melting” of the crucial components and entrance of the system in the viscoelastic state, the state with typical flowing of the crucial components. The temperature scenario finishes by thermal destruction of the product.

In agricultural products, a big role in their rheology is usually played by the cell walls. Water plays two roles in the materials of this type (cellular), the first one is the traditional role of plasticizer in the cell wall system, and the second is its participation in forming the turgor pressure inside the cells due to cell walls with selective permeability.

There are two ways for the description of the rheological properties of the agricultural products. The first one is a macroscopic phenomenology, which is based on rheological functions that copy changes in the structural character of the products (different states) respecting temperature, strain rate, and water content and further additives. The second one is based on a deeper understanding of the microscopic processes, which control flowing at different conditions.

RHEOLOGY IN SOILS

Wibke Markgraf

Institute for Plant Nutrition and Soil Science, Christian-Albrechts-University zu Kiel, Kiel, Germany

Definition

Rheology Greek: *rhei* ($\rho\epsilon\iota$): flow; *logos* ($\lambda\circ\gamma\circ\sigma$): science; science of flow behavior.

ta panta rhei ($\tau\alpha\pi\alpha\tau\alpha\rho\epsilon\iota$) Everything flows (Heraklit, ~2500 year BP).

Introduction

Rheology is a science dealing with the mechanical behavior of fluids and plastic bodies when subjected to external stresses. Hooke's law for a perfect elastic body, Newton's law for ideal fluids, and finally, Bingham's yield represent terms on which rheology is based (Bingham, 1922). Theoretical aspects of rheology are the relation of the flow/deformation behavior of material and its internal structure (e.g., the orientation of particles) and the flow/deformation behavior of materials that cannot be described by classical fluid mechanics or elasticity.

Fundamentals of rheology: thixotropy and rheopexy

Thixotropic (thixis ($\tau\iota\xi\iota\sigma$): touch; tropous ($\tau\rho\pi\circ\sigma$): turn, change) behavior is a time-dependent phenomenon. The viscosity η (Pa s) of a pseudoplastic non-Newtonian fluid decreases, the longer the influence of any applied shear stress σ (Pa) (= shear thinning). Hence, soil liquefaction (cp. quicksand) may occur due to mechanical disturbance (i.e., vibrations), or due to the influence of salt under saturated conditions. In opposite to this, the solidification of a non-Newtonian fluid due to an increasing shear rate $\dot{\gamma}$ (s^{-1}) is defined as rheoplectic, shear-thickening behavior (i.e., gypsum pastes), whereas dilatant flow is given under time-independent conditions (Bingham, 1922; McMillen, 1932; Barnes et al., 1989; Jasmund and Lagaly, 1993; Macosko, 1994; Mezger, 2002) (Figure 1).

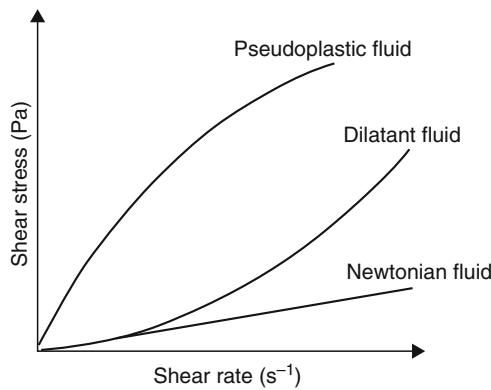

Rheometry

The measurement of rheological parameters (= rheometry) is commonly applied in chemical industry, e.g., food science (see *Rheology in Agricultural Products and Foods*),

polymer research, ceramics, coatings, or building material production, in which quality assurance is indispensable (Mezger, 2002). In soil science, rheological terms such as the liquid limit (yield stress), according to Atterberg

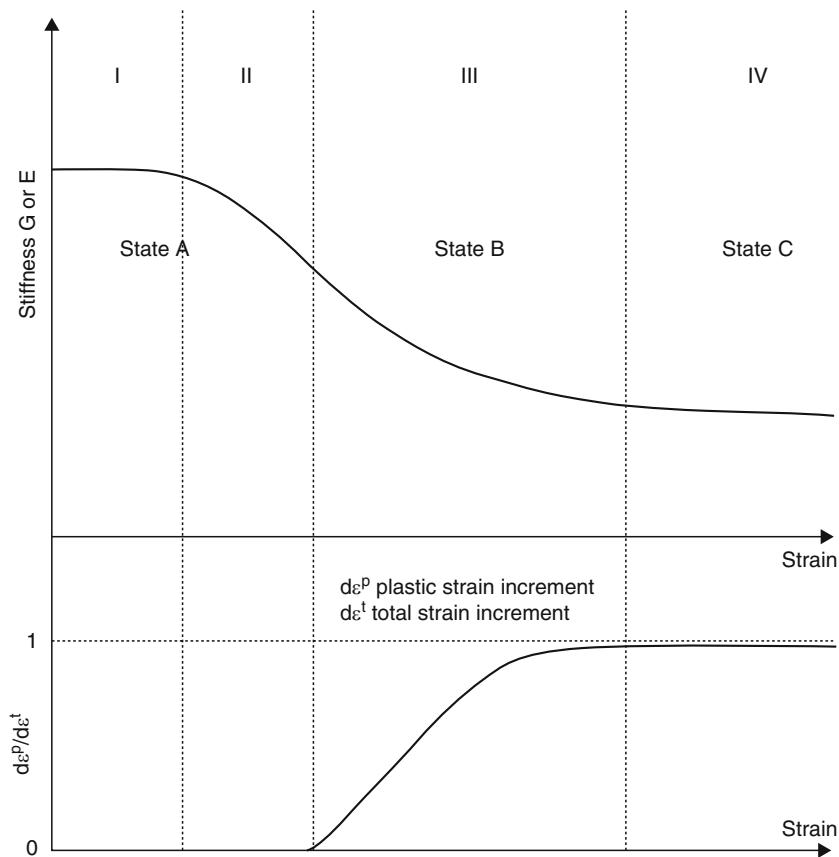

Rheology in Soils, Figure 1 Different types of responses (shear stress σ) to a change in strain rate ($d\varepsilon/dt$).

(1914), elasticity in terms of “full recovery,” plastic flow, or cohesion are well known but are generally regarded to mesoscale (core) stress–strain considerations. With regard to colloidal science, shear tests of clay suspensions have been applied to achieve rheological data (Jasmund and Lagaly, 1993); this knowledge has been transferred and adapted to soil scientific considerations. However, due to technical progress and development of new and powerful, sensitive measuring devices, rheometry could be established in the research field of soil micromechanics within the last 20 years. In research works of Ghezzehei and Or (2001), Markgraf (2006), Markgraf and Horn (2006a), Markgraf and Horn (2006b), Markgraf et al. (2006), Markgraf and Horn (2007), rheometry is introduced as soil mechanical method and is being optimized continuously (Markgraf and Horn, 2009).

Rheometry in soil micromechanics

Kézdi (1974) and Mitchell and Soga (2005) give a general introduction to deformation characteristics. They state that strains consist of elastic and plastic parts. Transferred to

Rheology in Soils, Figure 2 Four zones of deformation characterization: stiffness degradation and plastic strain development; an increasing stiffness degradation is associated by an increase of plastic strain. The part of plastic strain ($d\varepsilon^p$) is 0 in state A, the region of true and nonlinear elasticity, is approximating in state B, the region of pre-yielding, and equals total strain ($d\varepsilon^t$) in state C, the full plastic region. (After Jardine, 1992.)

rheological understanding, combinations of elastic and plastic or plastic and viscous compounds are possible. Soil can be defined as viscoelastic material (Markgraf et al., 2006). In soil mechanics, it is assumed that plastic strains develop only when the stress state satisfies some failure criterion (see [Stress–Strain Relations](#)).

According to this fundamental definition, the yield point differentiates the state of soil between elastic and plastic (viscous). From a soil mechanical point of view, there is no distinct transition from elastic to plastic behavior, which is related to cyclic loading. In solid mechanics, the small strain shear modulus G (Pa) (or Young's modulus E) is defined as:

$$G = \tau_c / \gamma_c \quad (1)$$

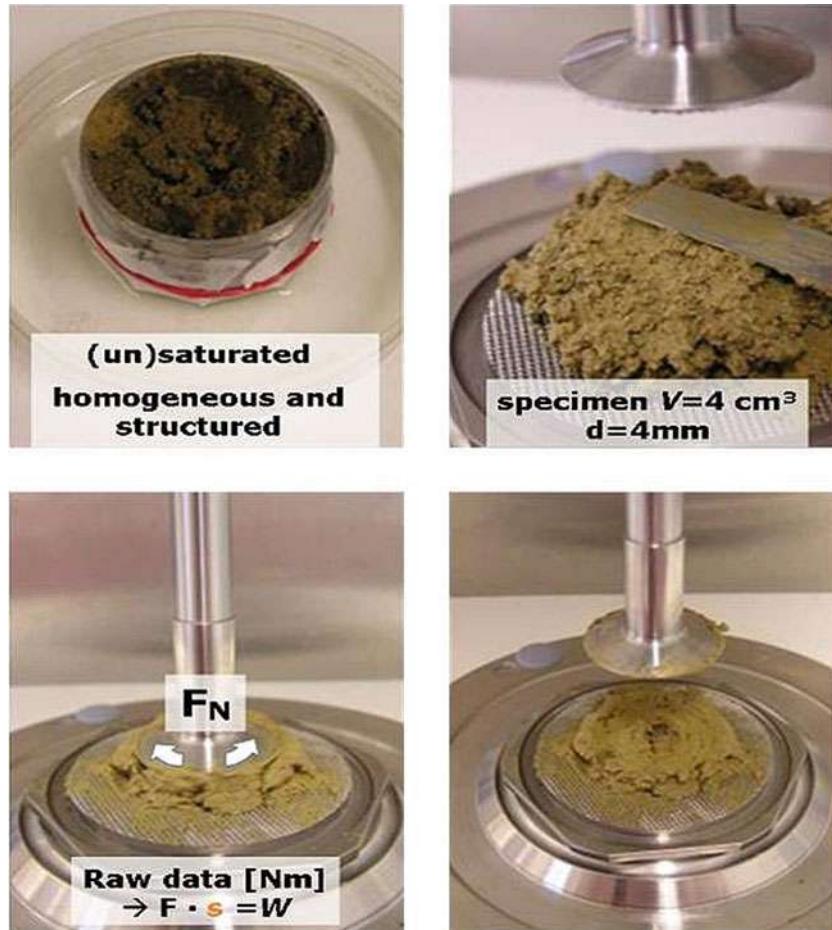

τ_c is the applied shear stress (Pa) and γ_c is the corresponding shear strain (%).

Under small stresses, strains of solid materials are more or less proportional to the applied stress. The constant of

proportionality (elasticity) is given by the inverse of Young's modulus of elasticity, which is a parameter of stiffness. Thus, elasticity is typically modeled by using the linear relationship between stress and strain. The classic theoretical example of linear elasticity is the perfect spring, whose behavior is described by Hooke's law. However, linear elasticity is an approximation, whereas natural, real materials exhibit some degree of nonlinear behavior.

Viscoelastic material models are frequently used to describe the behavior of plastics, polymers, or soil particles (soil network as three phase system). Commonly applied viscoelastic models are the Kelvin–Vogt and the Maxwell model for viscoelastic fluids or solids, respectively. Each model can be represented by spring and dashpot sets in combinations of series and parallel elements (Kézdi, 1974; Mezger, 2002).

Fundamental knowledge of soil stiffness in the linear elastic region is important for evaluating soil response

Rheology in Soils, Figure 3 Preparation and application of soil material for an Amplitude sweep test with controlled shear deformation. A rotational rheometer (MCR 300, Paar Physica, Ostfildern, Germany), profiled parallel-plate-measuring system (25 mm) is used; raw data is achieved by path-controlled force and recorded as torsional moment. This data defines storage and loss modulus G' (Pa); G'' (Pa), and deriving parameters, such as the dimensionless loss factor $\tan \delta$ ($= G''/G'$).

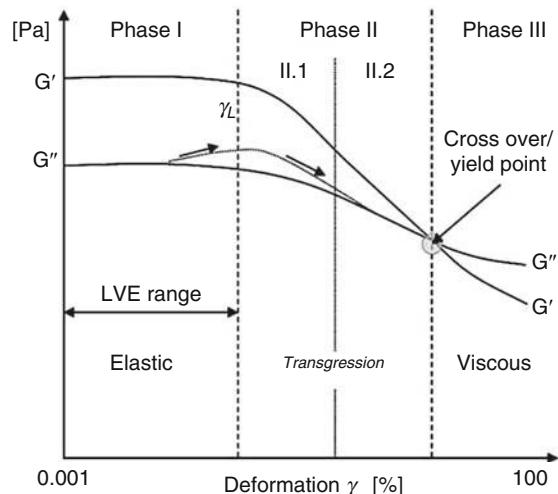

under dynamic loadings such as mechanical or vehicle vibrations (Garciano et al., 2001). It also provides indirect information regarding the state and structure of natural soil. Therefore, stiffness values can be used to assess the quality of soil samples. The linear elastic stiffness of soils is evaluated from measurements of elastic wave velocities or use of displacement transducers. Theoretical analyses of elastic waves are described in detail in Santamarina (2001). For a characterization of deformation, it is useful to differentiate between four zones and three states (Figure 2) (Jardine, 1992):

- Zone 1: True elastic region
- Zone 2: Nonlinear elastic region
- Zone 3: Pre-yield plastic region
- Zone 4: Full plastic region

Above a certain stress known as the elastic limit or the yield strength of an elastic material, the relationship between stress and strain is breaking down. Beyond this limit, the solid may deform irreversibly, exhibiting plasticity. This phenomenon is often observed using stress-strain curves.

Amplitude sweep test: quantifying stiffness degradation

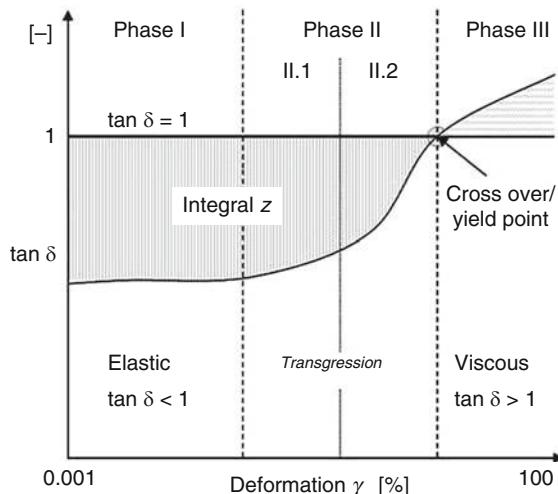

A rotational rheometer with a parallel-plate measuring device can be used to achieve parameters, which define soil as viscoelastic material (Figure 3) according to Maxwell's model, in which both Hooke's law of ideal elastic bodies and Newton's law of ideal viscous fluids are considered (Mezger, 2002). Amplitude sweep tests (AST) under oscillatory condition are conducted, with controlled shear deformation (CSD) $\gamma = 0.0001\dots$

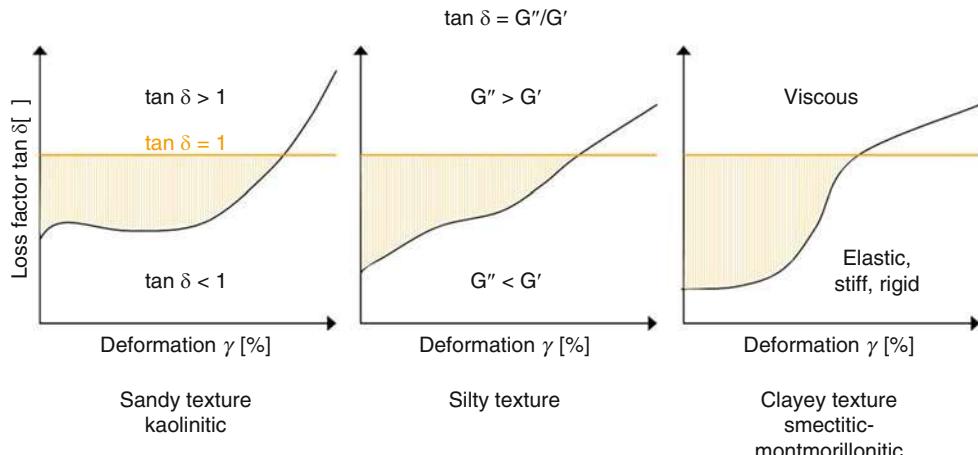

100%, an angular frequency $\omega = \pi s^{-1}$ ($f = 0.5$ Hz), and 30 measuring points, which lead to an average test duration of 15 min. A plate distance of 4 mm is preset according to a plate radius of the rotating bob of 25 mm and the given texture ($>2\text{ }\mu\text{m}$). Tests are operated by using the software US 200 (Paar Physica, Ostfildern, Germany). During all tests, a constant temperature of 20°C is maintained, regulated by a Peltier unit (see Video 1) (Markgraf, 2006; Markgraf et al., 2006).

From the stress-strain relationship in oscillation, with preset deformation γ (%), specific parameters such as the storage modulus G' (Pa), representing elasticity, stiffness, or rigidity of a material, the loss modulus G'' (Pa), representing viscosity, and the loss factor $\tan \delta$ ($= G''/G'$) are achieved, including the linear viscoelastic (LVE) deformation range, and deformation limiting value γ_L . Plots of storage and loss modulus (G' and G'') are generated automatically during a test. Three phases of elasticity loss can be identified (Figure 4).

In phase I, the initial or plateau phase, $G' > G''$, a quasi-elastic behavior can be observed. This can be described by an analog of a spring for ideal elastic substances according to Hooke's law. The quasi-elastic stage of soil as viscoelastic solid is defined by the linear viscoelastic (LVE) range and the deriving deformation limit γ_L . At this stage of low strain, a full recovery of the microstructure can be assumed. In phase II.1, a stage of pre-yielding occurs due to higher strain; soil particles are reorientating and microstructural stability is given, but decreasing. At the end of phase II.2, an intersection of G' and G'' indicates the yield point. In comparison, the intersection of $\tan \delta$ with the $\tan \delta = 1$ -line also indicates a complete loss of stiffness and rigidity of the soil microstructure (Markgraf

Rheology in Soils, Figure 4 Representative results from a conducted Amplitude sweep test with controlled shear deformation (CSD). Left: plots of storage and loss modulus G' (Pa); G'' (Pa) vs. deformation γ ; three phases of stiffness degradation are given: Phase I: quasi-elastic stage, Phase II: pre-yielding (II.1), yield point (end of II.2), Phase III: viscous stage, microstructural breakdown, yielding. Right: (same database) loss factor $\tan \delta$ (G''/G') vs. deformation γ ; if $\tan \delta = 1$ is crossed, a viscous character is given. By calculating integral z , stiffness (rigidity; elasticity) can be quantified.

Rheology in Soils, Figure 5 Plots of $\tan \delta$ vs. deformation γ : Classification of different textured soil material. Similar schemes are adaptable for, e.g., influence of cations, organic compounds, water content (menisci forces – pore water pressure).

and Horn, 2009). Due to a calculation of integral z (Figure 4 right), stiffness (structural strength), which includes quasi-elasticity, and pre-yielding behavior, can be quantified. Hence, phase III defines the final stage of structural collapse, $G' < G''$; a viscous character predominates, and substances are creeping or running. This behavior can be represented by a dashpot, an analog for ideal fluids according to Newton's law.

Classification of stiffness degradation

By using loss factor $\tan \delta$, a semiquantitative classification of rigid–nonrigid or elastic–viscous substrates can be done (Figure 5), considering, i.e., water content, sandy, silty, and/or clayey texture, clay mineralogy, (hydr)oxides, organic matter compounds (see *Organic Matter, Effects on Soil Physical Properties and Processes*), and ionic forces due to the application of fertilizer (see *Liming, Effects on Soil Properties*), irrigation water, or naturally given factor (e.g., soils in arid regions, coastal areas) (Markgraf and Horn, 2006b; Markgraf and Horn, 2007; Markgraf and Horn, 2009) (see *Alkalinity, Physical Effects on Soils* and *Salinity, Physical Effects on Soils*).

Conclusion

Rheological techniques are an appropriate tool to investigate and quantify microstructural stability and stiffness degradation of soil on a particle–particle scale. Furthermore, it can be combined with and extended by other methods that are intertwined in micromechanics and physico-chemical investigations on the microscale (microaggregate scale) (see *Soil Aggregates, Structure, and Stability*), i.e., ζ potential measurements (see *Diffuse Double Layer (DDL); Electrokinetic (Zeta) Potential of Soils; Flocculation and Dispersion Phenomena in Soils*), scanning electron microscopy (Markgraf and Horn, 2007), and X-ray diffractometry, or compared to well-known soil physical parameters that are used to achieve

soil mechanical data, i.e., shear strengths, angle of internal friction, cohesion, and soil hydraulics, i.e., shrinkage and swelling processes on the mesoscale (core scale) (see *Shrinkage and Swelling Phenomena in Soils*). With regard to upscaling concepts, rheometry is adaptable to several research areas that are related to soil mechanics and stress–strain considerations, i.e., geophysics, geohydrology, and geochemistry.

The hidden half (of plant) of the hidden half (of roots)

Definition

Considering the phenomena occurring at the root–soil boundary, it is essential to define such terms as: root–soil

interface, rhizoplane, rhizosphere, and bulk soil. The term root–soil interface is defined as a boundary between the outermost root tissues and the particles of soil which are closest to them. The rhizoplane refers to the zone of the external root surface itself (it is the external root surface) (Bowen and Rovira, 1991). The rhizosphere is a zone of soil or other growing medium in which the environment for microbial activity in general is influenced by any root growing in it, distinguishing it from the “bulk” or “non-rhizosphere” soil, which is influenced by growing roots only by the withdrawal of water and nutrients. A reasonable assumption is that the diameter of the rhizosphere at least equals that of the cylinder of soil around a root which root hairs explore and into which they may release root exudates (Russell, 1977). The rhizosphere can be divided into two regions (Lynch, 1982): endorhizosphere, including the inner root region (stele with conducting elements: xylem and phloem, epidermis, cortex, endodermis, and root cap), and ectorhizosphere, including the outer root region (plant and bacterial mucigel, root hairs, root mucilage, and sloughed root cap cells).

Introduction

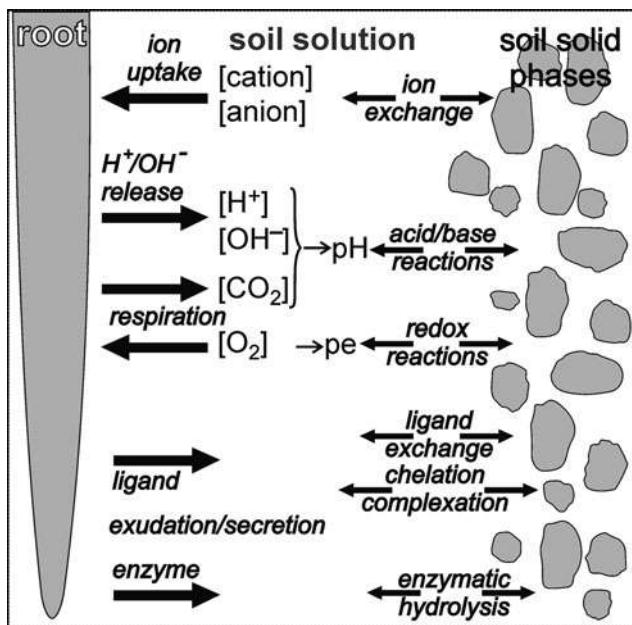

Roots of many higher plants release about 20% of C assimilated by photosynthesis into the soil as rhizodeposits that are substrate for the growth of microbial communities. As a result, the roots are embedded in mucilaginous layers released into the soil by outer root cap cells or produced by root-colonizing microorganisms. These enhance population and activities of microorganisms in the rhizosphere. Typical populations are 10⁹ bacteria, 10⁷ actinomycetes, 10⁶ fungi, 10³ protozoa, and 10³ algae per gram of rhizosphere soil being 50–100 times as many microorganisms as the bulk soil (the rhizosphere effect). Each gram of root can support 36 mg of bacteria which is equal to 2 × 10¹⁰ cells. Some are free-living; others are symbiotic (e.g., root nodule bacteria and mycorrhizal fungi) (Foster et al., 1983). The above microbial changes affect physical and chemical processes and characteristics of the soil. The processes occurring in the rhizosphere influence spatial and temporal heterogeneities in the soil and result in gradients of different sizes (Gliński and Lipiec, 1990; Hinsinger et al., 2005; 2009). The rhizosphere is considered as one of the most fascinating hot spots of activity and diversity in soils (Jones and Hinsinger 2008).

Physical aspects

Figure 1 illustrates the effects of root growth and functions on physical processes occurring in the rhizosphere. The processes affect soil structure and stability, bulk density, porosity, textural composition, root–soil contact, and water relations in the soil.

Soil structure

The role of plant roots in soil structure formation consists generally in soil aggregation (see [Plant Roots and Soil](#)

Rhizosphere, Figure 1 Schematic representation of root functions involved in changes in physical properties in the rhizosphere (After Hinsinger et al., 2005).

Structure. Roots and root hairs penetrating the soil produce lines of weakness along which the clod or soil mass break into smaller aggregates that are stabilized by root exudation with its associated rhizosphere microbial activity (Amellal et al., 1998; Six et al., 2004) and wetting-drying cycles during crop growth (see *Soil Aggregates, Structure, and Stability*). Also the pressure exerted by developing roots may enhance the aggregation. Root hairs and mucilage can form specific structures “rhizosheaths” (McCully, 1999; Hinsinger et al., 2005) around the roots that are particularly strong and affect root–soil water transfer and soil porosity. Functioning of “rhizosheaths” depends on their spatial and temporal geometry (Crawford et al., 2005; Hinsinger et al., 2009). Noninvasive methods (e.g., X-ray, neutron radio) may provide insight for visualizing spatial and temporal dimensions of rhizosphere processes (Hinsinger et al., 2009).

The effects of living roots on soil structure and stability depend on the plant species. Research showed that interactions of root- and microbial-derived mucilages with soil minerals appreciably improve soil structure and stability (see *Mineral–Organic–Microbial Interactions*) (Czarnes et al., 2000). The increase in aggregate stability by maize, soybeans, and wheat roots was attributed to the physical entanglement of aggregates by roots and to the increased production of root exudates resulting from increased root growth (Monroe and Kladivko, 1987). Maize roots, in some cases, can decrease structure stability of soils by chelating iron and aluminum, thus destroying chemical bonds with organic matter.

The mucilaginous layers around the roots affect water transport (Alami et al., 2000; Czarnes et al., 2000) and protect plants against heavy metal toxicity (Gliński and Lipiec, 1990). Soil structure and water status around the root affect spatial distribution of root pathogens (e.g., *Rhizoctonia solani*) (Harris et al., 2003) and minimize the effects of soil drying on bacterial populations within the biofilms (Alami et al., 2000; Hinsinger et al., 2009).

Association composed of fungal hyphae and roots, named mycorrhiza, alters soil acidity and enhances adhesion of soil particles to the root, microbial population, and root exudation; improves soil aggregation; and facilitates uptake of nutrient elements (Jones et al., 2004; Skwaryło-Bednarz and Krzepiłko, 2009). Recent results indicate that the use of arbuscular mycorrhiza may reduce the stressful effects of soil compaction on growth of wheat (Miransari et al., 2008) and maize (Miransari et al., 2007).

Bulk density and strength of soil

Roots growing in the soil occupy space that was previously occupied by soil pore space and soil particles. Since root diameters of most agricultural plants (0.1–3 mm) are usually larger than soil pores (0.002–0.2 mm), soil particles are pushed aside and the bulk density and porosity close to the root–soil interface change (Gliński and Lipiec, 1990; Young, 1998.). In a study by Bruand et al. (1996), maize root reduced porosity by 22–24% and increased bulk density up to 1.80 Mg m^{-3} close by the root–soil interface, although it was 1.54 Mg m^{-3} in the bulk soil. The modeling work of Dexter (1987) indicated that the soil density around roots decreases exponentially with distance from the root surface with an exponent, which is a constant multiple of the root diameter. This can be enhanced in compacted soil where roots are typically shorter and thicker (Lipiec and Simota, 1994). The area is characterized by a higher incidence of oriented clay and greater percent of elongated grains oriented within 30° tangent to the root surface (Gliński and Lipiec, 1990) and micropore porosity (Feeney et al., 2006). Also aggregates adherent to plant roots (“root aggregates”) were denser than those taken from bulk soil due to a decrease in the contribution of larger pores (Guidi et al., 1985). Increase in soil bulk density together with root network results in greater soil strength, shearing resistance, and bearing capacity (Gliński and Lipiec, 1990), and thus increases soil resistance to erosion. (see *Plant Root Strength and Slope Stability*).

Textural and mineralogical composition

Plant roots can modify the textural and mineralogical composition of the soil adjacent to the root. As shown by Sakkar et al. (1979), the rhizosphere in the silty loam compared to bulk soil was relatively higher in the finer fractions ($<6.3 \mu\text{m}$) of 25–35% and of the fine silt ($6.3\text{--}2.0 \mu\text{m}$) in particular, at the expense of the medium and coarse silt fractions. It was explained by an accelerated disaggregation of compound shale fragments into

their component silt/clay particles and by differential packing of soil particles in the volume near the root. The mineralogical changes in the same study were manifested most clearly in the finest clay fractions ($<0.0063\text{ }\mu\text{m}$) and involved a decrease in both regularly and irregularly interstratified $0.0010\text{--}0.0014\text{ }\mu\text{m}$ material: amorphous (extractable) Al, Fe, and C accumulated in the rhizosphere, while Si was depleted. It was due to intensified weathering of soil materials in the vicinity of the plant root.

Root–soil contact

An important physical aspect of the root–soil interface is the contact area between the root and the soil (Gliński and Lipiec, 1990). The degree of this contact affects the movement of water and nutrients from the bulk soil to the root. The contact area in the case of dicotyledons can be increased with time due to cambial increase in root diameter. The monocotyledons have no such progressive thickening. It is known that this contact is not continuous, and it can be weakened either by the enlargement of the cavities or by the decrease in diameter of the roots themselves due to shrinkage at low soil water potentials, and root aging and associated the degeneration of the cortex due to invasion by microorganisms or dessication.

Lack of contact between root and soil may be reduced by the following effects:

- Root hairs proliferation in the humid air of large soil pores and channels
- Formation of a film of water on the root and root hair surfaces, linking them to the soil moisture continuum
- Excretion a layer of root mucilage up to $5\text{ }\mu\text{m}$ thick (on average $1\text{ }\mu\text{m}$), which will bridge small gaps

Root–soil water relations

Root growth and uptake of water affect are primary functions of plant roots that directly alter physical properties of the rhizosphere (Hinsinger et al., 2005). In general, the root water uptake rate decreases with lowering soil water content. The decrease is explained by the increase of hydraulic resistance in the soil–plant system. This resistance, named “the rhizosphere resistance” or “interfacial resistance” appearing in the soil immediately adjacent to each single root, is distinguished from the so-called “pararhizal resistance,” which concerns the movement of water through the bulk soil to the roots (Russell, 1977; Gliński and Lipiec, 1990). If the interfacial resistance is sufficiently high, the roots of a rapidly transpiring plant may reduce the water potential of the neighboring soil to the value near the wilting point, even though the water potential at a short distance away is close to field capacity. Roots affect water in their immediate vicinity, and the quantity of water they can extract is closely related to the soil hydraulic conductivity, soil water potential gradients between roots and soil, and soil water–root contact area (Hasegawa, 1986). Enough water to plant roots was moved until the hydraulic conductivity of the soil fell to around the order of $10^{-5}\text{ cm day}^{-1}$. The root–soil water

relations affect proportion of water-filled and air-filled pores and thereby relative contribution of anaerobic and aerobic organisms (Young and Ritz, 2000).

Physicochemical and chemical aspects

Acidity and redox potential

Through many studies, it is clear that most plant species in their apical root zones increase: the acidification (expressed in pH values), the reducing capacity, and the rate of iron and manganese reduction and their uptake. Also soil microbes can contribute to rhizosphere acidification by producing organic acids (Casarin et al., 2004). Between the rhizosphere and bulk soil, distinct pH gradients up to two units are observed along the root axes (e.g., Nye, 1981). The pH changes are influenced by redox processes in the rhizosphere (Hinsinger et al., 2009).

A particular case of differences in rhizospheric pH within a root system can be observed in the so-called cluster-rooted plants (Gliński and Lipiec, 1990). The root system of these plants is characterized by clusters of finely divided, highly branched sections of roots, called the proteoid roots. Their capacity for acidification of the cluster-rhizosphere soil may drop pH to about 4.5 compared to about 7.0 in the other root zones. Increasing soil acidity leads to the deficiency in soil and uptake by plants of some elements, e.g., phosphate (e.g., Richardson et al., 2009), and decreasing the diversity and richness of soil microbial communities (Fierer and Jackson, 2006; Hinsinger et al., 2009). Root activity in calcareous soils is connected with the formation of water flux toward the root and acidification of root environment. These phenomena form various types of soil structure due to dissolution, movement, and reprecipitation of soil carbonates (Jaillard, 1987).

Two-dimensional developments for studying the changes of pH, redox potential (Eh), and partial pressure of O_2 provide new opportunities for improved understanding rhizosphere processes (Hinsinger et al., 2009).

Water and ions

The uptake behavior of roots changes water and ion movement and the accumulation profile in the rhizosphere differing salt concentration between the rhizosphere soil and the bulk soil (Jungk, 2002). The root system influences ion uptake directly through their flux in aqueous solution to the root surface by diffusion and mass flow induced by the transpiration stream and also by modification of the rhizosphere pH (Gliński and Lipiec, 1990). If water together with ions and other solutes arrive at the root faster than they are absorbed, their accumulation in the rhizosphere increases, increasing the osmotic potential. It causes the diffusion of ions away from the root until a steady state is reached when diffusion away just balances arrival by mass flow. Preferential uptake of either ions or water leads to depletion or accumulation profiles of ions. Examples of this are the depletion zones of phosphorus and potassium (Jungk and Claassen, 1986), the

accumulation in the rhizosphere of calcium (Malzer and Barber, 1971), and the accumulation of sodium and chloride in saline soils (Schleiff, 1980). The examples indicate that the rhizosphere effects on plant nutrition can be beneficial or detrimental.

Examining water content and ion concentration gradients (using the root plane technique) in soil near a plane of onion seedling roots, Dunham and Nye (1973) found that soil water potential gradients near roots were steeper in drier than in wetter soil. The process of root growth, if rapid enough, can reduce the effect of the localized draw down of both matric and osmotic potential around each root. In the rhizospheric saline soil, the water uptake rates by barley roots were reduced to a greater extent by decreasing soil matric water potentials than by decreasing soil osmotic water potential (Schleiff, 1986).

Summary

There is substantial evidence that the root-mediated processes within the rhizosphere enhance soil aggregation and stability, increase the soil bulk density and strength next to the roots, alter soil acidity, and affect accessibility of nutrients to the plants and root water uptake. The water extracted by roots is related to the soil hydraulic conductivity, soil water potential gradients between roots and soil and soil water–root contact area. The rhizosphere processes induce much spatial and temporal heterogeneity in the soil. Root–microbial–mineral interactions associations may reduce the stressful effects of soil drying and compaction on root growth and biological activity. Further research on holistic perception of the rhizosphere, including the connections between the biology, physics, and chemistry, and on how to bridge the rhizosphere of individual roots to soils at field scales and larger is needed (Hinsinger et al., 2009).

RIGIDITY

The property of a body (e.g., soils, plant stalks) that makes it inflexible, or stiff.

RILL EROSION

An erosion process on sloping fields in which numerous and randomly occurring small channels of only several centimetres in depth are formed; occurs mainly on recently cultivated soils.

Synonyms

Effects of soil physical properties on root growth; Hypoxia; Root responses to mechanical impedance; Water stress

Definition

Root responses: Changes in the growth of individual roots and of the root system as a whole. This includes changes in elongation rate, diameter, number of roots, and branching pattern.

Soil physical limitations: The physical properties (soil strength, soil aeration, soil matric potential) of a soil that may restrict root growth.

Context – why soil physical limitations to roots are increasingly important

For good growth, plants require a root system of sufficient size to obtain water and mineral nutrients from the soil they are growing in. In nutrient-poor or dry soils, limitations to root system growth will often restrict water and nutrient uptake, resulting in slower plant growth and restricting crop yield of agricultural plants. Physical limitations – particularly mechanical impedance, hypoxia, water stress, and non-optimal temperature – represent a major restriction to root system growth in many soils (Bengough et al., 2006). The first three limitations occur when the soil water content is non-optimal for root growth and depend on the soil strength, structure, and water

regime. Mechanical impedance occurs where the strength of the soil physical matrix mechanically restricts root growth. Hypoxia occurs where oxygen diffusion to the root, and particularly growing root tips, limits growth. Water stress occurs when the soil water potential surrounding the root tip is sufficiently negative that it restricts water uptake for cell expansion and root tip growth. More than one stress can occur in different parts of a single root system, and even an individual root tip may experience multiple stresses.

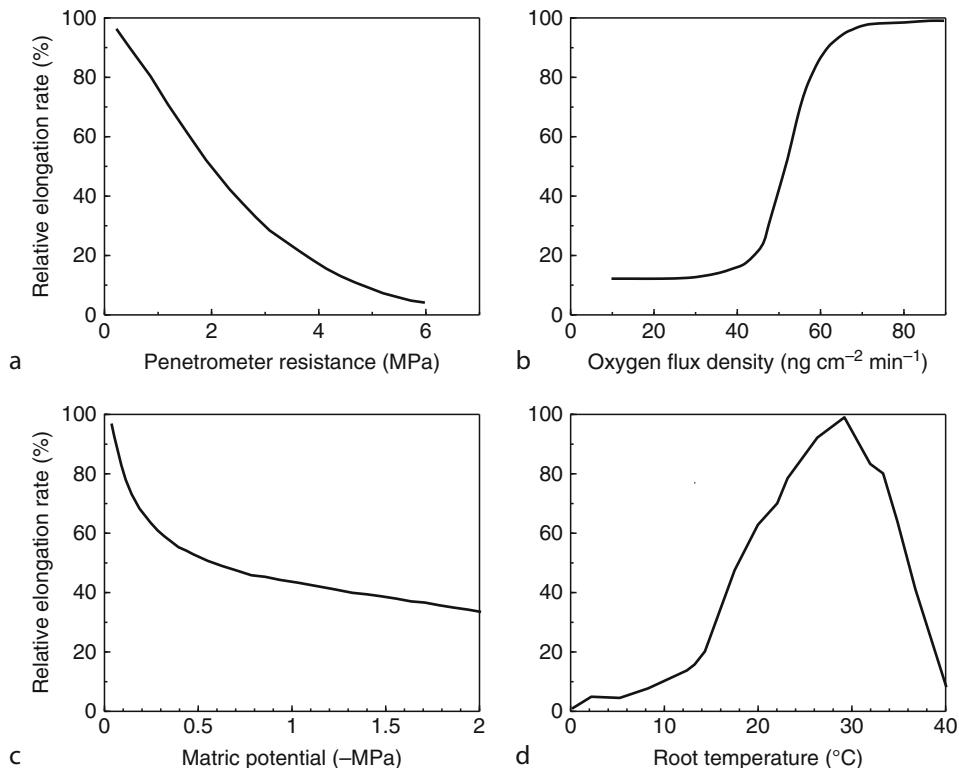

The pressure to increase food production, to satisfy the demand of a rising global population, increases the pressure to put more land under intensive agricultural production. Intensive cultivation, if not carefully managed, can lead to decrease in soil organic matter and hard-setting soils that restrict root growth (Mullins et al., 1987). Predictions of global climate change scenarios include greater local variability of rainfall patterns in many areas that may cause greater oscillations in soil water regime – more intense rainfall events, with longer periods of drought between in many parts of the world. Such large fluctuations in the soil water regime are likely to create adverse physical conditions for root growth. Global environmental change is therefore a strong motivation to understand and, where possible overcome, physical limitations to root

growth, through crop breeding and improved soil management.

In this article, root responses to soil physical stresses are considered, and it should be noted that root responses differ significantly from shoot responses. Readers interested in further information on root responses to the soil physical environment are referred to books by de Kroon and Visser (2003) and Gregory (2006).

Root response to mechanical impedance

Mechanical impedance will be a major restriction to root growth in soils where the penetrometer resistance is greater than 2 MPa, and there are no continuous channels available to provide an alternative pathway for root growth (Bengough and Mullins, 1990; Bengough et al., 2006). In hard soils roots elongate more slowly and root tips thicken (Figure 1a). Root cortical cells are shorter and fatter in mechanically impeded roots, and the cell flux (the rate of adding new cells onto a cell file) is also decreased. Border cells and mucilage are produced by the root tip to create a low-friction sheath around the root that eases its passage into hard soil. These border cells are root cap cells that become detached from the root cap like a disposable drilling tissue. Mucilage is a gel, produced by root cap cells,

Root Responses to Soil Physical Limitations, Figure 1 Examples of relations between root elongation rate and soil physical stresses. (a) Peanut root elongation slows as penetrometer resistance increases (Taylor and Ratliff, 1969). (b) Hypoxia – oat root elongation slows as oxygen diffusion decreases below threshold (Blackwell and Wells, 1983). (c) Maize root elongation slows as matric potential decreases (Sharp et al. 1988). (d) Pecan root growth is greatest at about 30°C (Woodroof, 1934).

that is very slippery and acts as a lubricant between the border cells and the root proper. Mucilage and border cell production are maintained or increased in mechanically impeded roots and have the advantage of decreasing root-soil friction – which is often a major component of penetration resistance for probes pushed into soil.

Root response to hypoxia

Hypoxia is likely to limit root growth if the soil air-filled porosity is less than 10% (i.e., less than 10% of the soil volume is filled with air). In hypoxic soil, root elongation slows, and root tips may thicken (Figure 1b; Blackwell and Wells, 1983). Plants may adapt to hypoxia, depending on species, by producing gas-filled passages in the root cortex called aerenchyma (Armstrong, 1979). Aerenchyma increases the rate of oxygen diffusion along the root axis to the root tip, helping to maintain the oxygen supply to the growing root tip where new cells are being produced in the meristem. In many flooding-resistant plants, new adventitious roots may appear on stem tissue in response to water logging (Blom et al., 1994). These roots contain aerenchyma and may have fewer branches than in non-waterlogged plants.

Root response to water stress

Studies of root responses to water stress are often confounded by changes in soil strength that occur as the soil dries: In most soils, soil drying causes major increase in mechanical impedance to root growth as well as in water stress (Bengough et al., 2006; Whalley et al., 2006). Studies that have carefully separated the effects of water stress from those of mechanical impedance have shown that root tips of non-transpiring seedlings can continue to extend even beyond the permanent wilting point of mesophytic plants (-1.5 MPa matric potential; Figure 1c) in soft growing media such as vermiculite (Sharp et al., 1988). This shows that roots are much less sensitive than shoots to water stress in loose growing media. Root elongation is decreased by water stress and roots become thinner, in contrast to the hypoxia and mechanical impedance responses. Root cortical cells in water-stressed roots are shorter and the rate of cell flux is slower.

Root response to temperature

Temperature affects both the processes of root development and root extension, with root growth slowing or halting if the temperature becomes too hot or too cold (Cooper, 1973; Kaspar and Bland, 1992). The optimum temperature for root growth is between 10°C and 35°C for most species that have been studied experimentally (e.g., Figure 1d; Cooper, 1973). The number of stem-borne (nodal) root axes for cereals increases with the number of leaf nodes – which can be predicted from accumulated thermal time above a base temperature. Indeed, the number of root axes increased linearly with accumulated thermal time at the shoot meristem for pearl millet (Vincent and Gregory, 1989). Primary roots of maize grown at cooler temperature

grew more slowly and were thinner than those at more optimal temperature (Pahlavanian and Silk, 1988). This slower elongation was associated with decreased growth strain rate in the elongation zone, but there was negligible change in the length of this zone.

Interactions between stresses and feedback effects

The underlying growth responses to physical stresses are mediated by biophysical changes in cell wall properties that control cell expansion and in changes in cell flux. More than one stress may affect a single root tip at a particular time. In dry compacted soil, both mechanical impedance and water stress may limit root tip growth whilst, in wet compacted soil, a combination of mechanical impedance and hypoxia may limit growth. Feedback effects will be of considerable importance for crop plants: For example, a compacted plow pan may limit root penetration to depth by creating a large mechanical impedance to growth, resulting in water stress that limits crop yield if sufficient water is not available in the topsoil.

Gaps in knowledge

The most important limitations to root growth in the many different climatic zones and soil types that exist worldwide have not been quantified adequately. The least limiting water range concept provides a useful framework for considering the major soil physical limitations to root growth as a function of time in different soils, and so may allow this problem to be addressed. This could be used to highlight the priorities for future plant breeding and root system selection for problem soils.

The extent to which it will be possible to overcome physical limitations to root growth by breeding plants better adapted to these physical stresses requires more study. Most plant breeding has been centered on improving the yield of crops grown in relatively optimum conditions, and so we need to address the problem of breeding varieties for stressed environments.

Summary

Soil physical stresses represent important limitations to root growth in many soils, and are likely to become of increasing importance in many regions of the world. Root elongation is slowed in response to mechanical impedance, hypoxia, water stress, and temperature stress. This results in decreased root system size with potential reductions in crop yield.

ROOT SYSTEM ARCHITECTURE: ANALYSIS FROM ROOT SYSTEMS TO INDIVIDUAL ROOTS

Loïc Pagès

INRA Centre d'Avignon, Avignon cedex 9, France

What is the root system architecture? Importance for functioning

The term “architecture” includes two important aspects of the root system: its shape and its structure.

The shape is the three-dimensional arrangement of roots that can be described through several geometrical criteria, as lateral root extension, root depth, or more thoroughly by the distribution of root length density throughout the soil.

The structure refers to the diversity of the components (roots) and their relationships. According to their age and position within the root system, roots have specific physiological characteristics and functions (Waisel and Eshel, 2002). The way they are distributed and connected to each other (i.e., the topology of the system) is usually specific and important for the functioning of the whole system (Fitter, 1987).

Water and mineral uptake, the main function of root systems, requires several steps which illustrate the role of the root system architecture: (1) during the soil-to-root transport of any resource, the shape of the system will determine the length of the transport pathways for this resource; (2) when entering into the plant, permeability of the root surface (a structural attribute) is a main parameter; (3) then, the within-plant transport, from the absorbing root to the final place of use, depends on the conducting capacities of the branching system.

Other functions, such as carbon efflux from the plants to the soil, or anchorage, are also linked to the architecture. Regarding anchorage especially, the geometry and mechanical properties of the main roots will determine the efficiency of the system for this function (Fourcaud et al., 2008).

The dynamics of the architecture are important to consider, since the plant is a changing organism in a changing environment. Moreover, the success of competition with other organisms at the same place depends usually on dynamic aspects and rates of development.

Overview of the root system architecture: classification and diversity

A first overview, although static, can be given through some words that often qualify the diversity of root systems. A common distinction is made between: (1) fibrous (or diffuse, or fasciculate) root systems on the one hand, that are formed by a large number of equivalent roots, directly connected to the stem, and (2) taproot (or central, or conical) root systems on the other hand, that are made by a central and vertical main root (often called the taproot) along which a number of lateral roots originate at various

depths. It is worth noticing that many plants may begin their life exhibiting a taproot system, because the taproot is the dominant root, developed from the embryonic root (radicle). Then, the root system will become fibrous if the lateral roots are numerous and have a dominant development. The distinction is still more difficult when the taproot stays short and the lateral roots are superficial.

Therefore, it is helpful to consider not only the morphology at a given stage, but also the developmental sequence (or “growth strategy”), as suggested by Cannon (1949). Cannon has classified the root system architecture, starting from two fundamental categories (see Figure 1): (1) the primary root system originates from the radicle, which grows downward, and branches acropetally (i.e., from its base to its tip); (2) the secondary root system (also called adventitious root system) originates from the shoot system: roots emerge continuously during shoot development, whereas the radicle gives only a small and temporary root system. In the first category, the architectural types are defined by the relative importance of the taproot and lateral roots, and the distribution of lateral roots’ vigor along the taproot. Most dicotyledonous plants and gymnosperms exhibit a primary root system, associated with a significant radial growth and storage function of the taproot. In the second category, the architectural types depend on the distribution of the adventitious root system on the shoots. It can be centralized when all adventitious roots appear at the shoot base, or diffuse when adventitious roots appear along a running shoot or rhizome or even throughout the erected shoot system. Monocotyledonous plants, which do not have radial growth, develop their root system according to this secondary strategy.

This classification has been applied and completed by Krasilnikov (1968) on trees (see Figure 2). Krasilnikov has also defined a number of morphological types in these two basic categories, and has shown that many root systems are built by combining the two categories. The primary root system is preeminent during the young stages of the plant, while secondary root system will superimpose during the older stages. This superposition makes what he called mixed root systems.

Even though these general developmental patterns of the root system are kept, root system architecture can be deeply modified by special adaptations of some roots. Among these adaptations, let us mention roots playing a particular role for anchorage or support: buttress and stilt roots. Buttress roots develop along the base of the trunk, stabilizing the tree, especially in shallow saturated soils. Stilt roots grow down from lateral branches, and branch into the soil. They are common among mangroves. Regarding nutrition, roots exhibit also several specializations. Aerating roots (or pneumatophores) rise above the ground, have breathing pores to catch air, and provide oxygen to the root system. Tuberous roots are modified lateral roots which work as storage organs, able to store and distribute later various resources. Haustorial roots can absorb water and nutrients from another plant, in the case of parasitic plants.

Because of particular morphogenetic capacities, roots can play an important role in extension and vegetative multiplication of plants. For example, in some species, roots produce shoot buds giving rise to suckers (e.g., Poplars, Black Locust, Cherry tree, Raspberry).

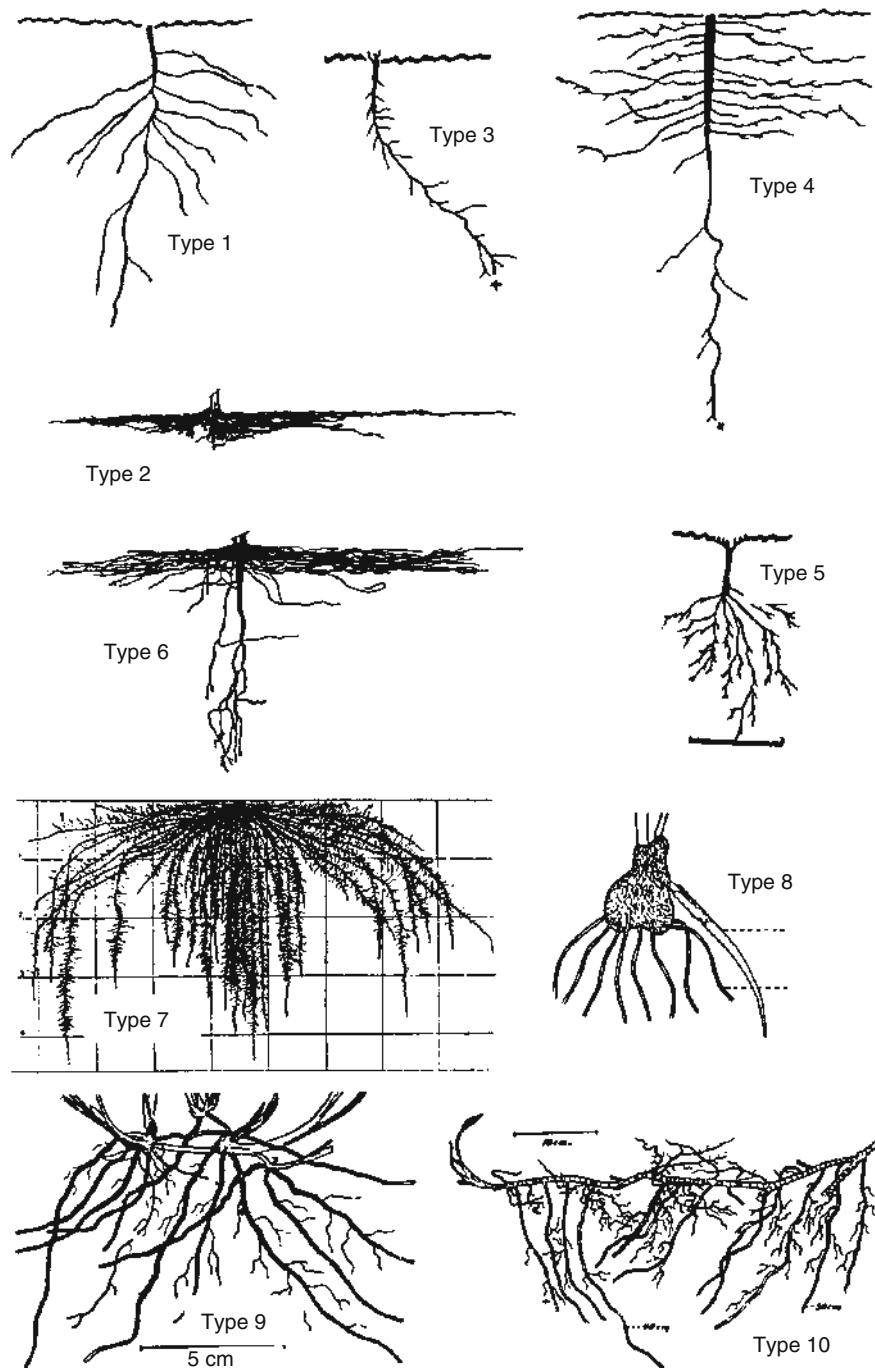

Analysis of the root system architecture through components and developmental processes

To understand better the root system architecture and its dynamics, it is worth considering the system through its main components and developmental processes.

A large part of the architectural diversity comes from the distribution and diversity of root apical meristems that are the key substructures for root elongation and generation of the young (subapical) root tissues. These meristems provide the new cells in the apical part of the root, allowing apical elongation and maintenance of the root cap. In many plants, apical meristems exhibit large variations in diameter, up to one or two orders of magnitude, and these variations are correlated to their morphogenetic capacities (Coutts, 1987). Big meristems generally make fast growing roots, with a long life span, able to orient themselves through various tropisms. These roots extend the volume colonized by the root system. On the opposite, small meristems make short roots, which follow the soil porosity and stop growing after some days. Then, they senesce and die quickly, and thus exploit only temporarily the very local soil. After having completed their role for the plant, their decomposition contributes also to the carbon efflux to the soil.

Branching is the major process for increasing root number and so root length and surface. It is spatially and temporally organized, since lateral roots appear acropetally on their mother root, i.e., following the progression of its tip. Lateral meristems are initiated as primordia very close to the meristem in the mother root, and emerge some days later as new lateral roots. Because of this process, the most distal lateral roots are also the youngest.

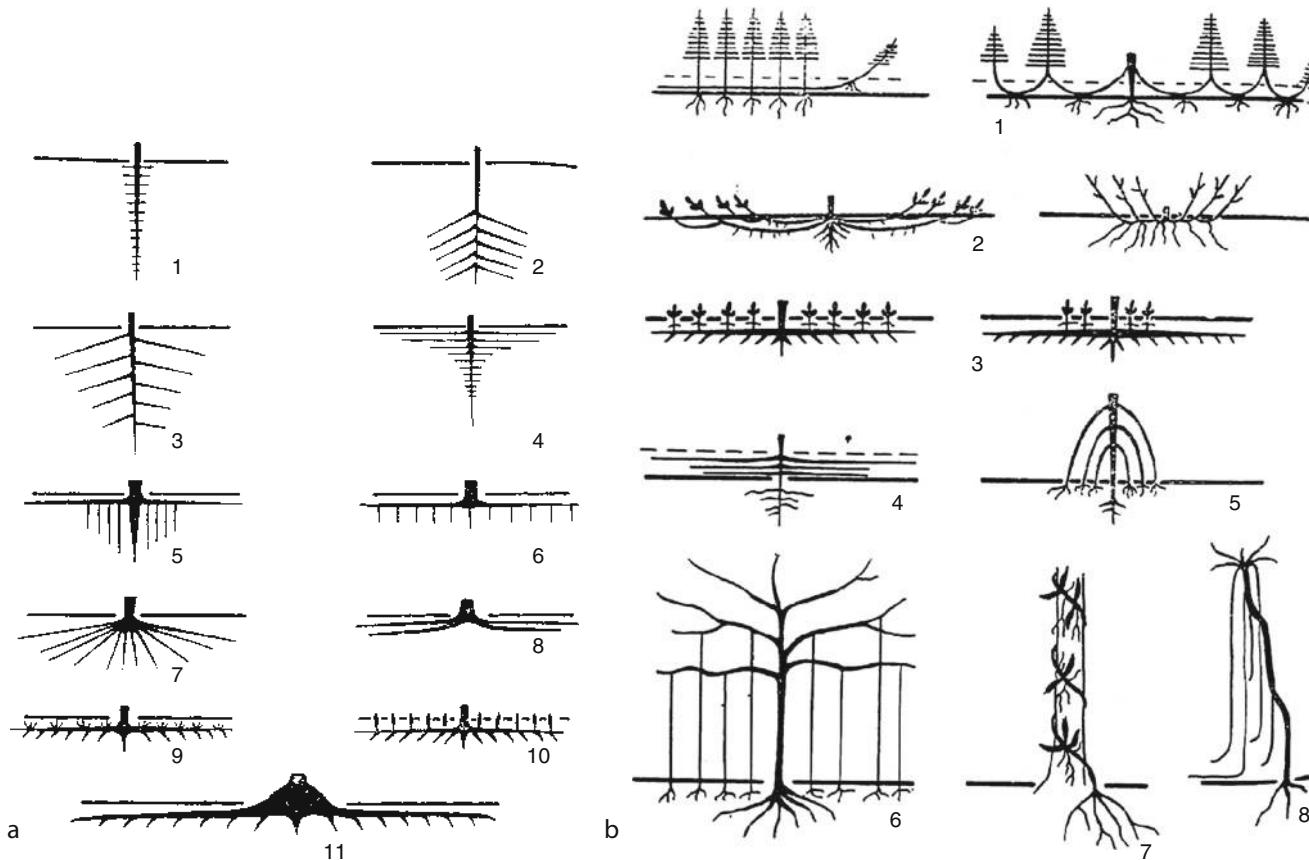

In order to reinforce conducting and support capacities of the roots, dicotyledonous plants have secondary meristems, which add layers of vessels and stiff tissues to the existing roots. Thanks to this secondary meristem functioning, the roots become thicker, highly conductive for sap, and are better protected against adverse organisms and mechanical constraints. In monocotyledonous plants, original tissues are gradually complemented by stiff and protective substances, like lignin and suberin, but without any significant radial growth, because there are not secondary meristems producing additional tissues. These different strategies induce large differences in the dynamics of these two categories of plants. The development of lateral roots is much higher on plants that exhibit radial growth. The increase of conducting capacity of the root allows it to bear daughter roots. On those plants with radial growth, tight relationships are observed at each branching point between the sectional area of a mother root and the sum of the sectional areas of its daughter roots.

Root System Architecture: Analysis from Root Systems to Individual Roots, Figure 1 Classification of root systems, according to Cannon (1949). Types 1–6 are primary root systems, where a taproot is developed from the radicle. Types 7–10 are secondary root systems, where most main roots emerge from the shoot system (adventitious roots).

It is also important to notice that a large number of roots are very short-lived. On trees, these fine and short-lived roots can be compared to the leaves on the shoot system. They represent a large area and have a transient role of exchange with the medium.

All these developmental processes are deeply affected by the soil, through a number of its physical and chemical characteristics. For example, the distribution of temperature in the soil modifies the developmental kinetics. Mechanical impedance of the soil is also a main factor

Root System Architecture: Analysis from Root Systems to Individual Roots, Figure 2 Classification of root systems for trees and shrubs, according to Krasilnikov (1968). (a) Primary root systems, with 11 different types. (b) Secondary and mixed root systems, with eight different types.

affecting root elongation and branching, and consequently the root system architecture.

Modeling the root system architecture

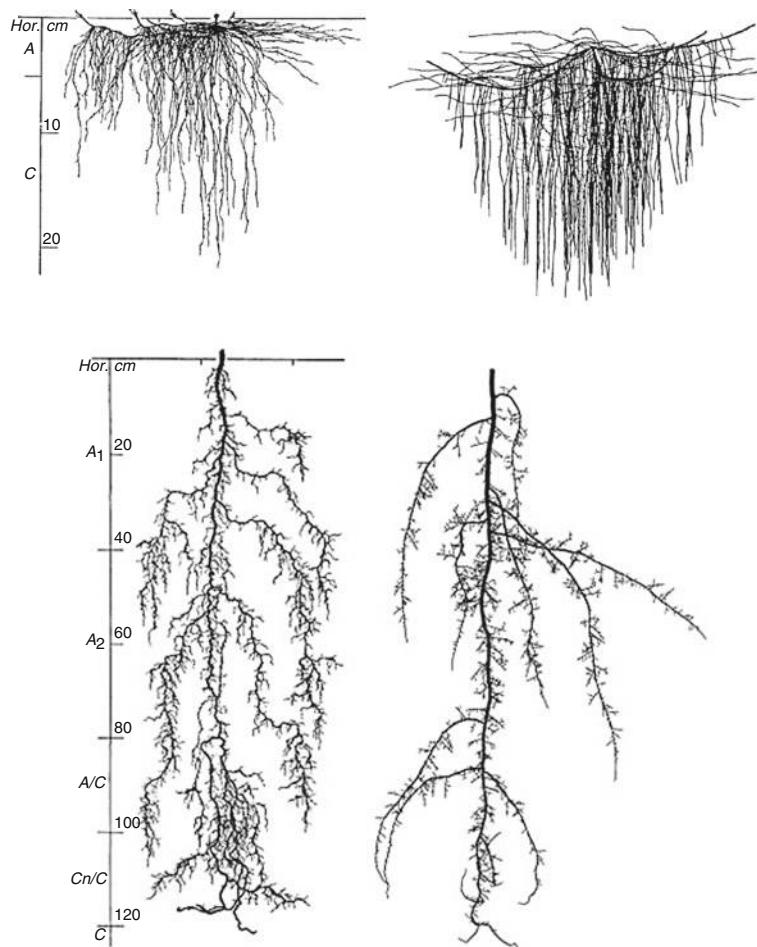

Mathematical modeling and simulation have been shown to be very important tools for representing both the combination of all these processes, together with interactions with soil and various organisms.

Early models of the three-dimensional architecture (Diggle, 1988; Pagès and Aries, 1988) have shown the interest of making such a combination of several developmental processes in order to get a dynamic and quantitative representation of this complex object, the root system architecture. These models made the link between the root level and the root system level. This link is important because comprehensive experimental data are usually easier to acquire on individual roots and on simple developmental processes at the root level (like elongation, branching), but the root system is an integrated system whose functioning comprehension requires standing back and looking at this higher organization level. The approach has been extended and validated on various plant species, including tree species.

Later architectural models have integrated several root–soil interactions (Pagès et al., 2004; see Figure 3) and have been merged with models of water and mineral transport in the soil (Clausnitzer and Hopmans, 1994). This approach allows a much more realistic simulation of plant development in a transient environment, and the quantitative study of the soil–plant system. Increasing the quality of our predictions regarding the soil–plant–atmosphere fluxes is an important challenge, in which architectural models have a prime position.

Another important comprehensive step has been made by modeling water (Doussan et al., 1998) and sugar (Bidel et al., 2000) transport within the root system architecture. These approaches make another bridge between functional and morphological aspects of the root system architecture, by integrating both developmental processes and transport processes of various resources described on root parts (meristems and root segments). These approaches make possible the emergence, at the root system organization level, of the overall consequences of local mechanisms described at the root part level.

Models allow the simulation of a virtual infinity of combinations, crossing plant and environmental

Root System Architecture: Analysis from Root Systems to Individual Roots, Figure 3 Examples of drawn and simulated root systems, after Pagès et al. (2004). Drawn root systems (on the left) have been observed in the field. Simulated root systems (on the right) come from a model which combines several developmental processes, and takes into account interactions with the soil.

situations. In this way, architectural diversity and functional consequences can be explored further.

Conclusions

The root system architecture (shape and structure) is a key concept that should be considered for understanding better many functions of the soil plant systems. For this purpose, it is helpful to consider architecture with a dynamic point of view, and to relate it to the developmental processes, which combine during the plant cycle. In this task, simulation models are necessary tools for representing a number of soil–plant interactions in a quantitative perspective.

Definition

Root water uptake (water extraction or water absorption): water flow from the soil to the root.

3D functional approaches (or functional–structural plant modeling): modeling approach aiming at representing virtual plants with their three-dimensional (3D) architecture and selected physiological functions.

Introduction

Water is an essential resource for plant life. Typically, cropped plants transpire 200–1,000 kg of water for each kilogram of dry matter produced (Martin et al., 1976), and this water is principally extracted from the soil by the roots. Therefore, modeling of soil water uptake by plant roots is of importance for a series of environmental and agronomic purposes. Numerous practical applications like yield prediction, irrigation management, or pollutant fate prediction under cropped fields need a detailed

understanding of the interactions between soil water and roots to be investigated as well as advanced modeling approaches.

The uptake of water by roots is mainly a passive process driven by water potential gradient between the soil around the root and the xylem (Steudle and Peterson, 1998). At the root scale, uptake depends on the local soil and root hydraulic properties (including the interface between soil and root). At the plant scale, the root water uptake (RWU) is, amongst others, linked to the plant root xylem network topology, the location of the roots in the soil, the distribution of the soil water, the regulation of transpiration by the leaves, and the vapor pressure deficit in the atmosphere (Feddes and Raats, 2004). Root locations and distribution in the soil but also root hydraulic properties and xylem network are therefore key parameters for modeling of root water uptake at the plant scale. Yet, they are relatively difficult to assess and are extremely variable in space and time.

Plant root systems develop spatially to optimize the extraction of nutrients and water from the heterogeneous and varying soil environment (Fitter, 1987; Schymanski et al., 2008). In turn, the spatial distribution of the roots impacts the soil water content distribution and the drainage to deeper layers. Across time, the root system growth and spatial deployment (its architecture) will result from genetic traits modulated by root plasticity, i.e., the capability of roots to adapt their development to soil spatio-temporal variations and growth constraints (see [Root Responses to Soil Physical Limitations](#)). In addition, within a root system, the size, diameter, location, and hydraulic properties (cortex and xylem conductivities) of root segments also vary with the root type (e.g., branching order) and age (Pierret et al., 2007) (see [Root System Architecture: Analysis from Root Systems to Individual Roots](#)). On the other hand, the distribution of water in soils is usually quite variable, especially close to the surface because of interception/redistribution processes (canopy interception, surface runoff, etc.) and soil natural heterogeneity. As a consequence, it is expected that root water uptake patterns will be spatially heterogeneous and vary with time as a function of soil and root properties and the climatic demand. The use of three-dimensional modeling based on an accurate description of the root architecture should thus help to gain better insights into soil exploration and foraging processes by roots (Draye et al., 2010).

Several models describing 3D root growth are now available (Wu et al., 2005). However, to date, only a few models with explicit account of the full 3D root architecture to predict water uptake have been developed (Green et al., 2006). Clausnitzer and Hopmans (1994) developed such a model. It consists of a three-dimensional root growth model combined with a three-dimensional, transient soil water flow and solute transport model based on the finite-element method. In their model, root growth depends on the spatial distribution of temperature, water content, and soil strength. Root water uptake is taken as

proportional to the local root length density. However, water flow within the root system is not modeled, and thus the distributed root sink term does not depend on the water potential gradient between the soil and roots but only on the soil water potential, by means of a stress function. On the other hand, Doussan et al. (1998) proposed a modeling of water uptake and flow within the root system, where the soil was not limiting water transfer. Recently, Doussan et al. (2006), Javaux et al. (2008), and Schneider et al. (2010) developed a fully coupled root architecture soil water transfer model, where the water flow equation is solved in both the soil matrix and the root xylem network. Such 3D functional models offer the possibility of explicitly considering the spatial and temporal changes of the root and soil conductivity and thus, are the basis of a fully integrated approach for modeling fluxes at the plant scale.

Other 2D or 2,5D approaches which attempt to simplify the 3D root systems to predict root water uptake (Roose and Fowler, 2004; Siqueira et al., 2008; Amenu and Kumar, 2008; De Willigen and Noordwijk, 1987) are also being developed, but these will not be reviewed here.

Modeling principles

3D Root water flow model

Doussan et al. (1998) proposed an algorithm to solve the water flow within the whole root system as a function of the soil water status. They simplified the root architecture as a series of interconnected nodes, in which radial (soil to root) and longitudinal (along xylem vessels) flow take place. Assuming that the osmotic potential gradient generates negligible water fluxes, the volumetric radial water flow [$L^3 T^{-1}$] between the soil–root interface and the root xylem can be written as

$$J_r = K_r s_r [H_s(z) - H_x(z)], \quad (1)$$

where H_s and H_x are the total water potentials (written on height basis, or water head) at the root surface and in the xylem [L], K_r is the radial conductivity [T^{-1}], and $s_r = 2\pi r_{int} l$ is the root–soil interface area [L^2] with l , length of the root segment and r , the root radius. Note that the total (negative) water potential is $H = h + z$ [L], where h is the matric (in soil) or the hydrostatic (in root) heads and z , the altitude (oriented upward). Longitudinal water flow in the xylem [$L^3 T^{-1}$] is defined as

$$J_x = -K_x^* A_x \frac{dH_x(z)}{dl} = -K_x \left[\frac{dh_x(z)}{dl} + \frac{dz}{dl} \right] \quad (2)$$

with H_x – the total xylem water head, A_x – the xylem cross-sectional area [L^2], dl – an infinitesimal segment length [L], K_x^* – the axial conductivity [$L T^{-1}$], and $K_x = K_x^* A_x$ [$L^3 T^{-1}$] – the xylem conductance. Note that, in Equations 1 and 2, radial and xylem conductivities may be considered as variables dependent on water potential value or root type and age.

Equations 1 and 2 can be used to define the water mass balance for a given root node i as:

$$\begin{aligned} & K_{x,i:i-1} \frac{(H_{x,i} - H_{x,i-1})}{l_{i:i-1}} \\ &= K_{x,i+1:i} \frac{(H_{x,i} - H_{x,i+1})}{l_{i+1:i}} + K_{r,i}^* s_r (H_s - H_x), \end{aligned} \quad (3)$$

where the right-hand side term refers to the water flow from node i to node $i - 1$ (mother node) through the segment $i : i - 1$ with a length $l_{i:i-1}$ and a root xylem conductance $K_{x,i:i-1}$ while the subscripts $i + 1 : i$ refer to the segment between the nodes $i + 1$ and i . Equations 1 and 2 (discretized by Equation 3) can be solved analytically for one-root segment (Landsberg and Fowkes, 1978). When generalized to the whole root system, the water potential distribution in the xylem is obtained by solving a system of linear equations derived from Equation 3, which writes in matrix notation (Doussan et al., 1998),

$$\mathbf{C} \cdot \mathbf{H}_x = \mathbf{Q}, \quad (4)$$

where \mathbf{C} (dimensions $n_p \times n_p$ with n_p the number of root nodes) is called the “conductance matrix,” \mathbf{Q} (dimensions $n_p \times 1$) contains the soil factors, and \mathbf{H}_x (dimensions $n_p \times 1$) is the unknown xylem water potential vector.

Soil water flow

Water flow in soils with root uptake can be described by the Richards equation with a 3D root sink term (Vrugt et al., 2001):

$$\frac{\partial \theta}{\partial t} = \nabla \cdot [\mathbf{K} \nabla (h + z)] - S, \quad (5)$$

where θ is the volumetric water content [$L^3 L^{-3}$], t is the time [T], \mathbf{K} the hydraulic conductivity tensor [LT^{-1}], h the matric head [L], S the sink term representing the distributed root water uptake [T^{-1}], and z the vertical coordinate [L]. Both θ and \mathbf{K} are nonlinear functions of the matric head, which are called the unsaturated hydraulic soil properties.

Different numerical solutions exist to this nonlinear equation based on finite element or finite volume methods, which require a soil discretization with a 3D grid (see [Soil Water Flow](#)).

Coupled model

Coupling soil and root water flow requires the merging of two very different geometrical domains: the three-dimensional numerical soil grid made of voxels and a tree-like root network. This coupling is necessary since the Richards equation (Equation 1) needs the sink term distribution S to be known, while the root system depends on soil water potential distribution h around the roots

(Equation 5). In the coupled model, the root sink term for soil a voxel j is defined as

$$S_j = \frac{\sum_{i=1}^{n_j} J_{r,i}}{V_j}, \quad (6)$$

where the numerator represents the sum of all the radial fluxes toward the n_j root nodes located inside a soil voxel j [$\text{L}^3 \text{T}^{-1}$], and V_j is the volume of the j th soil voxel [L^3].

To solve the root flow equation for the whole root system, the soil water potential around each root node $\langle H_s \rangle_i$ is needed. Assuming that the water potential at the soil–root interface would be the same as the bulk soil, water potential at the soil–root interface can be defined as a weighed average of the soil pressure head $H_{s,k}$ of the soil voxel nodes (n_{vox}) which surround the root node i as follows:

$$\langle H_s \rangle_i = \frac{\left(\sum_{k=1}^{n_{\text{vox}}} \frac{1}{dist_k} H_{s,k} \right)}{\sum_{k=1}^{n_{\text{vox}}} \frac{1}{dist_k}}, \quad (7)$$

where $dist_k$ [L] represents the spatial distance between the root node i and the soil node k . The radial flow rate from soil to root node i is then written as:

$$J_{r,i} = K_{r,i}^* s_{r,i} [\langle H_s \rangle_i - H_{x,i}]. \quad (8)$$

The radial fluxes of all root nodes located inside a soil voxel j are then summed up to estimate the soil sink term in Equation 6. The sink term is now defined as a function of the local root water uptake, which explicitly depends on the water potential gradient between soil and root.

Equation 7 holds for fine soil mesh (small soil voxel size). Indeed, in that case, the water potential at the soil nodes is relatively close to the water potential at the root–soil interface. However, alternatives to Equation 7 exist for estimating the water potential at the soil–root interface with greater voxel sizes, like adding an analytical solution of the soil water flow equation at the sub-voxel scale (Schroder et al., 2009a). Also, local grid refinement may be used to describe the water potential field around the roots more accurately (Schroder et al., 2009b).

For coupling the water flow in both the soil and root systems, an implicit iterative scheme must be used (Garrigues et al., 2006; Javaux et al., 2008). First, the root flow is solved, given an initial estimate of the pressure head distribution in the soil. This generates a first estimate of the xylem pressure head H_x and water flow distribution (Equation 7). A 3D sink term distribution can thus be calculated from Equation 6 and used in the numerical solution of the Richards equation (Equation 1). These two steps are repeated until the maximum change in root and

soil pressure head over all the nodes does not exceed a given threshold value and there is no change in the total water uptake between consecutive iterations.

Potentials of 3D RWU models

Figure 1 illustrates typical outcome of 3D RWU model simulations. It shows the distribution of the water potential distribution in the soil and within the xylem network for a maize root subject to a 1-week dry period and the corresponding sink-term profile from Equation 6 aggregated in 1D. Doussan et al. (2006) used such a model to investigate the effect of root architecture on water uptake. He showed that tap-rooted architecture induced more concentrated uptake zone than fibrous systems. Javaux et al. (2008) showed that classical stress function could not be used to account for the effect of soil water availability on root water uptake and suggested that such models could be used to deduce effective stress equation for simpler models.

Other uses for soil–plant models include the investigation of water uptake with root architectural traits (De Dorlodot et al., 2007; Lynch, 2007), the study of the influence of the soil heterogeneity or irrigation conditions (Hodge et al., 2009), the simulation of the responses of virtual plants carrying diverse combinations of alleles under different scenarios of abiotic stress (Tardieu, 2003), or the understanding of optimal root development under various climate conditions. Such models can also be used as tools to integrate our knowledge on plant uptake processes and when confronted to real measurements, emphasize gaps in our knowledge and models.

Challenges

Numerous challenges associated with the development of these detailed 3D root water uptake models still remain. Two types of challenges can be identified.

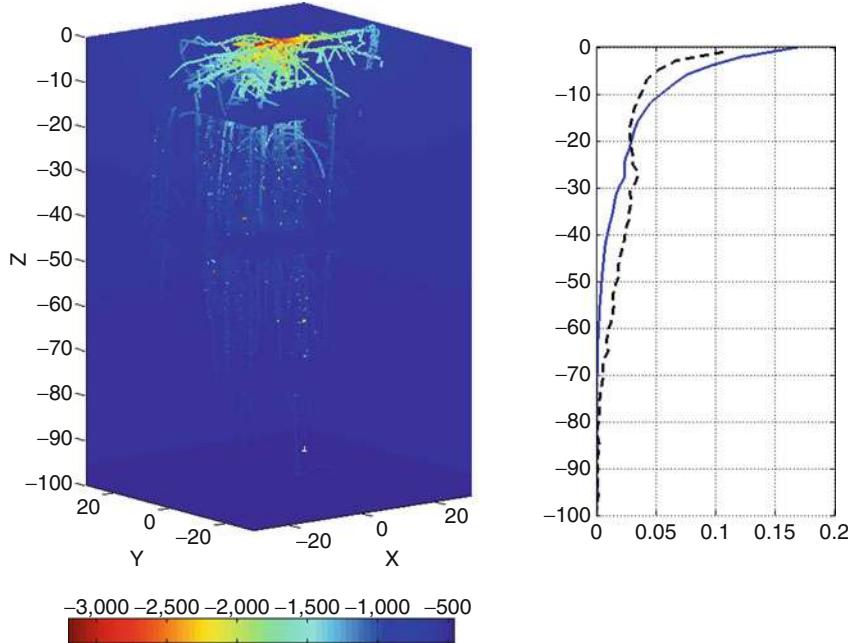

Improving numerical solutions

Such models are complex and computationally demanding. Further development in the numerical solutions of the underlying model equations includes:

- Improvement of model numerical accuracy: in particular, very heterogeneous and rapid changes in water fluxes induced by plant uptake may render the solution of the flow equations difficult and prone to errors. On the other hand, analytical solutions hardly exist and this makes the comparison difficult.
- Reduction of model computation time: 3D models are computationally expensive and time demanding. Parallelization is one way to speed up the computation time (Hardelauf et al., 2007).

Improving process modeling

Soil–Plant/Root water uptake models are relatively demanding regarding parameters. Each root segment has its own hydraulic properties. Root architecture in three

Root Water Uptake: Toward 3-D Functional Approaches, Figure 1 *Left:* Distribution of the soil and xylem water potential (cm) after a 7-day dry period for a maize root. *Right:* depth-normalized root length density profile (—) (dashed line) and depth-normalized sink term profile (—) (blue line) computed from 3D computations.

dimensions as well as the parameterization of the soil must be known. Many of these parameters are not readily available, which makes the use of such complex models difficult today. In addition, some processes are still unknown. Improvement of such models will require strong interaction between modelers, soil hydrologists, agronomists, and biologists. Amongst others, remaining open issues are:

- Root architecture characterization: Root architecture can either be modeled or measured. New imaging methods have recently been developed and allow the detailed assessment of the root architecture needed for these 3D models (Oswald et al., 2008; Pohlmeier et al., 2008; Moradi et al., 2009). Root growth models could also be used to generate replicates of probable root systems in case no real data is available.
- Root soil interface: a model is always a simplified representation of the reality. The level of details involved in the root description cannot explicitly resolve root hairs or very fine roots or mycorrhiza, which may actually be an important pathway or uptake. Air gaps may appear and change the interface area between soil and roots (Carminati et al., 2009). This could be taken into account by varying s_r in Equation 1 in function of the root water potential.
- Rhizosphere: the rhizosphere is the volume of soil shared by bacteria, where roots have a direct influence

(Gregory, 2006). Many biological, biochemical, chemical, and physical processes occur in rhizosphere, and these will have a direct influence on the root and soil properties, potentially affecting the root water uptake. Incorporating rhizospheric processes in a plant scale model still remains challenging (Luster et al., 2009) (**Rhizosphere**).

- Biological processes and parameterization: knowledge gaps still exist regarding how certain parameters vary with time. Lateral flow through plant cortex, for instance, depends on active mechanisms which may change the root radial conductivity (Vandeleur et al., 2005). Xylem vessels are also prone to embolism (Sperry et al., 2003), which would make xylem conductance (K_x in Equation 2) dependent to water potential as well. On the other hand, very complex mechanisms mediate the response of plants to biotic and abiotic stresses (Hodge et al., 2009). Many of these mechanisms are likely to affect the water flow resistance through the soil–plant atmosphere system but are still unknown.

Conclusions

The development of numerical facilities and the current interests for sustainable food productions open new avenues for investigating root–soil interactions with water uptake models based on root architecture. New models have recently been developed and are today capable of

dealing with complex soil and plant descriptions. These 3D soil–plant functional models represent the basis of a coupled model, where energy and matter fluxes and related biochemical, chemical, and physical processes are fully integrated at the plant level. Advances made in noninvasive measurement techniques and in understanding the mechanisms underlying the plant water regulation will probably improve the prediction performance of such models in the near future and make them an instrumental to understanding the complex mechanisms controlling water and nutrient fluxes in the soil/plant continuum.

Definition

Salinity is the presence of soluble salts in soils or waters. It is a general term used to describe the presence of elevated level of different salts such as sodium chloride, magnesium and calcium sulfates, and bicarbonates in liquid phase of soil and in water.

Introduction

The natural and man-induced salt accumulation is a major threat for agricultural activity in arid and semi-arid regions. Several processes of climate change might strengthen the salt accumulation. Because of the decreasing amount of precipitation, leaching is getting more and more limited. The rising temperature increases the evaporation, which accompanied with upward water movement, transferring salts from underground to the soil surface. The consequence of the increasing frequency of drought situation is the rising demand for irrigation water.

The global warming would substantially impact the availability and quality of irrigation water. Scarcity of good quality water emphasizes the use of marginal waters with higher salt content. Because of the possible increasing salt stress, it is very important to investigate the effect of salts on soil properties for establishing a sustainable land use on the areas threatened by secondary salinization.

Indicators of salinity

Soil salinity is estimated from the electrical conductivity (EC) of a saturated soil paste. It is expressed in dSm^{-1} . The sodium adsorption ratio (SAR) is a measure of comparative concentration of Na^+ to Ca^{2+} and Mg^{2+} ions in a soil solution or in irrigation water.

Effect of salinity on soil structure

It is generally accepted that an increasing electrolyte concentration has a flocculating effect on the soil colloids and strengthens the stability of micro-aggregates (Abu-Shara et al., 1987; Goldberg et al., 1988; Tajik et al., 2003). Regarding the macro-aggregate stability, the positive effect of higher salt concentration is not unanimously proved. In several experiments, despite the better microaggregate stability, the macro-aggregates were not affected by the electrolyte concentration (Goldberg et al., 1988; Shainberg et al., 1992).

Effect of EC and SAR on soil permeability

The simply saline soils usually occur on parent materials with low colloid content. On soils with colloidal particles, both the water soluble and the exchangeable forms of cations can be found.

For characterizing the simultaneous effect of EC and SAR or ESP, the threshold concentration concept was elaborated by Quirk and Schofield (1955). They measured the permeability of soils saturated to varying degrees with exchangeable sodium, and obtained a threshold concentration that was defined as that concentration of electrolyte at which clay swelling and deflocculation had an appreciable effect in decreasing the permeability.

Several investigators concluded that a higher EC value (especially if it is caused by neutral salts) could counterbalance the adverse effect of SAR or ESP on the hydraulic conductivity (Quirk, 1971; Agassi et al., 1981; Várallyay, 1981; Shainberg and Letey, 1984; Abu-Shara et al., 1987).

Effect of Ca^{2+} and Mg^{2+} on physical properties of soils

The effect of salinity on the structural properties and transport processes depends not only on the salt and sodium concentration of the soil or of the irrigation water, but on the other cation and anion composition of water as well. Among the cations, the positive effect of Ca^{2+} on the soil structural and transport properties has been proved. The main goal of the chemical amelioration of waters and soils is increasing the Ca^{2+} concentration in the water and the Ca^{2+} saturation of the colloidal surface. The usual amelioration practice of saline soils is to apply gypsum or other soluble calcium compounds to the soil to keep a high electrolyte concentration with low SAR level, which is suitable to maintain a high infiltration rate and to leach the sodium salts with irrigation water.

The judgment of the soil physical role of Mg^{2+} is not so consistent. From the viewpoint of potentially different physical effect, the Ca^{2+} and Mg^{2+} are not distinguished when calculating the SAR value of waters by Richards (1954). Negative effects of Mg^{2+} were observed in the countries where well-water with high Mg^{2+} content was used due to the scarcity of good quality water. Girdhar and Yadav (1981) pointed out that increasing Mg^{2+} in water caused increased water retention of the soil at 15 bar suction. They found that the irrigation water with high Mg content increased the exchangeable Mg content of a CaCO_3 containing soil lesser than that of non-calcareous soil. Alperovich et al. (1981) found that exchangeable Mg did not have a specific effect on the clay dispersion and on the hydraulic conductivity in calcareous soils. In contrast with these findings, Keren (1991) concluded from the result of a rainfall simulation experiment that the Mg soil surface was more susceptible to sealing than the Ca soil, regardless of the presence of CaCO_3 .

There are results showing a higher dispersion of montmorillonite and illite in the presence of Na and Mg, than in a Ca and Na system (Bakker and Emerson, 1973; Emerson and Chi, 1977).

Blaskó and Karuczka (2001) investigated the effect of water with increasing MgSO_4 concentration (from 0 to 30 meq l^{-1}) on some physical properties of the soil. The infiltration rate, in accordance with the general rule by which a higher electrolyte concentration causes faster infiltration, was higher under the influence of higher Mg^{2+} concentration in irrigation water. The stability of micro-aggregates of the irrigated soils did not change. The swelling and shrinking properties were not influenced by the MgSO_4 in spite of the fact that the exchangeable magnesium percentage, as a consequence of irrigation with water of high magnesium content, got higher than 30, which was considered according to Ellis and Caldwell (1935) to be limit value of "magnesium solonet." Beside the high magnesium saturation, the exchangeable sodium content was negligible. It seems from the results, that the damaging effect of Mg to soil physical properties is expressed more in the presence of Na than in Ca–Mg system.

The partly contradictory results on the physical effects of Mg^{2+} give the reason for further investigations, especially in countries where irrigation water rich in magnesium is widely used.

Effect of anions on physical properties of soil

Taking into account the anion components of soils, two main groups of salt-affected soils can be distinguished (Szabolcs, 1969):

- Soils affected by neutral sodium salts (NaCl , Na_2SO_4).
- Soils affected by sodium salts capable of alkaline hydrolysis (NaHCO_3 , Na_2CO_3 , Na_2SiO_3).

The specific effects of different anions are well known. The carbonate and hydrocarbonate type of salinization is much more dangerous from the viewpoint of soil physical properties than the chloride and sulfate type of salinization, especially in soils with smectite type clay mineral. Even a very little amount (0.1%) of sodium carbonate can cause dispersion and swelling reducing the soil hydraulic conductivity and leading to a stop of the leaching process (Szabolcs, 1969; Várallyay, 1981).

Salinity, availability of water and osmotic stress

In spite of the positive effect of neutral salt content on the water transport in the soil, the whole water regime of the soil–plant system is adversely affected by increasing salt content, because the total available water is much less in soils with high salinity than in non-salt-affected soils (Ayers and Westcot, 1976). Because of the high wilting percentage and higher osmotic potential of the soil water, a salty soil needs more frequent irrigation and higher leaching fraction of irrigation water to leach out the salts from the root zone.

From the point of view of osmotic stress, salinity caused by soluble calcium salts is the same or sometimes more dangerous than the salinity caused by sodium salts (Aceves et al., 1975).

Conclusions

Increasing salinity, in general, caused by neutral salts, creates better conditions for flocculation and mitigates the swelling of clay minerals. The consequences of these processes are the better structural and water transport characteristics. The cation and anion composition of the soil water can modify the general rule. The higher the SAR value of the soil or of the irrigation water, the higher EC volume is necessary to maintain the good structural and transport properties.

The diverse effect of neutral and alkali sodium salts is well defined, but there are partly contradictory results concerning the physical effects of Mg^{2+} .

In spite of the favorable physical effects of neutral salts, the extreme increase of their concentration must not be the solution for the soil physical problems, because the high salt concentration causes an osmotic stress even in the case of neutral calcium and magnesium salts.

SCALING OF SOIL PHYSICAL PROPERTIES

Asim Biswas, Bing Cheng Si
Department of Soil Science, University of Saskatchewan,
Saskatoon, SK, Canada

Definition

Soil spatial variability. Soil properties measured at different locations exhibit different values.

Self similarity. Soil properties measured at points close to each other are more similar than those located far apart.

Scale. It is a characteristic length or time.

Scale dependency. The statistical measure of soil properties change with change in scale.

Scale invariance. A measure of a soil property at a scale is a power function of the scale with the exponent independent of scale.

Introduction

Soil physical properties are highly variable and exhibit scale-dependent spatial variability (Nielsen et al., 1973; Burrough, 1983). For environmental, hydrological, and agricultural applications, some questions are always being asked about soil physical properties: What is the most representative scale of variability and at which scale should we measure the soil physical properties? How does the variability change with scales? How can we interpret and correlate soil processes over scales, given the information collected at a given scale? Can we interpolate (disaggregation) or extrapolate (aggregation) the information from one measurement scale to others? Can we transfer the information from local observation to large scales?

These issues arise as the scale of measurements differs from the scale of application. In another word, the scale at which the information is collected is different from the scale at which the prediction is necessary or the information will be used. Similarly, the actual scale of soil processes is quite different from our scale of observation. There is always a gap between the scales at which real soil processes are going on; we measure the soil physical

properties, and we predict them or we want to use the information. To make a bridge for the gap, we need to understand the scaling of soil physical properties.

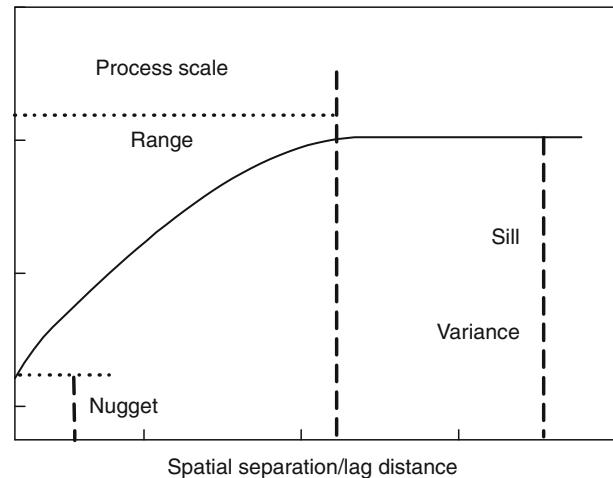

Concept of scale

Soil physical properties can vary frequently in space and are called small-scale variability. Similarly, they can vary slowly in space and are called large-scale variability. The scale at which the actual soil processes are going on is generally considered as process scales, whereas the scale at which measurements of soil physical properties are taken in field is known as measurement scale or observation scale. The scale, at which a model is established or used for validation and prediction, is known as model scale.

Process scale

Though the process scales are related to the spatial dimension of the natural variability of soil processes, it is defined as the range of their correlation. This correlation range is the representative spatial distance within which a soil physical property behaves similar or the relationship between multiple soil physical properties does not change. Within this range, soil physical properties are autocorrelated as a result of spatial continuity or inter-sample dependence and are explained as self-similar (Goovaerts, 1997). The correlation range can be estimated from the experimental semivariogram, which is the backbone of geostatistics. A detailed review of geostatistics can be found in Trangmar et al. (1985) and Si et al. (2007). Semivariogram measures the average dissimilarity between the pairs of data points. It is a plot of semivariance (half of the average squared difference between points that are separated by lag distances) as a function of spatial separation or lag distance. A well-behaved semivariogram (Figure 1) increases from a minimum value at smallest lag (lag = 1) distance or unit separation until a plateau is reached, where the semivariance remains constant with increasing lag. The extrapolated minimum semivariance at lag = 0 is known as the “nugget,” the lag at which the semivariance reaches its maximum is called “range,” and the maximum semivariance value is known as the “sill” (Figure 1).

Different soil physical property may have different correlation range. For example, Zeleke and Si (2005) reported the correlation range of different soil physical properties including sand (116 m), silt (173 m), clay (43 m), and organic carbon (43 m) from a gently undulating field in cold and subhumid climate in Canada. Further, for the same soil physical properties, the correlation range changes from field to field. For example, Ceddia et al. (2009) reported the correlation length of 56.9 and 86.8 m for bulk density and sand, respectively in a Brazilian soil. Sometimes, there may be several processes operating together contributing to the variability of soil physical properties, which can be represented as the nested spatial structure with multiple ranges. Each range is the characteristic scale of a particular process. Biswas and Si (2009)

Scaling of Soil Physical Properties, Figure 1 A typical semivariogram showing its components and indicating process scale.

reported two ranges of 20 and 120 m, suggesting two different processes that controlled the variability of soil physical properties including bulk density, sand, silt, and clay. The joint correlation length for two soil physical properties can be identified from the cross semivariogram analysis. Once the characteristic scales are identified, the scale information can be used to interpolate the information for unsampled locations through a process called “kriging.” Kriging can produce a detailed map of soil properties once the dominant scale is identified from the semivariogram spatial structure.

Multiple processes can operate together at different scales, thus creating multiple ranges in soil physical properties. Similarly, the intensity of the processes can vary over scales and make their contribution to the total variance scale dependent. For example, one process contributes majority of variance to the total variance at one scale, while at other scales, it has a different level of contribution or even may not have any contribution to the total variance. Some of the processes can also be transient in time and/or location. Like mean and variance, semivariogram is a global measure and cannot deal with transient and location-specific, nonstationary features. Wavelet analysis can be used in this situation to identify and separate out dominant scales of variability of soil physical properties. It is an advanced statistical method that can partition total variation into different scales and locations. For example, using wavelet analysis, Si and Zeleke (2005) reported the scale for organic carbon as 6–24, 60, and 100 m. The dominant scale of variation between two physical properties can also be identified from wavelet coherency analysis. The details of wavelet and wavelet coherency analysis technique in explaining the variability of soil properties is available in Lark and Webster (1999), Si (2003), Si and Zeleke (2005), and Biswas and Si (2008).

Measurement scale

The scale at which measurements for any soil properties has been taken is called measurement scale. According to Blöschl and Sivapalan (1995), measurement scale consists of three important characteristics: spacing, extent, and support, which are also known as the “scale triplet” (Figure 2).

Spacing is the distance between samples, extent refers to the total coverage of the measurements, and support is the area over which a measurement is taken. All the three components are needed to uniquely specify the space dimension of a measurement. The measurement scale can be small and restricted to ground-based measurement of a small field (where spacing and extent is small, but support can be little bigger as each point averages the soil property over a certain area) or an aerial measurement by remote sensing for a large area (spacing can be variable based on image resolution, extent is large, and support is small and represented by a point).

Model scale

Model scale also consists of the “scale triplet” (Blöschl and Sivapalan, 1995) similar to the measurement scale (Figure 2). However, it is related to the spatial properties of model rather than those of measurements. Scale triplets depend on the resolution of the map to be produced, the area to be mapped and the area, of which each point in the map is representative.

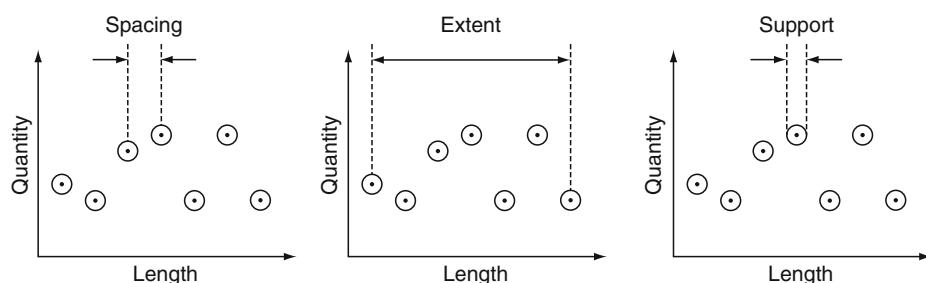

Scaling

We often need to use the information from one scale to another. This change in scale is known as scaling (Beven, 1995). Generally, there are two changes in scale, from the true processes to the observation (i.e., scaling by measurement) and from the observation to the prediction (i.e., scaling by model). How the measurement scale triplets change the true pattern to be reflected in the observation and how the model scale triplets change the observation to be reflected in predictions are the main interest in understanding scaling. There are some similarities in this scaling (Blöschl and Sivapalan, 1995; Blöschl, 1999). For example, small-scale variability will not be captured if the observation spacing is too large and the large-scale

variability will not be captured if the extent is too small. Similarly, if the support of the observation is too large, most of the variability will be averaged and smoothed out. Therefore, the pattern reflected in the measurement is a filtered true pattern in a real field. The effect of filter is closely related to the ratio of the measurement scale to process scales. The small-scale variability will not be captured if the spacing of the measurement is too large compared to the process scales. Model scale also has the similar effect. If the model scale is larger than the process scales, most of the variability will not be captured in prediction. The interpolation, extrapolation, disaggregation, and aggregation of information always imply the change in scales, which can also be viewed as filtering. This scaling issue can merely be solved by simply considering the differences in space. It is further compounded by the spatial variability of soil properties and the nonlinear nature of soil processes. The spatial variability of soil properties can be taken into account using geostatistics as a linear stochastic filter, and the nonlinearity of soil processes can be taken into account through physically based modeling as nonlinear deterministic filter.

In linear approximation, the small-scale variability within elements and large-scale variability between elements add up to the total variability (Isaaks and Srivastava, 1989). The large-scale processes (larger than element size) are explicitly presented in the model, and the small-scale processes (smaller than element size) are parameterized through some lumped relationships (Blöschl, 1999). In most cases, the small-scale variability within an element is unknown (Beven, 1995), and hence a lumped representation as sub-grid variability (variability within a sub-grid cells) is appropriate and necessary. The spatial interpolation through geostatistics is used to represent the spatial variability of soil processes between elements.

In geostatistics, the processes can be aggregated through simple arithmetic averaging and therefore, it assumes that (1) upscaling from measurements through simple arithmetic averaging will not have an effect on the expectation (of mean) and (2) the variable to be examined is a second-order stationary random variable. In nature, sometimes it is difficult to satisfy both

Scaling of Soil Physical Properties, Figure 2 The scale triplet (spacing, extent, and support). (After Blöschl and Sivapalan, 1995.)

assumptions as many processes aggregate nonlinearly. Nonlinearity does not allow aggregating the processes through simple arithmetic averaging. For example, suppose that soil hydraulic conductivity is measured at every $5 \times 5 \text{ cm}^2$ from an area of $10 \times 10 \text{ m}^2$. The simple arithmetic average of the 4,000 small-scale soil hydraulic conductivity measurements will be much smaller than the measurement made at $10 \times 10 \text{ m}^2$. If soil pores are vertically straight, then the simple arithmetic averaging will lead to a similar result to the large-scale measurement. In reality, soil pores are extremely tortuous, and pore connectivity (especially preferential pores) is much smaller in small soil cores than in a large area, resulting in much smaller hydraulic conductivity from small-scale than from large-scale measurements. This nonlinearity requires a distributed physically based model that incorporates the complexity of the physical processes as much as possible. In distributed modeling, the extent of a scale is subdivided into different square grid cells. This is done through splitting the total spatial variability into a small-scale part of variability within elements and large-scale parts of variability between elements (Blöschl, 1999).

The above-mentioned scaling methodology is very pragmatic but is limited to mean and variances. And there are no theoretical bases for determining if the proposed scaling method is accurate. An elegant theory was proposed by Mandelbrot (1982) and is very applicable in upscaling or downscaling of these statistical moments. The spatial patterns of soil properties observed at different scales may be related to each other by a power function (power law relations) (Mandelbrot, 1982), whose exponent is known as fractal dimension:

$$\langle X^q \rangle(s) \rightarrow s^\alpha, \quad (1)$$

where X is the spatial series representing soil physical property, q is the order of moment, s represents scale, and α is the fractal dimension. Therefore, any statistical moment of the soil physical property at any scale can be obtained, once the fractal dimension is known. Fractal theory has been utilized to investigate and quantitatively characterize spatial variability over a range of measurement scales (Mandelbrot, 1982; Burrough, 1983). Fractals were first introduced into soil science in representation of the particle size distribution, where cumulative mass or volume is a power function of particle size (Tyler and Wheatcraft, 1992; Taguas et al., 1999; Millán et al., 2003). A detail presentation of fractal theory and its application to soil science is available in Mandelbrot (1982), Tyler and Wheatcraft (1992), Perfect and Kay (1995), and Millán et al. (2003). When the variability of a soil property can be explained by a single fractal dimension, it is known as monofractal. Zeleke and Si (2006) found the monofractal behavior of bulk density and sand and silt contents in an agricultural field. More often than not, any spatial statistical moments of soil physical properties

exhibit fractal properties (obey the power law), but the exponents are different for different order of statistical moments:

$$\langle X^q \rangle(s) \rightarrow s^{\alpha(q)}, \quad (2)$$

where $\alpha(q)$ is a function of moment order q . We call this soil physical property multifractal. For each order of moment, the soil physical property is monofractal, but different q requires a different α . Multifractal soil properties are governed by a random multiplicative process, and systematic analysis of this behavior enables characterization of complex phenomenon in a fully quantitative fashion (Stanley and Meakin, 1988). Multifractal is also a technique that transfers irregular observation into a more compact form and amplifies slight differences among the variables distribution (Lee, 2002). The knowledge of soil physical properties being monofractal or multifractal is very important for scaling. For monofractal soil properties, any statistical moments can be scaled through a single exponent (fractal dimension). For multifractal soil properties, scaling can be done for any statistical moment, but the scaling exponent is different for different order of statistical moments. While fractal analysis is a very powerful tool for obtaining scaling exponents, different soil physical properties can be fractal or nonfractal, and there are a priori methods to determine if a soil physical property is fractal or nonfractal. Therefore, measurements at different scales have to be taken before we can determine whether the soil properties are fractal or not. The organic matter (Kravchenko et al., 1999; Zeleke and Si, 2005; Zeleke and Si, 2006) and clay content (Zeleke and Si, 2005; Zeleke and Si, 2006) showed multifractal behavior, while bulk density, sand, and silt (Zeleke and Si, 2005; Zeleke and Si, 2006) showed monofractal behavior, indicating that organic matter and clay content are more heterogeneous than bulk density, sand, or silt.

Summary

Soil physical properties vary from location to location and at scales. This article addresses the basic concepts of scale and the scaling or the transfer of information from one scale to another. The spatial distance of the natural variability of soil processes, which can be identified as the distance within which a soil property behaves similar or the correlation between multiple properties does not change is known as the processes scale. Geostatistics can identify the distance of spatial correlation as the “range.” The process scale varies with field and environmental situation. Sometimes, there can be several processes operating together in a field representing through multiple ranges. These processes sometimes may operate at different intensities and at different locations. Wavelet, an advanced mathematical analysis, can deal with scale- and location-specific variability. The scale- and location-specific variability between two properties can be identified through wavelet coherency analysis. The characteristic scales can

be used to predict the soil properties at unsampled locations through “kriging.” The process scale is the actual scale of occurrence of soil processes. However, the measurements are not always recorded at process scales. The measurement scale depends on the spacing or distance between measurement, extent, or total coverage of measurement, and the support or the area of the measurement. These “scale triplets” are also important for model scale, which depends more on the spatial properties of models than measurements.

Now the change in information from true processes to observation and from observation to prediction is known as scaling. The aggregation, disaggregation, interpolation, and extrapolation always imply change in scale or scaling. However, the spatial variability and the nonlinear nature of soil process do not allow simple consideration of space. The former can be taken into consideration as a linear stochastic filter and the later through physically based modeling as deterministic filter. However, these methods are limited to means and variances. The higher-order statistical moments can be upscaled or downscaled if the spatial pattern of soil properties observed at different scale can be represented through a power function. This is known as power law relationship. Once the relationship is observed, any statistical moments of soil physical properties can be obtained at any scales. This is known as fractal relationship. The relationship over scales can be represented through a single dimension, which is known as monofractal or can be different for different statistical moments, which is known as multifractal. This type of behavior of soil properties is important for scaling.

Shrinkage and swelling of food

Definition

Shrinkage—The physical phenomenon of a body becoming smaller frequently observed during drying.

Swelling—The physical phenomenon where a porous body becomes larger by absorbing water or during imbibition and hydration processes.

Introduction

The present demand for high-quality products in the food market requires dehydrated foods that maintain most of the quality characteristic of the fresh product. Dehydration of agricultural products is one of the most common processes used to improve food stability, because it decreases considerably the water activity of the material, reduces microbiological activity, and minimizes physical and chemical changes during its storage (Mayor and Sereno, 2004).

One of the most important physical changes that agricultural products undergo during drying is reduction of external volume due to shrinkage. Shrinkage of food materials has a negative impact on the quality of the dehydrated product. Loss of water and heating cause collapse in the cellular structure of products. Changes in shape and volume increase hardness, which in most cases has a negative impression on the consumer. However, some dried food, such as raisins, dried plums, peaches, and dates, have consumer acceptance as traditionally shrunken products.

Shrinkage of agricultural products and food

When water is removed from material, a pressure unbalance is produced between the interior of the material and the exterior, generating contracting stresses that lead to material shrinkage or collapse, changes in shape, and occasionally cracking of the product. For this reason, drying under vacuum, as in freeze-drying, leads generally to much less shrinkage (Mayor and Sereno, 2004). Shrinkage of food materials increases with the volume of water removed. In some cases, the mechanical equilibrium is reached when shrinkage of the material equals volume of removed water. This behavior is observed during the whole drying process. In other cases, however, the volume of removed water during the final stages of drying is larger than the reduction in sample volume. This behavior can be explained by the decrease in the mobility of the solid matrix of the material at low moisture contents, as described below.

In food systems shrinkage is rarely negligible, and it is advisable to take it into account when predicting moisture content profiles in the material undergoing dehydration. For such purposes, different types of models that predict volume change in the material are available and should be used. Several authors have reviewed the process of food dehydration both from an experimental and modeling viewpoint, pinpointing new approaches and methodologies (Mayor and Sereno, 2004).

White and Bell (1999) tried to relate the effect of collapse and porosity with the kinetics and extension of some chemical reactions in foods undergoing drying and further storage. In this case, a model food system was composed by glucose and glycine included in an inner matrix. They tried to eliminate porosity due to structural collapse by decreasing the glucose loss rate constant, but this had a minimal effect on the rate of brown pigment development associated with the Maillard reaction.

Mechanism of shrinkage

Given a physical description of the shrinkage mechanism, a classification of the different models was presented by Mayor and Sereno (2004) to describe this behavior in food and agricultural materials undergoing dehydration. The models were classified in two main groups: empirical and fundamental models. Empirical models are obtained by means of regression analysis of shrinkage data. Fundamental models are based on a physical interpretation of the structure of food materials and try to predict dimensional changes due to volume variation of the different phases in the food system during the drying process. Several models were compared with experimental data on air drying of several fruits and vegetables. Average relative deviations between experimental and predicted values of shrinkage found were, in most cases, less than 10% (Mayor and Sereno, 2004). This approach is more fundamental and based on a physical interpretation of the food system and tries to predict geometrical changes based on conservation laws of mass and volume. In both cases, linear and nonlinear models result to describe shrinkage behavior versus moisture content.

Most of agricultural products are solid or semi-solid food and are highly heterogeneous materials that may be considered as consisting of a three-dimensional solid network or matrix holding usually large quantities of a liquid phase, in most cases an aqueous solution. Biopolymers are the common structural elements of the solid matrix. The particular structure of the material and the mechanical characteristics of its elements at equilibrium define sample volume and determine its size and shape.

The mobility of the solid matrix is closely related to its physical state; high mobility corresponds to a viscoelastic behavior typical of a rubbery state while low mobility corresponds to an elastic behavior typical of a glassy state. Levi and Karel (1995) found that mobility of the solid matrix is a dynamic process with rates that depend on the difference of temperature of the sample undergoing

dehydration and glass transition temperature. At high moistures, when the material is in the rubbery state, shrinkage almost entirely compensates for moisture loss, and volume of the material decreases linearly with moisture content. At low moisture content, glass transition temperature increases, allowing the material to pass from the rubbery to glassy state, and the rate and extension of shrinkage decreases significantly. When the drying process is in the range of low moisture content where phase transition from rubbery to glassy state is going on, rigidity of the material stops shrinkage and parallel pore formation may occur.

The mechanism of shrinkage in seeds and grain

In the early 1970s, Overhults et al. (1973) observed the physical damage in soybeans, as indentations or cracks and splits, during drying. In view of these problems, especially in the legume seed industry, several authors elaborated on the optimum drying conditions for minimizing seed coat cracking. The major problem in the drying of beans and seeds with heated air is the splitting of the seed coat (Liu et al., 1989; 1990). However, in the study of stress cracking due to drying, the decreasing moisture content of grains is essential to this mechanism. On the other hand, the modulus of elasticity of the seed coat varies with moisture level (Dobrzański, 1998; 2000). Looking for the mechanism responsible for the splitting of seed coat, a determination of the elasticity limit of the seed coat and its resistance to tension for various legume seeds, was the essential in understanding the mechanism of cracking due to seed coat shrinkage.

All results reported by Dobrzański (2002a) made the bases for the shrinkage model of the seed coat being drying with a hot air. The model presents a spherical seed in a stream of hot air. The wet seed of large volume is surrounded by the seed coat. During drying, the seed coat reduces its size, which leads to rapid shrinkage. The shrinkage leads to a tension stress in the seed coat, involving an increase of inner pressure of low compressibility cotyledons. In this case, each point of spherical shell represents a plane stress, where the principal stress in each direction is equal. To determine a criterion of tension strength for the seed coat, it is sufficient to estimate circumferential stress in a cross-section of the seed (Dobrzański, 1998).

Unbalanced seed coat shrinkage of the seed in layer

Most seeds in real conditions are located on the layer or inside the layer where each seed has three or more contacts with others. In these areas, the contact zone limits the inflow of air so that free parts only are subject to shrinkage. The shrinkage leads to tension and elongation in the wet part of the contact area. Determination of the strain of the seed coat and elasticity modulus allows estimating criteria of tension. For this purpose, the shrinkage, strain, ultimate elongation at rupture, and modulus of elasticity

must be determined experimentally at wide ranges of moisture. The results obtained at tension of the seed coat showed that the increase of moisture content involves the decrease of force at breakage. In seed coat strength-differentiated cultivars, however, shrinkage stress was frequently higher than tension strength of the seed coat. The force induced by the shrinkage also depended on drying conditions. The highest shrinkage of the seed coat for all cultivars was noticed in heated air. Low temperature and slow stream of air involved less shrinkage. The relevance was the phenomenon that rapid decrease of temperature during drying involved additional 25% shrinkage. Dobrzański (1998) clarified the reason for the coat split in cold air after drying in hot air. He observed this phenomenon for all beans, peas, and other legume seeds. Shrinkage of the seed coat at drying lead to its stress and splitting. The results obtained in all experiments proved that frequently the stress was higher than the strength of the seed coat. It is the main reason for seed coat cracking during drying (Dobrzański, 2002b).

Surface cracking

Surface cracking is another phenomenon that may occur during drying. This happens when shrinkage is not uniform during the drying process, leading to the formation of unbalanced stresses and failure of the material. Cracking of food materials has been reported by several authors: in soybeans (Mensah et al., 1984; Dobrzański, 2000) and corn (Fortes and Okos, 1980). This cracking phenomenon has been successfully modeled by coupling equations of heat and mass transfer by Akiyama et al. (1997) and Litchfield and Okos (1988). Another important consequence of shrinkage is the decrease of rehydration capability of the dried product. McMinn and Magee (1997), in the air drying of potatoes at different process temperatures, reported that when comparing samples with the same moisture content but a different degree of shrinkage due to the different drying conditions used, a lower dehydration capacity corresponded to most shrunk samples.

Swelling of seeds and grain

Shrinkage of seeds is a physical phenomenon observed during maturing or dehydrating processes. On the other hand, swelling of seeds is the opposite process and physical phenomena observed during soaking of grain or during hydration of formerly dried material for long storage as sieving material. For legume seeds, the first stage only, connected with imbibitions of water is a physical phenomenon; however, further hydration is related to biological or chemical processes.

Dobrzański (1998) has tested the influence of water capacity on seed volume increase of different pea seed, soya, french bean (yellow-pod and green-pod), bean, faba bean, and bread bean. The effect of moisture content on expansion volume and dimensions of beans was observed in the initial phase of swelling. Further, a rapid decrease of moisture content of the seed coat caused the shrinkage

during drying, leading to stress. With an increase of moisture content, the seed coat of legume seeds decreased its strength (Dobrzański, 2002b). The increase of moisture content of legume seeds caused considerable deformations in its shape that lead to increase of volume. In the initial phase of swelling, only the shell is soaked and its shrunken area increased. Further, seed cotyledons become larger, causing seed coat filling, leading the shell tensioning till its disruption. The relative elongation of the seed coat allows calculating stress during seed swelling. The problem consists of determining the surface area of the seed coat surrounding two cotyledons. It is characteristic that the shape and volume of wet seed is not equal after drying and second soaking.

Rate and temperature of drying

If rapid drying rate conditions are used and intense moisture gradients through the material are observed, low moisture content of the external surface may induce a rubber–glass transition and the formation of a porous outer rigid crust or shell that fixes the volume and complicates subsequent shrinkage of the still rubbery inner part of the food. If low drying rate conditions are used, diffusion of water from the inner to the outer zone of the material happens at the same rate as evaporation from the surface and no sharp moisture gradients are formed in the material, which shrinks uniformly until the last stages of drying. This behavior was noticed by Mayor and Sereno (2004). The shell formation effect cannot be observed if drying conditions do not allow a phase transition in the outer zone material, even at high drying rates. Willis et al. (1999), during drying of pasta, observed a higher shrinkage when samples were dehydrated at higher temperature (100°C) than in samples dehydrated at 40°C at the same relative humidity of air. In the first case, drying temperature was greater than the glass transition temperature of the pasta, and the product remained in the rubbery state and shrank uniformly during the whole drying process. In the second case, the case hardening effect was observed due to a glass transition in the surface of the material that decreased shrinkage and increased residual stresses in the dried material, which underwent cracking and breakage during storage. Mayor and Sereno (2004) presented the influence of different process conditions in volume change of the materials during dehydration. In most cases, such analysis has been done, studying the effect of each single process condition like temperature, velocity of air, or relative humidity of air. Unfortunately, the results of these works are often unclear as to the influence of these process conditions on shrinkage.

Drying of foods is a complex process involving simultaneous mass and energy transport in a system that suffers different changes in its chemical composition, structure, and physical properties. As suggested before, it is the combined effect of process conditions when facilitating the formation of a crust or shell in the external surface of

the product during the initial stage of the drying process that determines the type and extent of shrinkage.

The force induced by the shrinkage depended also on drying conditions. Dobrzański (1998) presented that, in some cases, an increase of drying temperature produced less shrinkage. However, the highest shrinkage of the seed coat for all cultivars was noticed in heated air. Low temperature and slow stream of air involve less shrinkage. This approach is more fundamental and is based on a physical interpretation of the food system that tries to predict geometrical changes based on conservation laws of mass and volume. In this case, both linear and nonlinear models result to describe shrinkage behavior versus moisture content.

Summary

Shrinkage of agricultural products is a common physical phenomenon observed during different dehydration processes. On the other hand, swelling of various agricultural products is a physical phenomenon observed during soaking of plant materials or during hydration of formerly prepared-for-preservation dried food. For some plant materials, e.g., legume seeds, the first stage only, connected with imbibition of water, is a physical phenomena, however, further hydration is related to biological or chemical processes. Shrinkage of food materials increases with the volume of water removed, since the more water removed, the more contraction stresses are originated in the material. In some cases, the mechanical equilibrium is reached when shrinkage of the material equals volume of removed water. These changes affect the quality of the hydrated or dehydrated product and should be taken into consideration when predicting moisture and temperature profiles in the dried or soaked material. Temperature and moisture gradients can cause stresses in agricultural products. However, shrinkage in the seed coat is a phenomenon observed during drying, leading to its stress and splitting.

SHRINKAGE AND SWELLING PHENOMENA IN SOILS

Pascal Boivin

University of Applied Sciences of Western Switzerland (HES-SO), Geneva, Switzerland

Definition

The soil shrinkage is defined as the specific volume change of soil relative to its water content and is mainly due to clay swelling properties (Haines, 1923; Stirk, 1954). It can be measured in most soils with more than 10% clay content (Boivin et al., 2006) and shows a typical S-shape (Figure 1). This process is reversible with changes in water content and the reverse to shrinkage is swelling.

Shrinkage and Swelling Phenomena in Soils, Figure 1 Typical shrinkage curve of an undisturbed soil sample, with the transition points between the shrinkage domains. Note the position of the saturation line, delimiting air in the porosity (above) and water in the porosity (below).

Shrinkage is due to the volume change of the soil plasma and to some extent of the structural porosity with water content. The plasma is made of the colloidal constituents of the soil and is often referred to as clay matrix. Its porosity is often assimilated to the textural porosity as introduced by Childs (1969). The swelling factors in the plasma are the phyllosilicates and the organic matter, while binding elements (e.g., oxides and salts) tend to limit the plasma swelling. Therefore, soil shrinkage is closely related to the type of and content in colloids (Braudeau and Bruand, 1993; Boivin et al., 2004, 2009). Shrinkage is at the origin of crack forming in soils, and is, therefore, a major factor of soil structure resilience.

Soil shrinkage was first studied with the aim to quantify the soil structural behavior (Haines, 1923; Lauritzen and Stewart, 1941; Stirk, 1954; McGarry and Daniells, 1987), based on the observation that the swelling capacity of the soil quantifies the ability of the structure to withstand the drying forces, thus quantifying the hydrostructural stability with the slope of the shrinkage curve (Schäffer et al., 2008).

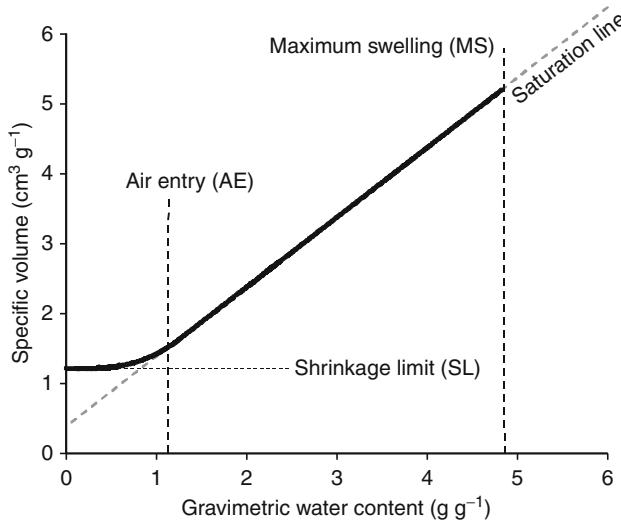

Based on the modeling of the shrinkage curve with the conceptual model XP (Braudeau et al., 1999), shrinkage analysis is now used to provide a full quantification of the soil pore systems (plasma and structural porosity), their deformation and air and water content at any soil water content, the pore size distribution of the structural pores, and the hydrostructural stability (Schäffer et al., 2008; Milleret et al., 2009), with applications to the

diagnosis of soil biota or soil management impact on soil properties.

The shrinkage curve of undisturbed soil clods was first estimated by measuring the volume of multiple soil clods at different water content (Haines, 1923). It is now determined continuously together with the water retention curve using a shrinkage apparatus, thus providing inexpensive, accurate, and reliable data (Braudeau et al., 1999; Boivin et al., 2004). In some cases it has been determined in situ (Coquet et al., 1998; Cabidoche and Ruy, 2001).

Shrinkage models were developed at two scales: namely plasma (clay matrix) and soil clods. All plasma models (Sposito, 1973; Chertkov, 2003) acknowledge the shrinkage behavior of clay pastes (Tessier et al., 1992), which remain saturated along most of their water content range, thus following the saturation line (load line) until the limit of plasma deformation allows air to enter the plasma porosity upon loss of water (air entry point) (Figure 2).

Shrinkage models can be split in shape fitting, deterministic and conceptual models. In the first category, Peng and Horn (2005) proposed to fit the Van Genuchten Equation to both shrinkage and water retention curves, and Boivin et al. (2006) follow this line using the XP model to show the similarity between the curves. In the second category, Chertkov (2008) proposed to model the S-shape behavior based on the clay-paste behavior and simple assumptions on aggregate structure. The conceptual XP model is widely used because it allows a unique

characterization of the soil physical properties with shrinkage analysis (cited refs).

Summary

Shrinkage is a general property of soils mostly due to its colloidal constituents, and play a major role in structure forming and resilience. The shrinkage curve of an undisturbed soil clod can be measured easily and quasi continuously together with the water retention curve. Shrinkage analysis based on the fitting of a conceptual model on the shrinkage curve allows a full characterization of the soil pore systems and their swelling dynamic with water. The corresponding properties show large correlations with the content in soil colloids and allow unique assessment of the impact of soil management on soil properties. Shrinkage analysis is, therefore, of growing interest in soil science as acknowledged by the increasing number of references.

SNOWMELT INFILTRATION

Yukiyo Iwata

Climate and Land-use Change Research Team, National Agricultural Research Center for Hokkaido Region, NARO, Sinsei Memuro, Hokkaido, Japan

Definition

Snowmelt infiltration is the process by which snowmelt water enters the soil.

In this process, the winter precipitation stored on the soil surface as snow melts and infiltrates the soil when the snow temperature rises to above 0°C. This may occur in response to periods of warm weather during winter, but primarily occurs in early spring.

The infiltration rate is heavily influenced by the existence of frozen soil and a layer of ice on the soil surface. However, soil does not freeze in the field when there is enough snowcover to insulate the soil from the cold air during winter (Iwata et al., 2010). In such cases, the infiltration process of the snowmelt water is the same as that of rainwater in summer and the infiltration rate is determined by pore geometry and its continuity. However, the process of the snowmelt infiltration into the frozen ground is significantly different from that of rainwater infiltration. During the early snowmelt period, the water infiltrating into large pores, such as macropores, freezes quickly and does not percolate to deeper soil layers. However, the snowmelt water can infiltrate into small pores because the water in such pores does not freeze (Miller, 1980), even when the soil temperature is below zero, although the movement of water through these pores is slow. During the late snowmelt period, the soil temperature of the frozen layer increases to almost 0°C. The liquid water can move through large pores during this stage, but the ice in large pores, which is formed by the soil freezing during winter or the refreezing of infiltrated meltwater in early spring, reduces the rate at which water infiltrates frozen soil. Snowmelt water or surface ponding after the snowmelt period infiltrates the ground rapidly after the ice in the large pores melts in response to heat supply from the upper and bottom portion of the frozen layer. The ice layer at the soil surface, which is formed by surface ponding by rain or snowmelt in the beginning of winter or refreezing of snowmelt water in late winter, also impedes the infiltration of snowmelt (Bayard et al., 2005). Therefore, snowmelt infiltration into the frozen ground is determined by the movement of heat and water in the soil and snow layers, and it is strongly influenced by ice and liquid water content, air porosity, soil temperature, frost depth, and the presence of an ice layer at the soil surface, and not simply pore geometry.

Snowmelt infiltration has some harmful effects on agriculture. For example, a poor snowmelt infiltration rate induces a substantial amount of runoff, which is accompanied by soil erosion in some regions, even when the rate of snowmelt is not high. Prolonged surface ponding in level frozen lands causes excess water injury for grass and winter wheat. Decreased snowmelt infiltration into the ground results in shortages in the water available to plants in subsequent seasons.

Soil clod; Soil stability; Soil structure

Definition

Primary soil particles held together by cohesive forces, secondary particles and organic matter, form soil aggregates. Stability of an aggregate is its ability to resist stresses such as tillage, swelling, and shrinking processes and fast wetting by raindrops which cause aggregate disintegration.

Introduction

Soil aggregates vary in size and shape and the arrangement of soil aggregates is called soil structure which is

an important soil physical property. A well-structured soil aggregate, typically associated with agricultural importance, consists of primary particles in such arrangement to offer good aeration, water movement and storage, biological activity, and stability, which are vital for optimum plant growth. Soil aggregate stability is an important measure for assessing soil structural quality. Stable soil aggregates form a stable soil structure, which allows optimum movement and storage of gases, water, nutrients, biological activity, and energy. These activities occur in the pore structure which is created between the aggregated primary particles and are constantly at a dynamic state. The stability of soil structure is responsible for soil degradation, i.e., soil erosion and crusting, which affects negatively soil sustainability, crop establishment, and eventually, yield.

Measuring aggregate stability

Measuring soil aggregate stability is a mean of assessing soil structural condition. Various methods exist to measure soil aggregate stability and each of them simulates a mechanism of aggregate breakdown. Le Bissonnais (1996) reported four main mechanisms of aggregate breakdown: (a) slaking due to compression of entrapped air during wetting, (b) microcracking due to differential swelling, (c) mechanical breakdown, and (d) physico-chemical dispersion due to osmotic stress. A short overview of methods used for aggregate stability measurement can be found, e.g., in Le Bissonnais (1996) or in Diaz-Zorita et al. (2002). Selection of the methods and interpretation of its results depends on the purpose of the measurement. The most common method used for aggregate stability measurement is wet sieving. Other methods are based, e.g., on the simulation of raindrop energy impact, ultrasonic dispersion, or breakdown of aggregates after sudden immersion in water (Rohoskova and Valla, 2004). Among soils containing much organic carbon, fast wetting will probably give a better separation of values than slow wetting. By contrast, the low-energy slow-wetting treatments will be better for distinguishing among weak aggregate soils (Le Bissonnais, 1996).

Soil aggregation and stability

Oades (1984) suggested that macro-aggregates ($>250\text{ }\mu\text{m}$ diameter) do not just bind existing micro-aggregates ($<250\text{ }\mu\text{m}$ diameter) together, but that new micro-aggregates are formed preferentially within stable macro-aggregates. Mucilage produced during decomposition of organic fragments inside the macro-aggregate interacts with clay, which begins to encrust the organic fragment, eventually to an extent where the degradation of the organic material is retarded. Over time, binding agents in macro-aggregates degrade, resulting in a loss of macro-aggregate stability and the release of stable micro-aggregates, which become the building blocks of the next cycle of macro-aggregate formation (Six et al., 2000). Micro-aggregates exhibit greater stability than macro-aggregates and better protect soil organic matter

(SOM) against microbial decay (Tisdall and Oades, 1982; Skjemstad et al., 1990). Six et al. (2000) and Denef et al. (2001) reported that the formation of these micro-aggregates within macro-aggregates is negatively related to the rate of macro-aggregate turnover and therefore is strongly affected by management factors such as tillage and residue management. Therefore, the degree of stable micro-aggregation, rather than stable macro-aggregation, might play a more important and direct role in the relation between SOM sequestration and management of agricultural soils (Pulleman et al., 2005). Watts et al. (2001) also found that an understanding of the formation and stabilization of micro-aggregates is crucial not only because they are a key component of the soil structural hierarchy but also because they help control the dynamics of soil organic matter turnover. In addition to being the primary cause of crusting, aggregate breakdown is responsible for the production of micro-aggregates and particles, which are easily transported by runoff and splash (Le Bissonnais, 1996).

The measurement of aggregate stability is a particularly destructive method where thoroughly desiccated aggregates are submerged in water. The water drawn in to each aggregate over its entire periphery may trap and compress the air originally present in the dry aggregate. As the cohesive strength of the outer part of the aggregate is reduced by swelling, and as the pressure of the entrapped air builds up in proportion to its compression, the latter may eventually exceed the former and the clod may actually explode. More typically, however, a series of small explosions, each marked by the escape of a bubble of air, shatters the clod into fragments (Hillel, 1998).

Angers and Caron (1998) observed that wetting and drying cycles caused by crop roots influence the extent of soil fragmentation and aggregate formation, i.e., drying produces cracks and induces fracture of aggregates. Plant growth will influence the magnitude, frequency, and effects of these cycles on aggregation (Semmel et al., 1990). For instance, Materechera et al. (1992) observed that repeated wetting/drying cycles associated with root growth resulted in the production of smaller aggregates. Penetrating roots can mechanically break up existing aggregates, but they also stabilize surrounding aggregates through drying the soil and root exudation with its associated microbial activity (Six et al., 2004). Materechera et al. (1994) found that, even at constant water potentials, roots decreased the proportions of already formed large water stable aggregates by 20–50%.

Haynes et al. (1991) suggested that increase in aggregate stability during a short-term pasture is due principally to production of binding carbohydrates by the large microbial biomass present in the pasture rhizosphere. When pasture is ploughed under, the microbial biomass declines as does aggregate stability, and the increase in aggregate stability following pasture establishment is considerably more rapid than the increase in clod porosity. Six et al. (1998) suggested that the very small effect of organic farming on micro-aggregate characteristics and associated

carbon (C) stabilization may be caused by the effect of tillage on aggregate turnover. The paucity of organic resources that stimulate the formation of micro-aggregates during passage through earthworms and other biotic processes that result in the formation or stabilization of micro-aggregates may also play an important role. Hillel (1998) stated that in addition to increasing the strength and stability of intra-aggregate bonding, organic products may further promote aggregate stability by reducing wettability and swelling. Some of the organic materials are inherently hydrophobic, or become so as they dehydrate, so that the organo-clay complex may have a reduced affinity for water. It has been established that the inclusion of organic materials within soil aggregates reduces their decomposition rate (Oades, 1984). Six et al. (1998) suggested that increased macroaggregate turnover under conventional tillage is a primary mechanism causing decreases of soil C.

Organic matter and aggregate stability

Organic matter (OM) and soil structure are strongly related: OM binds mineral particles into aggregates and reduces the susceptibility of soil to slaking (Tisdall and Oades, 1982). In turn, stable aggregates may enhance the physical protection of OM against decomposition under grassland or reduced tillage compared with conventional tillage systems (Six et al., 1998). OM concentration and soil aggregate stability have therefore been proposed as important soil quality indicators (Six et al., 2000; Saggar et al., 2001). Organic matter is routinely added to soils in organic farming, while intensive arable agriculture can lead to a decline in both organic matter levels and stability of soil structure (Watts et al., 2001). The effects of organic amendments on aggregate stability will depend also on their composition and subsequent effects on biological activity. The important role of fresh OM in aggregate stability explains why most research has found better correlation between components of OM (e.g., water-soluble carbohydrates) and stability than between total OM and stability (Shepherd et al., 2002).

Concerns have been expressed that soils might suffer long-term degradation under intensive agriculture, particularly to soil structure, due to reductions in soil organic matter levels (MacRae and Mehuijs, 1985; Sommerfeldt and Chang, 1985). This has wide-reaching negative secondary effects, e.g., the ameliorative actions of soil organisms are decreased, resulting in a soil with a reduced A horizon, reduced range and size of pores, and less-developed, finer and weaker aggregates (Kay, 1990). These traits are associated with soils susceptible to physical degradation, i.e., erosion and surface crusting (Poincelot, 1986) resulting in poor crop establishment, and eventually, yield.

Six et al. (1998) developed a conceptual model to explain the influence of disturbance (e.g., tillage) on soil carbon (C) stabilization rates. Their model links a proportion of the C lost upon disturbance to the increased turnover of macro-aggregates. A disturbance-induced increase in

macro-aggregate turnover inhibits formation of micro-aggregates within macro-aggregates and the long-term sequestration of C within micro-aggregates.

Golchin et al. (1994) proposed that when fresh plant material (as surface residues or roots) enters the soil, it induces the formation of aggregates because it stimulates the production of microbial-derived binding agents by being a C source for microbial activity. During decomposition, plant material fragments or particulate organic matter (POM) gradually becomes encrusted with clay particles and microbial products to form the core of stable micro-aggregates. Microbial mucilages and metabolites further impregnate the mineral crust surrounding the still decomposing organic cores to form very stable micro-aggregates (Six et al., 2004).

Soil aggregation, slaking and pore morphology

Six et al. (2000) and Denef et al. (2001) reported that the formation of micro-aggregates within macro-aggregates is negatively related to the rate of macro-aggregate turnover and is therefore strongly affected by management factors such as tillage and residue incorporation. Aggregates released by the slaking of macro-aggregates contain less OM on average and appear unable to form stable macro-aggregates (Six et al., 1998, 2000). Papadopoulos et al. (2009) found contrasted results as the analysis of OM fractionation demonstrated that neither the light fraction nor the intra-aggregate fraction of OM affected aggregate stability. This suggests soil aggregates may be at different stages of aggregate turnover at the time of sampling. Therefore, within a soil sample, some macro-aggregates may have been formed recently by stable micro-aggregates, while others may be breaking down to release micro-aggregates. This would provide false results by applying the slaking method, although it has been proved stability measurements by slaking are constant and not affected by the aggregate turnover stage. Therefore, observations of stability can advise on the rate of aggregate turnover and how long stable-formed aggregates may last. It is likely that conventional management promotes a faster aggregate turnover (macro-aggregate breakdown) resulting in the production of unstable macro-aggregates comprised of micro-aggregates with less OM than organic management, as they are formed in less time inside macro-aggregates and typically there is less OM supplied in conventional management (Papadopoulos et al., 2009).

Slaking is dependent on increased pressure inside soil pores; therefore, pore morphology is an important factor influencing this process. These pores are formed by the binding of micro-aggregates into stable macro-aggregates. During this process, intra-aggregate pore morphology depends on the assemblage of the micro-aggregates which can be measured by pore roughness. Papadopoulos et al. (2009) performed fractal analysis between organic and conventionally managed soils which showed that organic

soils promoted the formation of soil aggregates which consisted of pores with slightly greater perimeter fractal D compared to conventional soils. Therefore, proposed that one of the factors affecting soil aggregate stability is the morphology of pores within both micro- and macro-aggregate pore spaces, the “rougher” the pores, the greater the aggregate stability. This is partially supported by the findings of Bresson and Moran (2004), who reported that aggregate stability does not necessarily decrease with decreasing macroporosity but is rather related to the balance between changes in macro- and microporosity.

Hallett et al. (2000) found that the soil aggregate strength increased exponentially with decreasing aggregate size. Fracture mechanics theory predicts that at each level of aggregate breakdown, the largest cracks are consumed. Results show a decrease in the proportion of cracks on soil fracture surfaces with decreasing aggregate size which is direct evidence that at each level of aggregate breakdown, the “weakest link” is stronger. Cracks are thought to affect soil strength by one of two mechanisms. The most basic is that cracks weaken soil by reducing the number of particle bonds. More recently, it has been disputed that this theory is incorrect and that cracks reduce strength by intensifying stresses at their tips as described by fracture mechanics theory (Hallett et al., 2000).

X-ray Computed Tomography (CT) together with other 3D imaging techniques including NMR and synchrotron are becoming increasingly popular in geoscience, offering the ability to further investigate the intact properties of soil aggregates. At the microscale, the topology and connectivity of the intra-aggregate pore network is of crucial importance for microbial processes, the sequestration of organic carbon, water storage, and transport properties which are greatly associated with processes evolving at the larger scale (for more reading see *Noninvasive Quantification of 3D Pore Space Structures in Soils*).

Summary

Soil aggregate stability is an important measure for the evaluation of soil structural quality. Several methodologies have been developed to assess aggregate stability in a destructive manner which has proved very useful and accurate. The study of aggregate formation and stability has received great attention in the last few decades, typically associated with soil organic matter. Nowadays, with the availability of sophisticated equipment (X-ray Computed Tomography, rheology, mechanical precision stress inducer, etc.) allowing the investigation of the intact aggregate pore structure and networks, the strength and degree of degradation, we are able to improve our understanding of soil aggregate formation and stability as it is a dynamic and complex process. Soil aggregation is a multi-scale, multi-temporal, and multi-spatial property which is essential for making improvements in agriculture as it is related to soil–root interactions, hydrological properties, and environmental issues.

SOIL AGGREGATION AND EVAPORATION

Barbara Witkowska-Walczak
 Institute of Agrophysics, Polish Academy of Sciences,
 Lublin, Poland

The primary particles of soil tend, in favorable circumstances, to group themselves into composite structural units known as *aggregates*. The presence of aggregates in soil is called *soil aggregation*. The soil aggregates are characterized neither by any universally fixed size nor by the stability. The aggregates of the order of several millimeters are called *macroaggregates*, the smaller ones are called *microaggregates*. The arrangement of aggregates and primary particles in the soil is called *soil structure*.

Evaporation is the process of change of the state of water from a liquid to gaseous phase. It is a principal process of water cycling in the environment. Evaporation of water from bare soil is one of the simple processes of water loss from land to atmosphere. Evaporation in soil involves the next events: transport of water to surface within soil profile, a phase change from liquid water to vapor water, and the transfer of water vapor from the soil surface to atmosphere. The evaporation management can be done by reducing the total energy responsible for it, modifying the albedo parameters, or reducing the water movement to soil surface.

Soil aggregation is one of the best important factors of the evaporation decrease, because it changes the transport of water to soil surface by reducing the upward flux of water by either lowering the water table or decreasing the diffusivity and conductivity of the soil profile. The upper layer of soil built of macroaggregates can be worked as mulching and it caused several times decrease in water loss from soil profiles in comparison to soil without aggregation.

SOIL BIOTA, IMPACT ON PHYSICAL PROPERTIES

Pascal Boivin¹, Roxane Kohler-Milleret²

²Institute of Biology, Soil & Vegetation Group, University of Neuchâtel, Neuchâtel, Switzerland

Definition

The *soil biota* is made of all soil living organisms from microorganisms to macrofauna, including roots. Most of these organisms are considered as soil ecosystem engineers (Jones et al., 1994) involved in the formation of aggregates in soils and in the generation of the structural porosity. Their impact greatly differs according to the type of organism, soil conditions, and the soil biodiversity.

Soil biota: impact on physical properties

The soil living organisms range from eye-invisible microbes (bacteria and fungi) to macrofauna (termites, earthworms, etc.) with organisms of intermediary size as microfauna (protozoa, nematodes, etc.) and mesofauna (microarthropods, enchytraeids, etc.). Furthermore, although plants are primary producers and determine the

amounts of carbon that enter the system via the above-ground system (Wardle, 2002), the root system, as a heterotrophic part of the plant, may also be considered as a soil organism as it is in close relationship with other soil biota. All these soil organisms are interacting together in very complex trophic and nontrophic webs (Wardle, 2002; Bardgett, 2005; Coleman, 2008) that affect in turn the aboveground system (Van der Putten et al., 2001; Wardle, 2002; Coleman, 2008). Moreover, they utilize the soil as a habitat and a source of energy (Bardgett, 2005) and have therefore a strong effect on soil properties.

It is first worthwhile to recall that a major factor of soil structure formation and stabilization is the soil organic matter (SOM). An increase in organic matter content results in a proportional increase in most soil physical properties such as porosity and aggregate stability (Kay, 1998). Hence, plants as a source of SOM have a strong impact on soil physical properties. Root-related processes affecting soil structure are reviewed by Angers and Caron (1998): root penetration, enhancement of wetting–drying cycles, root entanglement of soil particles, production of binding agents, and stimulation of the microbial activity.

The impact of bacteria and fungi on soil aggregation has received growing interest (Six et al., 2002; Young and Crawford, 2004). Arbuscular mycorrhizal fungi (AMF) influence soil aggregation via three processes. First, AMF affect soil aggregation formation or stabilization physically by the enmeshment of primary particles, organic matter, and small aggregates to macro aggregates, and the alignment of primary particles (Thomas et al., 1993; Andrade et al., 1998). Second, AMF affect soil aggregation chemically by the secretion of extracellular compounds as mucilages, polysaccharides, or glomalin-related soil proteins (Wright and Upadhyaya, 1996). These compounds have been shown to act as a glue substance (Six et al., 2004; Bronick and Lal, 2005). Finally, AMF affect soil aggregation biologically by interacting with the soil food web, thus influencing bacterial communities that would in turn influence soil aggregation through the secretion of polysaccharides (Andrade et al., 1997, 1998; Artursson et al., 2005).

Earthworms play a very important role on soil structure. By creating soil biogenic structures (casts, burrows), which are called drilosphere soil (Lavelle et al., 1997), earthworms influence physical, chemical, and biological soil properties. Through casting and burrowing activities, they affect the soil physically, by modifying soil porosity, aggregation, stability, aeration, and hydraulic conductivity (Shipitalo and Protz, 1989; Edwards and Bohlen, 1996). The burrow walls can form a stable structure that may persist in soil for several months, or even years (Lee, 1985). Earthworms may be cause to preferential flow (Zehe and Flühler, 2001). They are assumed to be a sign of “healthy” soil and to provide an improvement of soil permeability and structure.

Cases of heavy soil compaction by earthworms have been, however, reported (Chauvel et al., 1999; Milleret et al., 2009). In both cases, the compaction was attributed

to an exceptional development of endogeic species. The study of Milleret et al. (2009) shows that combined with root and AMF activity, the earthworm activity leaved the soil structure as it is. Further experiments showed that the compaction occurs with all worm species when alone on a soil which is not compacted, but mixing species and/or working with compacted soils leads to a soil decompaction (unpublished results).

Showing that roots generate a large volume of pores that cannot be attributed to the direct mechanical effect of the roots, Milleret et al. (2009) assumed that root exudates stimulated bacteria activity which in turn developed the structural porosity, thus supporting the “self-organization of the soil–plant–microbe system” theory.

Summary

The soil biota can be considered as the permanent engineer of the soil. Obviously, either by contribution to the SOM dynamic, direct entanglement of particles, and active interactions in between species, it contributes to renew and improve the soil structure. A “living soil” is, therefore, to be promoted. The impact of soil biota can be observed on short time ranges (e.g., from day to months), while the contribution of SOM occurs on larger time range dynamics (over years). The role of soil biota remains, however, largely unknown, and recent studies suggest that the positive role of soil biota on soil structure is only observed when the soil biodiversity is satisfactory, which means that the interaction between species is the key factor.

SOIL COMPACTIBILITY AND COMPRESSIBILITY

Stephan Peth

Institute for Plant Nutrition and Soil Science, Christian-Albrechts-University zu Kiel, Kiel, Germany

Definitions

k_0 -loading = vertical compression under confined lateral deformation

σ_i = normal stress [kPa], with $i = x, y, z$ indicating horizontal (x, y) and vertical (z) direction

n = porosity = ratio of pore volume to total volume [$\text{cm}^3 \text{ cm}^{-3}$]

ε = void ratio = ratio of pore volume to solid volume [$\text{cm}^3 \text{ cm}^{-3}$]

CCT = confined compression test (oedometer test)

PST = plate sinkage test

C_p = compaction point

P_c = pre-compaction stress

C_c = compressibility index

C_s = swelling index

C_n = cyclic compressibility

Introduction

Physical quality and functionality of soils is a prerequisite for sustainable land use. This target is increasingly compromised by the expansion of highly mechanized crop production systems with intensive field traffic. A fourfold mass increase of agricultural vehicles over the past 3–4 decades have put soils more and more under pressure (Horn et al., 2006). Moreover, heavier loads have to be borne by soils often under unfavorable moisture conditions (e.g., during sugar beet harvesting). Deep penetrating soil compaction under heavy machinery has therefore become a great concern in arable land (Peth et al., 2006), where repeated wheeling over years exacerbate compaction effects (Kirby, 2007). The consequence is a long term irreversible deterioration especially of subsoil functions. About 33 million ha of arable land in Europe and 68 million ha worldwide are seriously degraded by soil compaction (Oldeman, 1994). Detimental effects for crop yield and soil erosion are reported in many cases (Alakukku et al., 2003; Håkansson, 1994; Hamza and Anderson, 2005) and problems will probably be aggravated in the future by climate change.

Given the inevitable threat for subsoil compaction due to highly mechanized land use indicators for soil stability and compressibility are very important to assess the susceptibility of soils to mechanical loads. A commonly used value defining the potential risk for soil compaction is the so-called pre-compaction stress P_c , which determines the maximum mechanical stress a soil can sustain without experiencing significant plastic (=irreversible) deformation. The underlying principle dates back to Casagrande (1936) who proposed a method to estimate the geological stress history of clay deposits by determining the

pre-consolidation load by means of a confined compression test (*CCT*). CASAGRANDE outlined the practical significance of the method for settlement analysis and the test is still widely used due to its easy conductibility and reproducibility. The basic concept assumes that as long as stresses remain below P_c soil deformation is fully elastic while upon exceeding P_c plastic soil deformation will take place. While P_c is a suitable indicator for the overall soil stability it lacks information on the actual soil compressibility under specific stresses when the threshold stress P_c is exceeded. Such information, however, is very important because soils with the same P_c value may react quite differently with respect to deformation (i.e., volume changes) and hence also with respect to changes in soil functions. Soil compressibility indices are therefore additionally required to allow estimating the degree to which soils become compressed by mechanical loads during field traffic or animal trampling.

Soil compactibility/compressibility and its measurement

Soil compactibility and soil compressibility are often used in the literature as synonyms with a somewhat indistinct terminology. According to the definition suggested by Håkansson (2005) compaction denotes a process where a soil decreases its air filled pore volume after the application of an external mechanical stress. Håkansson (2005) hence distinguishes between the change in pore volume or void ratio associated with the expulsion of air and pore volume changes caused by drainage of excess pore water. Latter is usually referred to as consolidation. In contrast soil compressibility describes the overall sensitivity of a soil to react to a unit change in mechanical stress with a unit change in pore volume irrespective if water or air is expelled from the pore space. In any case solid particles are assumed to be incompressible so that each volume change is equal to a change in porosity n . However, while under field traffic conditions mostly short loading times prevail and predominantly air will be expelled from the soil, mechanical soil testing is usually conducted in a way that some equilibrium in settlement is reached for a given stress magnitude. Under such conditions water has sufficient time to drain from or redistribute within the pore space (internal drainage) which contributes to the total pore volume change. In this sense soil compactibility may be the more appropriate term to describe pore volume changes associated with short single stress applications encountered during field operation, whereas compressibility describes pore volume changes measured during field and laboratory soil testing where longer loading times or frequent successive load applications are imposed to the soil following a particular stress path. Depending on the stress path different compressibility indices may be defined as a sensitivity measure for volumetric soil deformation.

Although a full treatment of volume change behavior of soils would require also the consideration

of shrinking-swelling processes caused by hydraulic stresses (see *Stress–Strain Relations*) here we concentrate our view on soil compression evoked by external mechanical loads. This is justified because we are interested in the immediate change in pore volume after field traffic or animal trampling. Soil compression is influenced by many factors: three-dimensional stress state, time (duration of loading), stress path, pore water pressure, drainage and hydraulic conductivity, inter-particle and aggregate strength. These factors are not acting independently from each other and some of them (e.g., hydraulic conductivity, pore water pressure and hence effective stress) are continuously modified during the deformation process by particle rearrangements and associated changes in pore network geometries. Consequently, determining the relative influence of each individual factor on compaction is difficult and the description of soil deformation processes mostly relies on empirical soil tests. During soil testing external (e.g., drainage) and internal (e.g., pore water pressure) boundary conditions should therefore be well defined, measured, or if possible even controlled.

Depending on the expected in situ stress state/path and loading boundary conditions different soil tests are employed to derive volume change indices. The most commonly used laboratory test for determining compressibility of arable soils is the confined compression test (*CCT*), also standard oedometer test. It is a one-dimensional compression test where deformation is allowed only in the vertical direction (k_0 -loading: $d\sigma_x = d\sigma_y = \text{undefined}$). The advantage of the *CCT* is that vertical displacements during loading can readily be translated into porosity changes (Δn) which are usually expressed as changes in void ratio ($\Delta \varepsilon$) in order to keep the reference volume constant (volume of the solid phase). Soil tests with *uniaxial* ($d\sigma_x = d\sigma_y = 0$), *isotropic* ($d\sigma_x = d\sigma_y = d\sigma_z$), and *plane stress* ($d\sigma_x \neq d\sigma_z \neq 0, d\sigma_y = 0$) loading conditions shall not be treated here as they describe special situations useful for particular geotechnical problems. A comprehensive literature review on volume change theories and corresponding laboratory experiments for measuring volume change coefficients of unsaturated soils under specific loading conditions is presented in Fredlund and Rahardjo (1993). Although *triaxial* loading ($d\sigma_x = d\sigma_y \neq d\sigma_z$) would in terms of stress state be the closest representation of in situ stresses under wheels (at least assuming static loading) triaxial tests are seldom used in practice because they require special equipment and compared to oedometer tests are more difficult to conduct. Oedometer tests allow a higher number of replicate measurements which is beneficial for characterizing soil heterogeneities of field soils. A limitation, however, is that lateral soil displacement is prevented which is not necessarily the case in situ where additional lateral deformation may occur depending on the confining pressure.

Attempts have been made to use in situ methods such as the plate sinkage test (*PST*) to determine both pre-compaction stress and soil compressibility. Comparing the result to laboratory tests (*CCT*) it was found that up to a so-called compaction point (C_p), where lateral stresses

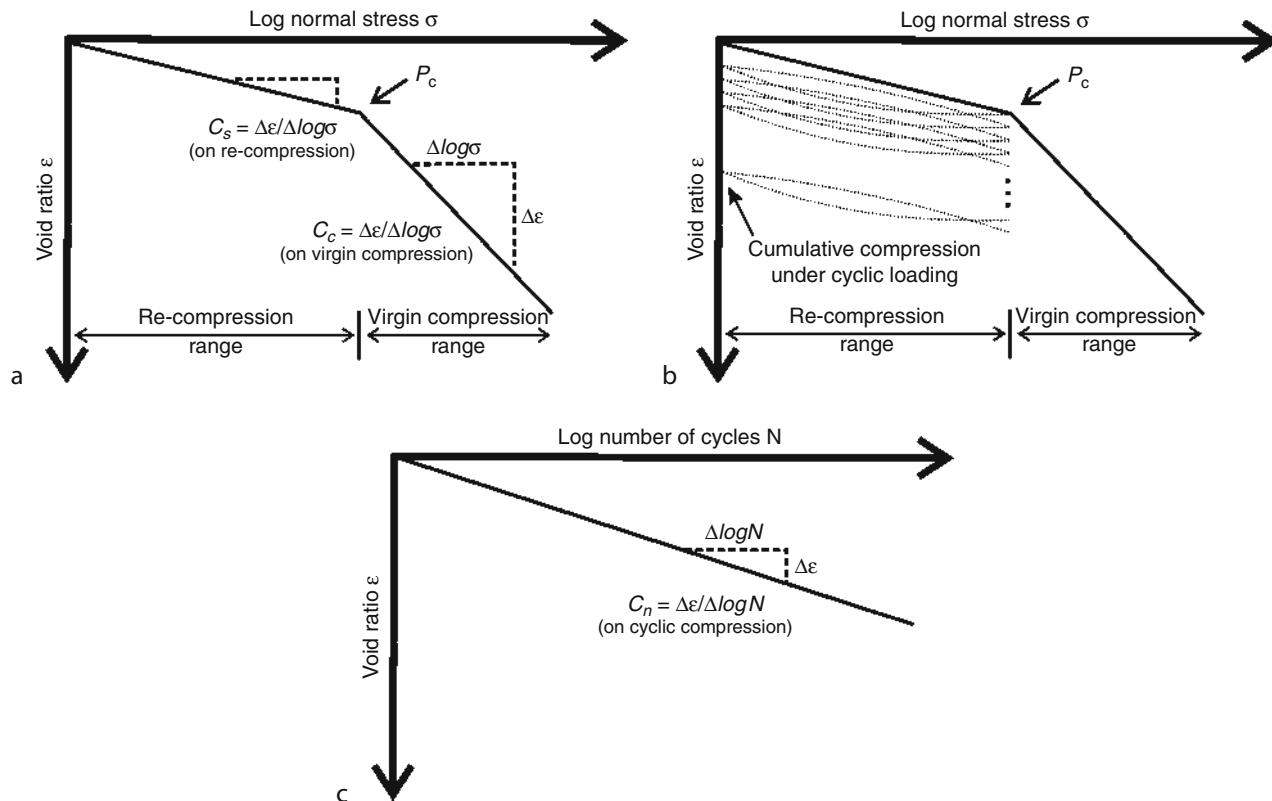

reach the confining stress, settlement under confined compression is very similar to the settlement measured in situ with a semi-confined *PST*. But as soon as stresses exceed C_p stress-strain curves of the two tests significantly deviate from each other, which is attributed to the change in mode of deformation with additional lateral soil displacement in the *PST* (Earl and Alexandrou, 2001). Deformation in this stage is a combination of both compaction and lateral displacement of the soil by shear. The determination of soil compressibility from *PST* measurements is limited since neither the two displacement components – compression and volume constant shear deformation – can be accurately separated nor is the volume affected by compaction constant and defined.

Compressibility indices

Compression and swelling index (re-compression index)

Soil compressibility under static loading is most commonly obtained from measurements of the pre-compaction stress by *CCT*. Compressibility is the change in pore volume or void ratio ($\Delta\varepsilon$) with stress increment ($\Delta\sigma$). The *CCT* is conducted under stepwise increasing loads until the sample settlement is considered to be

completed under the prevailing stress. Void ratios ε are calculated from corresponding final settlements for each load and plotted against the applied vertical stress σ on logarithmic scale. The obtained curve is referred to as *compression curve* which can be approximated by two linear lines separated by P_c . The re-compression line describes the deformation below P_c while the virgin compression line describes the deformation above P_c (Figure 1a). In the re-compression stress range deformation is considered fully elastic whereas in the virgin compression stress range elasto-plastic deformation is taking place. The respective slopes reflect the compressibility of the soil while under load and are referred to as the *compression index* C_c for the virgin compression line ($C_c = \Delta\varepsilon/\Delta\log\sigma$, for $\sigma > P_c$) and *swelling index* C_s for the re-compression line ($C_s = \Delta\varepsilon/\Delta\log\sigma$, for $\sigma < P_c$). Note that the linear lines in Figure 1 – virgin compression and re-compression line – represent approximations to the non-linear compression curve. The slope $\Delta\varepsilon/\Delta\log\sigma$ is strictly speaking a function of stress where the compressibility index $C_c(\sigma)$ increases with $\log\sigma$. Nevertheless, above mentioned linear approximation is reasonably accurate and provides a single parameter characterization of the soil sensitivity against compression under static loading.

Soil Compactibility and Compressibility, Figure 1 (a) Soil compression under static loading in the re-compression and virgin compression range, (b) cumulative soil compression in the re-compression range by repeated loading, (c) compressibility under cyclic loading.

Cyclic compressibility

The assumption of fully elastic soil behavior in the re-compression stress range does not hold true for a higher number of load repetitions (Figure 1b). Repeated (cyclic) loading tests have shown that loads even well below the pre-compression stress may cause significant cumulative soil deformation associated with changes in soil functions (Peth and Horn, 2006). High numbers of load repetitions may be assumed in the field due to repeated wheeling over long time spans (several years) resulting in irreversible cumulative deformation effects in the subsoil. Volume change behavior under repeated loading conditions can be investigated by *cyclic compression tests*. Samples are measured in a standard oedometer device with a constant load applied for a number of load cycles (e.g., 100 cycles). Loads are applied for a short time (e.g., 30 s) followed by unloading and subsequent reloading with one loading–unloading path corresponding to one loading cycle. Cumulative soil deformation expressed as change in void ratio ϵ in general follows a logarithmic trend with \log number of load cycles (Figure 1c). The slope of the log-linear trend is referred to as *cyclic compressibility* ($C_n = \Delta\epsilon/\Delta\log N$) which indicates the sensitivity of a soil against cyclic compression upon repeated loading. C_n is a useful parameter for estimating cumulative effects of specific loads on subsoil compaction with respect to long term field traffic. Modification of the loading–unloading time as a test boundary condition can change the cumulative deformation and consequently C_n values. Therefore, standardization of the measurement protocol is needed to allow for comparison between samples. Ideally loading time is short (few seconds) followed by a rest time after unloading allowing pore water pressure to dissipate.

Summary and conclusion

Determination of soil compressibility is crucial for estimating the impact of field traffic or animal trampling on soil porosity and related soil physical functions. The Compressibility index C_c is derived from compression curves obtained from standard oedometer tests (CCT) allowing to calculate volumetric soil deformation that may be expected when P_c is exceeded by a certain stress value. The index is determined under static loading conditions meaning that the slope reflects a loaded stress situation. While this stress condition is a realistic assumption for many geotechnical problems, where permanent loads are applied (e.g., building foundations), for arable land permanent loads do seldom occur. Instead soils are usually loaded for a short time (seconds) in the incidence of field traffic and then subsequently unloaded again. During unloading elastic rebound recovers a part of the plastic deformation which unfortunately is not quantified by applying standard CCT procedures. On the other hand soils are repeatedly loaded during long term land use and also on a short term basis by multiple axle machines. Concerning long term field traffic, especially in intensive cropping systems, the subsoil may be exposed to hundreds of load applications.

Considering the cumulative soil compression associated with this repeated loading the assumption of full elasticity in the re-compression stress range is not valid. Cyclic compressibility (C_n) of subsoils for estimated expected mean stresses of employed farm machinery should additionally be determined by repeated (cyclic) loading tests.

Soil compression depends on multiple interrelated factors where especially loading time, pore water pressure, stress path and stress state affect the parameters obtained from soil mechanical tests. Derivation of soil compressibility indices requires an adaption of the boundary conditions in soil mechanical laboratory testing to a more realistic representation of in situ stress paths, i.e., short loading time; short and long term repeated loading. Finally, due to the coupling of hydraulic and mechanical stresses in the course of loading, it is indispensable to standardize initial soil pore water pressure and measure its change during the loading process.

SOIL ERODIBILITY

A measure of the soil's susceptibility to raindrop impact and runoff.

SOIL EROSION MODELING

John N. Quinton

Lancaster Environment Centre, Lancaster University,
Lancaster, UK

Soil erosion is a globally significant environmental process. It degrades the soil upon which we rely on for food, fuel, clean water, carbon storage, and as substrate for buildings and infrastructure. Soil erosion also acts as a mechanism for transferring pollutants to surface waters and can reduce water availability for crops and increase flooding. Given soil erosion's importance it is not surprising that there have been a number of attempts to produce mathematical models of varying complexity to predict its magnitude and in some cases its spatial and temporal distribution.

Soil erosion models broadly fit into two groups: empirical and process-based models, and the reader is referred to edited volumes by Morgan and Nearing (in press) and Harmon and Doe III (2001) for more detailed information. The Universal Soil Loss Equation (USLE) (Wischmeir and Smith, 1978) is the most dominant empirical model. The USLE was developed from over 10,000 plot years of data collected across the eastern half of the USA. The result was a simple equation to predict annual field scale erosion rates, which had six parameters: slope, erodibility, slope length, erosivity, cover, and management and support practice (conservation measures) factor. This allowed the USLE to be adopted by the US soil conservation service as a simple tool for extension officers. The USLE has been incorporated into watershed models, revised, and re-calibrated and used throughout the world.

As a response to the lack of physical representation of erosion processes in the USLE the 1980s saw a number of groups begin to develop process-based approaches to soil erosion modeling. These included the Water Erosion Prediction Project (WEPP) (Nearing et al., 1989), European Soil Erosion Model (EUROSEM) (Morgan et al., 1998), and Griffith University Erosion System Template (GUEST) (Hairsine and Rose, 1992), originating from teams in the USA, Europe, and Australia, respectively. These models offered the potential to be transferable than the USLE, since they used mathematics to represent erosion processes without, for the most part, recourse to empiricisms. Because of their distributed nature they could also identify sites of erosion and deposition in the landscape and compute the delivery of sediment to surface waters. While this group of models were more

satisfying scientifically than the USLE, their predictions suffered from uncertainties associated with high numbers of parameters which were hard to measure in the field, e.g., Quinton (1997).

As we have become more aware of diffuse pollution problems and soil erosion's role in global biogeochemical cycling erosion modeling has responded. Erosion models have been linked to contaminant and carbon transport at scales ranging from tens of square meters up to the global scale. For example, Sander has further developed the Hairsine Rose model to simulate the selective erosion of contaminant containing soil particles. To address the impact of soil erosion on the global carbon cycle, Van Oost et al. (2007) have applied simple models of erosion across the globe to estimate the impact of these processes on the global carbon cycle.

There are now more erosion models available to use than ever before and they are being used to answer an ever wider number of questions – yet there is still room for development. Although scientific progress pushes us toward adding more complexity to our models by including new processes, it is likely that modelers will be forced to be more open and honest about model uncertainties and the ability of models to predict the soil erosion at a variety of temporal and spatial scales. This may focus model development on the production of parsimonious models which can be applied to data sets using uncertainty estimation procedures, such as Generalized Likelihood Uncertainty Estimation (GLUE) (Freer et al., 1996), allowing their predictive uncertainty to be quantified.

SOIL FUNCTIONS

Winfried E. H. Blum
Institute of Soil Research, University of Natural Resources and Applied Life Sciences (BOKU) Vienna, Vienna, Austria

Definition

Soil as a natural resource performs six environmental, social, and economic functions.

Introduction

Soil functions reflect the capacity of soil to function within natural or managed ecosystem boundaries, to sustain plant and animal productivity, maintain or enhance water and air

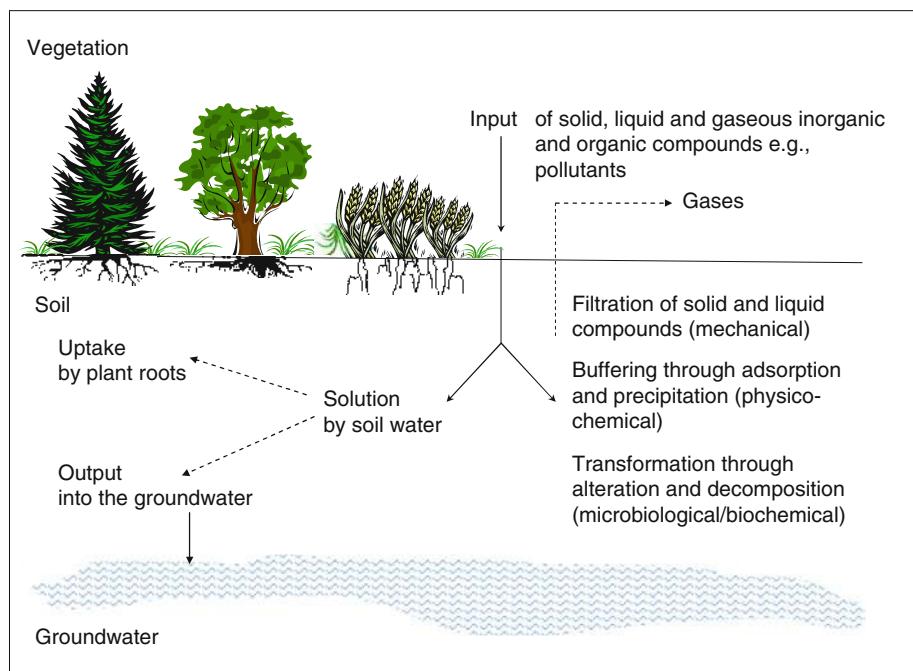

quality, and support human health and habitation (Mausbach and Tugel, 1995, modified).

Soil functions

The three ecological functions are:

1. Production of biomass, ensuring food, fodder, renewable energy, and raw materials. This function is the basis of human and animal life (Blum and Eswaran, 2004).
2. Filtering, buffering, and transformation between the atmosphere, the ground water, and the plant cover, strongly influencing the water cycle at the earth surface as well as the gas exchange between terrestrial and atmospheric systems, and protecting the environment, including human beings, against the contamination of ground water and the food chain (Blum, 1998). This function is most important, because of the many solid, liquid or gaseous, inorganic or organic depositions on which soils react through mechanical filtration, physico-chemical absorption, and precipitation or micro-biological and biochemical mineralization and metabolization, see [Figure 1](#).

These biological reactions may also contribute to global change through the emission of gases from the soil into the atmosphere, because globally the total pool of organic carbon of soils is about three times higher than the total organic carbon in the above ground biomass and about twice as high as the total organic carbon in the atmosphere. Therefore, soils are a central link in the biotransformation of organic carbon and continually play a role in releasing CO₂ and

Soil Functions, Figure 1 Soil as a filter, buffer and transformation substrate.

- other trace gases (e.g., N₂O and CH₄) into the atmosphere. These gases are most important for processes of global change, which in this case involves large-scale feed-back of many local small-scale processes. As long as these filtering, buffering, and transformation capacities can be maintained, there is no danger to the ground water or to the food chain. However, these capacities of soils are limited and vary according to the specific soil conditions.
3. Gene reservoir: Soils are a biological habitat, with a large variety of organisms. They contain two to three times more species in number and quantity than all other above ground biota together. Therefore, soils are the main basis of biodiversity. Human life depends on this biodiversity, because we do not know if we will need new genes for maintaining human life from soils in the near or the remote future. Moreover, genes from the soil are increasingly important for many biotechnological and bioengineering processes.

The three non-ecological functions are:

1. The physical basis for technical, industrial, and socio-economic structures and their development, e.g., industrial premises, housing, transport, sports, recreation, dumping of refuse etc. One of the main problems in this context is the sealing of soils through the continuous increase of urban and peri-urban as well as industrial areas, including transport facilities between them.
2. A source of raw materials, e.g., clay, sand, gravel, and minerals in general, as well as a source of energy and water. Raw materials are the basis for technical, industrial, and socio-economic development. The use of soils for infrastructural development and for the extraction of raw materials can be considered as irreversible.
3. Soils are also important as a geogenic and cultural heritage, forming an essential part of the landscape in which we live, concealing and protecting palaeontological and archaeological remains of importance for the understanding of the history of the earth.

Under holistic aspects, soil and land use can be defined as the temporarily and spatially simultaneous use of all these functions, minimizing irreversible ones.

Outlook

In view of the soil as an absolutely limited resource, which cannot be extended or enlarged, the harmonization between the uses of these six functions, which are often concomitant in the same area, is a key issue of sustainability. However, this is not a scientific but a political task (see COM(2006)231 final, 2006).

SOIL HYDRAULIC PROPERTIES AFFECTING ROOT WATER UPTAKE

Leilah Krounbi, Naftali Lazarovitch

Wyler Department of Dryland Agriculture, French
 Associates Institute for Agriculture and Biotechnology of
 Drylands, Jacob Blaustein Institutes for Desert Research,
 Ben-Gurion University of the Negev, Israel

Definitions

Soil water potential. The energy required to move a unit quantity of pure water from one point in the soil to another.

Compensatory uptake. The ability of a plant to transpire at its potential rate under drying conditions through root water uptake from the sparsely rooted, but wetter and less saline regions in the soil profile.

Root length density. The root length per unit volume of soil.

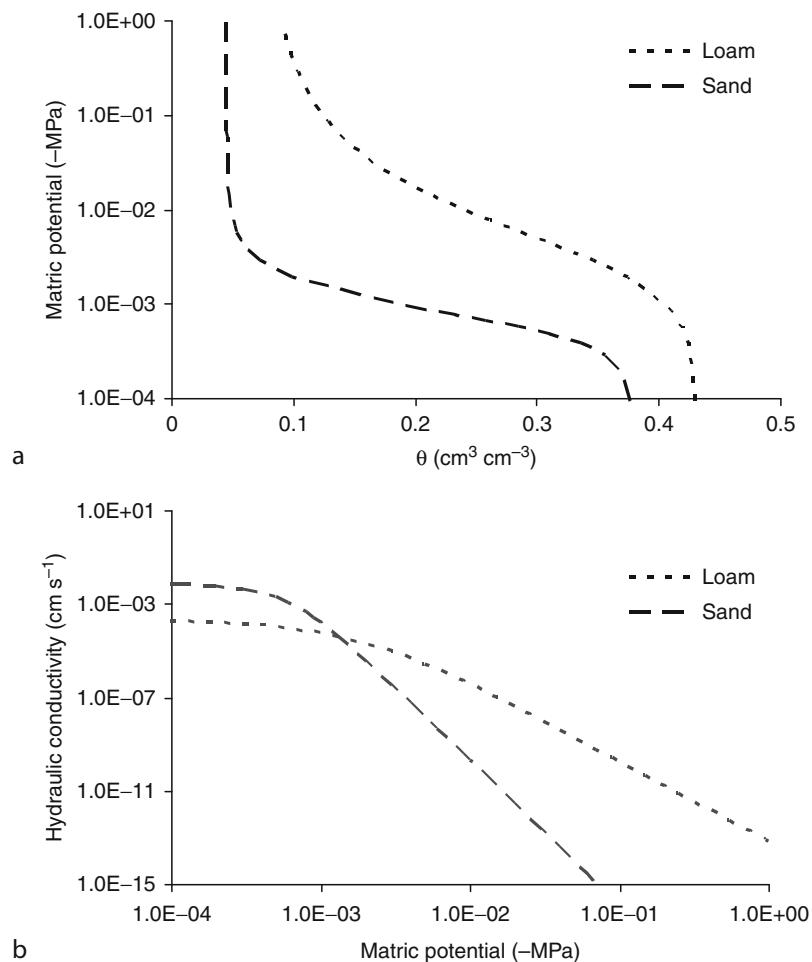

Introduction

Contemporary agriculture, with its dependence on irrigation, fertilizers, and pesticides, contributes significantly to water and solute fluxes through the soil, specifically in arid and semi-arid areas. The quality and quantity of this water as it passes through the vadose zone is governed primarily by plant water uptake (Vrugt et al., 2001; Simunek and Hopmans, 2008; Skaggs and Shouse, 2008). In non-limiting conditions, the atmospheric demand controls uptake, while in water deficit soils characteristic of field conditions, the soil hydraulic properties seem to determine root water uptake (Feddes and Raats, 2004). Compensatory uptake is one example of the latter scenario.

Therefore, accurately predicting the temporal and spatial root water uptake pattern in a drying soil, as a function of the soil hydraulic properties, is important for sustainable agricultural resource management that minimizes soil and groundwater pollution.

Soil hydraulic properties

The high nonlinearity of the soil hydraulic functions describing the relation between the soil water potential, water content, and the hydraulic conductivity (Lazarovitch et al., 2007) can be seen in the retention and conductivity curves depicted in Figure 1. Soil particle size distribution, or texture, is a primary factor in determining the slope of both the water content and hydraulic conductivity curves as a function of the soil water potential. Sand is characterized by larger sized soil particles, which aggregate into larger water-conducting pores. The wall surfaces of these soil capillaries adsorb a relatively small percentage of water molecules in the flow stream. The limited water holding capacity of sand therefore

Soil Hydraulic Properties Affecting Root Water Uptake, Figure 1 (a) The soil water content at varying water potentials for two soils, loam and sand. (b) The soil hydraulic conductivity at varying water potentials for two soils, loam and sand.

confers greater hydraulic conductivity, or easier drainage, near the saturation range. This is made evident by the drastic drop in the soil water content of sand at the onset of low potentials, depicted in [Figure 1a](#). The small-diameter pores typical of loamy soils are comprised primarily of finer particles characterized by a high water holding capacity. Slight changes in the soil water content necessitate the application of lower water potentials, and the residual water content of loam is markedly higher than that of sand ([Hillel, 1998](#)). The gradual change in the hydraulic conductivity of loamy soil with decreasing soil water potentials, as shown in [Figure 1b](#), can be attributed to the higher percentage of water molecules adsorbed to pore walls, coupled with the increasing difficulty of releasing them at low potentials. The change in the hydraulic conductivity of sandy soil with decreasing potentials is much more drastic, eventually dropping below that of loam once most of the soil water has been drained.

Water flow through the soil–plant–atmosphere continuum (SPAC)

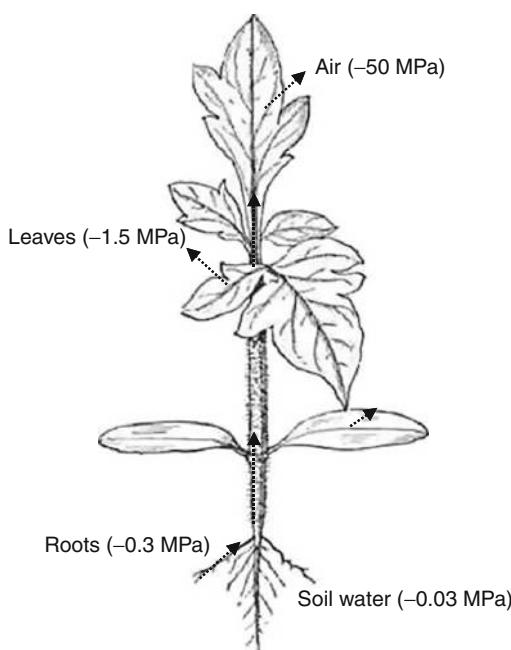

Water potential gradients serve as the force inducing flow within and between adjacent compartments in the SPAC ([Boyer, 1995](#); [van der Ploeg et al., 2008](#)). [Figure 2](#) highlights the typical potential differences between soil water and atmospheric water vapor, oftentimes amounting to tens of megapascals (MPa). The effectiveness of plants in meeting a continuous evaporative demand through

increased water extraction is primarily determined by the soil's ability to deliver water to the root surface. As the soil dries, the soil water potential decreases, leading to a subsequent reduction in the hydraulic conductivity. To maintain the water potential gradient powering the transpiration stream, the root water potential must decrease beyond that of the soil. But while the soil water potential can decrease to very low values, the root water potential is limited by a critical value, around -1.6 MPa for most agricultural crops ([Koorevaar et al., 1983](#)), below which plant death ensues. While root water uptake is often equated to transpiration, water flow through the SPAC may be affected by fluxes between the xylem and adjacent parenchyma cells. The lag time between the onset of maximum water potential gradients in the leaves and xylem demonstrates a lack of coordination in water potential changes between SPAC compartments, pointing to the effect of plant capacitance on the transpiration stream ([Nobel and Jordan, 1983](#)).

An Ohm's law type of relationship ([van den Honert, 1948](#); [Feddes and Raats, 2004](#)) describes the water flow through the SPAC. The flux is expressed as a function of the operating water potential per unit distance, and a proportionality factor that defines either the conductance or the resistance of the transmitting media to water flow; the flux is assumed constant from soil to atmosphere so that segments characterized by large gradients will also have large flow resistances. The definition of the proportionality factor changes between soil and plant systems according to the spatial scale of the water-transferring media ([Hopmans and Bristow, 2002](#)). The overall resistance is defined as the series combination of all resistances in the SPAC ([Campbell, 1985](#)). Water evaporation from the stomatal cavity to the atmosphere is met with the largest resistance in the SPAC.

While multiple methods exist for measuring both soil and leaf water fluxes and potentials from which respective compartmental flow resistances can be deduced, little success has resulted from attempts at measuring soil–root interface potentials and fluxes, and much controversy remains surrounding this subject ([Personne et al., 2003](#)). Steep water potentials and hydraulic conductivity gradients at the soil–root interface have been demonstrated experimentally ([Duham and Nye, 1973](#); [Hainsworth and Aylmore, 1989](#); [Schmidhalter, 1997](#)). Experimental data presented by [Taylor and Klepper \(1975\)](#) for water uptake by cotton roots show that in a wet soil, the soil–root interface hydraulic conductivity was up to six orders of magnitude smaller than the bulk soil hydraulic conductivity. These results indicate that in field conditions, most of the flow resistance from soil to plant lies in the soil–root interface. In very dry soils, the conductivities of both the bulk soil and the soil–root interface are of similar magnitude ([Raats, 2007](#)).

Recent research highlights the dominance of soil hydraulic conductivity in affecting root water uptake. [Schroeder et al. \(2008\)](#) used a three-dimensional numerical model to assess root water uptake with and without

Soil Hydraulic Properties Affecting Root Water Uptake,
Figure 2 The transpiration stream through the soil–plant–atmosphere continuum, with representative potential values indicated for various compartments.

a hydraulic conductivity drop in the rhizosphere. Results show that a sharp decrease in the hydraulic conductivity near the root greatly affects root water uptake, specifically in cases where the radial root hydraulic conductivity is greater than that of the bulk soil. Experiments designed to isolate the effects of the soil water potential and the soil hydraulic conductivity on root water uptake show that the latter has a much more pronounced effect on uptake patterns (Zeelim, 2009). The presence of dry soil layers within the rhizosphere has been put forth as one explanation for the steep hydraulic conductivity gradient in the vicinity of the root surface (Rendig and Taylor, 1989). Herkelrath et al. (1977) postulated that the soil hydraulic conductivity drop at the soil–root interface results from a decrease in the effective area of contact between root and soil with decreasing water content. During drying periods, soil and root shrinkage can result in roots diminishing to 60% of their original size, and in much of the root epidermis detaching from soil particles (Rendig and Taylor, 1989).

Root water uptake under stressed conditions

Root water uptake is a function of both a physical root parameter, commonly referred to as the root length density (Gardner, 1964; Taylor and Klepper, 1975; Feddes and Raats, 2004), and the soil water status (de Jong van Lier et al., 2008). The location of maximum water uptake in a homogenous soil profile of uniform water content and hydraulic conductivity is correlated with the soil layer containing the largest root length density. Under field conditions, plants are both subject to, and the source of, great spatial variability in the soil water content. The upper soil layers containing the bulk of the root zone are usually the most water depleted, while the deeper regions of the soil profile containing fewer roots are wetter.

Although plants can minimize transpiration and the resulting growth rates under limiting conditions to conserve water, many plants maintain a constant, potential transpiration rate long after the commencement of the drying process. One explanation for this is the elongation of deeper, finer roots into soil regions, saturated with untapped water stores. Experimentation with *Arabidopsis* seedlings subjected to drought and osmotic stress showed an increase in primary root growth in the deeper soil regions in response to stress, while lateral root elongation was temporarily arrested (Xiong et al., 2006). Another mechanism by which plants sustain potential transpiration rates in drying soils is compensatory uptake, whereby plants respond to nonuniform, limiting conditions by increasing water uptake from areas in the root zone characterized by more favorable conditions (Skaggs et al., 2006).

Reicosky et al. (1972) report on a pronounced example of compensatory uptake, where, in the vicinity of a water table, 20–25% of plant roots extracted 80–90% of the transpired water. In their study of alfalfa root uptake in a drying soil, Nimah and Hanks (1973a) found that plants

were able to continue transpiring at their potential rate by compensating for the loss in water uptake from the root dense, but drier surface soil layers through uptake from the deeper, wetter regions in the soil. They report that, in agreement with Reicosky et al. (1972), the maximum root extraction zone of alfalfa deepened over time as a result of upward flow from a water table (Nimah and Hanks (1973b)). The observed increase in uptake from the wetter soil regions under drying conditions, as reported by Reicosky et al. (1972) and Nimah and Hanks (1973b), sheds light on the more dominant role of the soil hydraulic properties over the root distribution in affecting root water uptake.

Devices to explore root water uptake

Root water uptake can be monitored using both invasive and noninvasive techniques. In situ devices such as tensiometers, time domain reflectrometry (TDR), and dual probe heat/temperature sensors can measure local changes in the soil water status over time. Studying soil–root water fluxes using invasive devices requires microsensors at the scale of millimeters, a range much smaller than presently available devices. Other difficulties in using invasive technology include the site-specific calibrations necessary for indirect methods such as heat dissipation and TDR, and the limited measurement range of tensiometers. Noninvasive techniques such as computer tomography (CT) and magnetic resonance imaging (MRI) produce two- and three-dimensional, high-resolution images of the rhizosphere from which root growth and changes in the soil water content can be measured. Noninvasive methods have significantly improved our understanding of plant responses to drought stress (Garrigues et al., 2006), but are complicated to operate and not suitable for field use.

Vetterlein and Reinhold (2004) used a ceramic capillary microtensiometer 1 mm in diameter and 5 mm in length to measure the differences between the soil water potential in the rhizosphere and the bulk soil. Segal et al. (2008) developed a pliable-tipped microtensiometer from a plastic pipette tip lined with geotextile, filled with milled quartz in contact with a water reservoir, and attached to a pressure transducer. A wick extending from the pipette tip into the rhizosphere enabled a close monitoring of rhizosphere water potentials from distances as close as 1 mm from the root surface. Segal et al. (2008) studied the soil water potential as a function of distance from the root surface using a growth container sectioned off into two portions by a diagonal screen, which confined root growth. Opposite the screen, six identical microtensiometers were inserted at 2.5 mm depth intervals, such that the distance of each microtensiometer tip from the screen upon which a root mat eventually formed, increased with depth. Results showed that the development of a significant potential gradient, or drawdown zone, as near as 3 mm from the root surface became noticeable following 1 day of root water extraction. van der Ploeg et al. (2008) recently developed a polymer tensiometer able to measure the full

range of soil water potentials encountered in a cropped soil, down to the wilting point value of -1.6 MPa . Root water uptake was monitored in cropped lysimeters subjected to three irrigation regimes – minimum, intermediate, and maximum stress – with both polymer tensiometers and TDR sensors. Results from the maximum stress treatment showed that after severe drying down to -0.7 MPa , larger potential gradients indicating water removal were detected between 0.4 and 0.6 m depths than at 0.2 and 0.4 m depths. TDR measurements showed a vertically uniform water content profile. The ability of the polymer tensiometers to detect extremely low potential gradients across various depth increments helped to identify root water uptake zones that would not have been noticeable from TDR measurements in that particular soil.

X-ray imaging techniques such as CT have been used to measure a variety of soil properties such as bulk density (Anderson et al., 1988), porosity (Phogat and Aylmore, 1999), and water content (Hopmans et al., 1992). CT outputs a series of linear attenuation coefficients for each image pixel that can be calibrated to known water content values (Hamza et al., 2001). Root imaging using CT on the scale of a few centimeters was reported by Gregory et al. (2003) and Perret et al. (2007). Hanisworth and Aylmore (1983, 1986) used CT to measure changes in the soil water content with time, and were able to calculate root water uptake from radishes transpiring at high and low rates. Hamza et al. (2001) studied the effect of low soil water content on prolonged radish root water uptake using CT scans. Results showed that as the water content decreased from 0.3 to $0.1\text{ cm}^3\text{ cm}^{-3}$, the transpiration rate decreased tenfold. The ability of plants to maintain transpiration in such dry conditions was attributed to osmotic adjustment by leaves. In addition, it was shown that the water content at the soil–root interface was 2.5 times smaller at the end of the experiment in drier soils than in wetter soils, and that the extent of the sharp potential gradient immediate to the root surface was also less.

Another noninvasive method for quantifying the water content in the root zone is MRI. MRI scans have been used to monitor water infiltration into soils (Vortrubova et al., 2003), image roots two-dimensionally (Cofer et al., 1989), and visualize root water uptake in porous media (Brown et al., 1990). Segal et al. (2008) used MRI images of the soil water content distribution in the rhizosphere to study the effect of water uptake by a single barley root on soil water depletion patterns. The soil water content of the imaged rhizosphere was quantified using a calibration curve of the MRI signal/noise ratio and the volumetric water content of two sandy soils. Results showed the development of a steep water content gradient near the soil–root interface 2 h after water uptake commenced, which gradually increased with distance from the root until approaching the bulk soil water content. Pohlmeier et al. (2008) used MRI to image the root architecture of 4-week old castor bean plants, and to study changes in the soil water content following root uptake. Results from

both types of imaging showed that soil regions containing the highest root densities, near the bottom and toward the surface of the plant container, experienced the greatest change in the soil water content due to root water uptake.

Summary

Various environmental and plant physiological factors play a role in determining root water uptake patterns. The soil physical properties such as the particle distribution affect the amount of soil water available for plant consumption, and the rate of water transfer from soil to root. Climate conditions determine the evaporative demand that is met by transpiring plants primarily through root water uptake. Steep water potential and hydraulic conductivity gradients have been observed in the vicinity of the root surface due to an increase in the flow resistance from the bulk soil to the soil–root interface. In drying soils, the soil hydraulic properties have a more dominant role in regulating water uptake than the physical properties of roots, and the effect of the soil hydraulic conductivity on root water uptake has recently been shown as much more significant than the soil water potential. Compensatory uptake is one example of how root water uptake patterns are controlled by the soil hydraulic properties in suboptimal conditions. The development of both invasive and noninvasive soil sensors has alleviated much of the difficulty in researching below-ground processes, and has enabled imaging of root development and changes in the soil water content due to root water uptake.

While much research has been carried out to examine the effect of drought conditions on root water uptake, the effects of other stresses, such as salinity, oxygen stress, and temperature extremes, as well as the combined effect of multiple stresses, are also important topics of research. Root water uptake studies usually focus on fully developed root zones, thereby taking the root density distribution throughout the soil profile as constant. New experiments should be performed to look at dynamic root water uptake patterns as a function of both variable soil conditions as well as a changing root density distribution. Nutrient uptake as affected by the water flow and nutrient transport in the soil remains another important topic of research, and can help in planning fertigation regimes that maximize root water uptake and the resulting crop yields while minimizing groundwater pollution by leachate.

SOIL HYDROPHOBICITY AND HYDRAULIC FLUXES

Peter Hartmann

Department of Soils and Environment, Forest Research Institute Baden-Wuerttemberg, Freiburg, i. Br., Germany

Synonyms

Soil hydrophobicity = soil water repellency

Definitions

Hydrophobicity derives from the Greek “hydro” and “phobos” that means water and fearing. The reverse is hydrophilic, from “philos” – loving.

Hydraulic derives from Greek “hydraulikos” – “aulos” means hollow tube.

Flux derives from Latin “fluere,” which means flow.

Soil hydrophobicity affects the soil water contact angle (CA) and thus the capillary forces of soil (Bauters et al., 2000). Hydraulic fluxes in soil are mainly capillary flows, which are driven by gravity and interfacial pressure differences. These depend on the geometry of the pores and on local wetting properties that are a time-dependent function of moisture content (Bachmann et al., 2007). Hydrophobicity is strongest in dry soils and decreases with remoistening and higher water contents. In a hydrophobic soil ($CA > 90^\circ$) water infiltrates not until the persistence of hydrophobicity is exceeded respectively a positive water entry pressure value is applied. In the latter case, first large pores will fill with water before fine pores are moistened and infiltration increases with time (Wang et al., 2000). Contrary is the infiltration in a hydrophilic soil ($CA < 90^\circ$), where water infiltrates first in fine pores with a constant infiltration rate (Hillel, 1980). Hydrophobicity causes unstable wetting fronts and is assumed to induce preferential flow, which is of major importance in the spatial distribution of water in soil (Ritsema and Dekker, 2000).

SOIL PENETRABILITY, EFFECT ON ANIMAL BURROWING

Petr Heneberg

Charles University in Prague, Prague 10, Czech Republic

Synonyms

Soil hardness, effect on animal burrowing; Soil penetrability, effect on animal digging behavior; Soil penetration resistance, effect on animal burrowing

Definition

Soil penetrability. Measure of the ease with which an object can be pushed or driven into the soil.

Burrow. A hole or tunnel dug into the ground by an animal, for habitation, temporary refuge, or as a byproduct of locomotion.

Introduction

Burrowing behavior evolved independently in species separated by >500 million years of evolution from two phyla (*Arthropoda* and *Chordata*), seven classes (*Arachnida*, *Insecta*, *Malacostraca*, *Osteichthyes*, *Amphibia*, *Reptilia*, and *Mammalia*). These species vary

by six orders of magnitude in their body mass, and occupy both marine and terrestrial habitats (White, 2005).

Numerous species of burrowing animals bear morphological and physiological adaptations for subterranean life, with strongly convergent traits, showing structural reduction of limbs, tails, eyes, and external ears, together with structural developments of incisors, forelimbs, pectoral girdle, claws, sense organs, and pineal gland that complement each other to optimize burrowing capacities and efficiency (Nevo, 1979).

For semifossorial or fossorial species, any reduction in burrowing costs increases the net energy yield from a given section of burrow. Given that burrowing cost is proportional to the volume of soil excavated (Vleck, 1979), it is apparent that any reduction in construction costs achieved through a reduction in burrow length, or cross section, will similarly reduce the energy yield from the burrow (White, 2005). However, the available habitat patches are not equal to each other. Among the main differences is the soil penetrability, which is not uniformly distributed either vertically or horizontally.

Soil penetrability and vertebrates

Soil penetrability was shown to affect burrowing behavior of mammals, such as tuco-tucos (*Ctenomys talarum*; Luna and Antinuchi, 2006), and wombats (*Lasiorhinus latifrons*, Walker et al., 2007). In birds, ~18% of bird species was shown to be primary or secondary cavity nesters (Newton, 1994), and the burrowing behavior of sand martins (*Riparia riparia*), bee-eaters (*Merops apiaster* and *Merops philippinus*), and Eurasian kingfishers (*Alcedo atthis*) were shown to be dependent on the soil penetrability (Yuan et al., 2006; Heneberg, 2009). Even the non-burrowing bird species that specialize in feeding on soil invertebrates were found to be soil-penetrability-dependent, among them lapwing (*Vanellus vanellus*; Lister, 1964), snipe (*Gallinago gallinago*; Green et al., 1990), song thrush (*Turdus philomelos*; Peach et al., 2004), and yellow wagtails (*Motacilla flava*; Gilroy et al., 2008). These birds were found to check the soil or intertidal substrates by probing with the bill. For the common snipe, the penetrability of wet grassland soils was even found to be a more important determinant of the duration of the breeding season and foraging site selection than prey abundance (Green et al., 1990).

Soil penetrability and semifossorial insect

Among semifossorial insect, soil penetrability has been studied in relation to the presence and nesting of numerous solitary hymenopteran species (wasps and bees). A large number of these species is ground-nesting, and soil is considered as a limiting factor for local bee communities (Kim et al., 2006). Nesting of at least 10 bee and wasp species was already shown to be dependent on the soil penetrability (Ghazoul, 2001; Kim et al., 2006; etc), thus one might speculate that the dependency on soil penetrability

is a shared phenomenon among all ground-nesting aculeate hymenopterans. However, individual species differ in their soil penetrability requirements, suggesting that these preferences may contribute to the decrease of potential interspecies competition. Some species tend to utilize the whole spectrum of substrates with low and medium penetrability resistance values (*Lasioglossum sp.*), some others were found to prefer soils with medium (*Halictus tripartitus*, *Sphex ichneumoneus*), or low penetrability resistance only (*Halictus ligatus*) (Brockman, 1979; Kim et al., 2006). The habitat selection may be even more complicated, as *Halictus rubicundus* was found to prefer localities with low penetrability resistance. However, within site, this species selects spots with medium soil penetrability (Potts and Willmer, 1997).

The semifossorial hymenopterans spend long time with predigging search, a complex behavioral pattern involving search for soil with appropriate penetrability, granulometrical characteristics, temperature, and plant cover (Brockman, 1979; Field, 1989). Simply, if the soil is too soft, it tends to collapse. If the soil is too hard-packed, the fossorial hymenopteran resumes the predigging search. Depending on the burrow length, species-specific techniques, and penetrability resistance, the digging of one burrow may last only 20 min, but it can take also more than 24 h.

Some species, such as *Mellinus arvensis*, were reported to prolong the time of digging accordingly to the increasing soil penetrability resistance (Ghazoul, 2001). Some other species, such as *Episyron quinquenotatus*, were reported to decrease the length of their burrows when the soil penetrability resistance increases (Kurzewski, 2001). Thus, the higher penetrability resistance leads to the increase of costs of nesting, or, alternatively, to the decrease of the burrow length. This in turn may lead to higher predation, higher nest usurpation rate, or to higher susceptibility to damage of the nest cells due to erosion or other external disturbances. At habitat patches lacking soils with low penetrability resistance, various species of wasps and bees were even shown to increase the frequency of nest usurpation and nest sharing. Such behavior has been shown for *Mellinus arvensis*, *Cerceris antipodes*, *Cerceris australis*, *Cerceris cibrosa*, *Cerceris simplex*, and *Andrena erythronii*. Nesting in substrates with higher penetrability resistance may also lead to the decreased fitness of digging individuals, as in fossorial ant communities the increased energy expenditure and desiccation due to cuticular abrasion is thought to be related to higher mortality rate of adult excavation specialists compared to the nonspecialists.

Soil penetrability and other invertebrates

Representatives of several other groups of invertebrates were also shown to be dependent on soil penetrability. Among them are springtails (*Collembola*), the density of which is reduced with decreasing penetrability and increasing bulk densities. This behavior is shared among

at least nine springtail species (Dittmer and Schrader, 2000; Larsen et al., 2004) and thus seems to be characteristic for springtails as a typical soil-specialist invertebrate group. Some of the arachnids (*Arachnida*) were also shown to be dependent on proper soil penetrability, as Bradley (1986) reported it for scorpion *Paruroctonus utahensis*. Soil penetrability and compaction is also a strong determinant of presence and activity of earthworms (*Lumbricina*), such as *Aporrectodea caliginosa* and *Lumbricus terrestris* (Joschko et al., 1989; Stovold et al., 2004). Despite very few studies being focused on fossorial invertebrates, it is highly probable that the soil penetrability dependence is associated with most of the other groups of invertebrate soil specialists.

Burrowing in aquatic species

Penetrability is also known to have strong influence on density and distribution of marine macrofauna in coastal intertidal zones. Among the groups influenced are *Mollusca* (*Bivalvia*), *Annelida* (*Polychaeta*), *Oligochaeta*, *Nemertea*, *Sipuncula*, *Arthropoda* (*Amphipoda*, *Brachyura*), and *Insecta* (Hsu et al., 2009). Among others, penetrability of coastal intertidal zones affects density and distribution of economically important species, such as shrimps (*Caridea*) (Eckrich and Holmquist, 2000). Marine sediments are dominated by mud – elastic solids that fracture under small tensile forces exerted by burrowers. Thus, numerous aquatic species had been shown to burrow by crack propagation, not by various forms of digging common among terrestrial burrowers. Among the groups shown to use crack propagation are polychaetes (*Nereis virens*) and bivalves (*Yoldia*) (Dorgan et al., 2005, 2006). However, it is still unclear how often and under what conditions a crack becomes a burrow.

The historical view of the function of animal burrow is that it represents a microrefuge, or shelter from environmental stresses such as temperature extremes, fire, or predation. Despite the burrowing costs, the burrowers have been extremely successful in the reinforcement of social life, in the alteration of habitats, in the exploitation of the resources of others, and in the invasion in new habitats.

Summary

Soil penetrability was shown to affect burrowing of both, terrestrial and aquatic animals. As soil penetrability is not uniformly distributed either vertically or horizontally, species-specific soil penetrability preferences result in spatiotemporal separation of habitats utilized by different burrowing species, and thus contribute to decrease in overlap between available resource patches.

Cone penetrometer; Profile penetrometer

Definition

Penetrability. The ability or ease at which an instrument can penetrate the soil.

Soil penetrometer. Device consisting of a rod (shaft) with a pointed or blunt tip on one end that is pushed or hammered into the soil to measure soil penetration resistance, soil penetrability or strength.

Introduction

Soil penetrometers are instruments that can be used to measure the strength, compactness, or cohesiveness of a soil. Originally, penetration tests were conducted to determine soil load bearing capacity for engineering purposes. They have also been used extensively in geotechnical engineering to describe the stratigraphy of geological layers. In agriculture, penetrometers are traditionally used

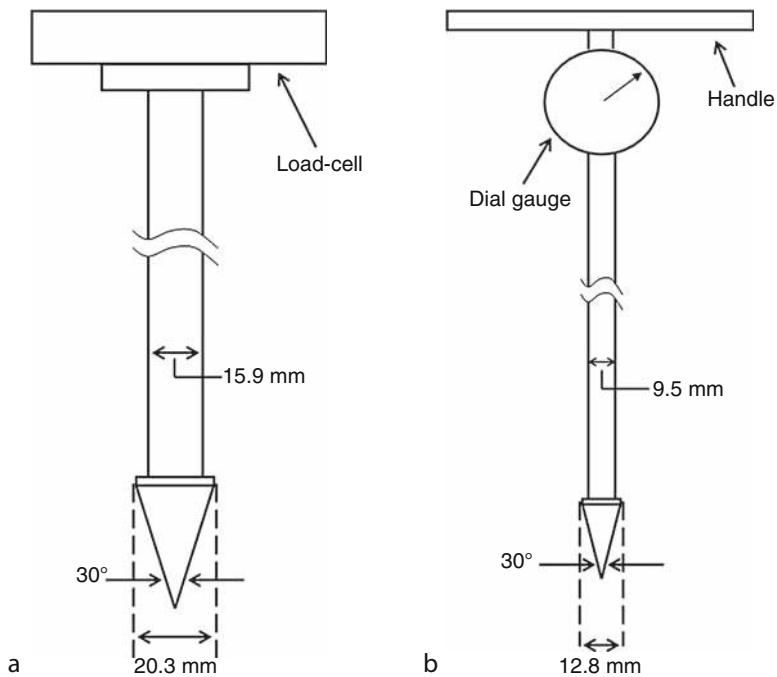

to measure soil compaction, although other uses, including soil mapping, have been implemented.

Design

Several designs have been proposed and are in use today, with many commercially available devices. Soil penetrometers in their most simple form consist of a metal rod that can be pushed or hammered into the ground manually. If it is pushed, the individual pushing the penetrometer would “sense” the force required to penetrate the soil. This requires a certain level of training and experience. However, most penetrometer designs incorporate a dial, spring loaded scale, or load cell to measure the force required to push the rod into the ground. The rod or shaft can have evenly spaced markings to measure the depth of readings. More complex designs incorporate electronic load cells and will be discussed in more detail later. Pocket penetrometers are convenient since, as the name implies, they can be easily carried in a pocket or bag. However, they have a blunt tip and only measure penetrability of very shallow depths, the soil surface, or exposed soil layers (Lowery and Morrison, 2002). Drop penetrometers are not pushed into the soil surface but rather dropped from a given height. The depth to which the drop penetrometer inserts itself into the ground gives the user an idea of soil compaction and penetrability at the soil surface. A laboratory version of the drop-cone penetrometer can be used to determine the liquid limit of cohesive soils (McBride, 2002). The dynamic cone penetrometer (Herrick and Jones, 2002) is yet another very simple device for measuring cone penetration resistance. According to Herrick and Jones (2002), the dynamic penetrometer method does not require one to push the penetrometer through the soil, nor does it need one to apply continuous force to the penetrometer. Dynamic penetrometers supply a known amount of kinetic energy (KE) to the penetrometer, which causes the penetrometer to move some distance through the soil. Penetration distance depends on the KE applied, the geometry of the penetrometer tip, and the soil penetration resistance.

The dimensions and geometry of the tip and the rod itself can affect penetration measurements. For agricultural purposes, most penetrometers consist of a stainless steel rod with a threaded, replaceable, tip attached to one end and a handle on the other. The tip is constructed of stainless steel with a 30° angle and can have two different base diameters, 12.8 or 20.3 mm (Figure 1) (ASAE, 1999a). The American Society of Testing and Materials (ASTM) suggests using a 60° cone; however, the application of this design is mainly intended for civil engineering purposes (ASTM, 2007). It is important to note that penetrometers with a cone that have an angle greater than 30° will exhibit lower penetrability (i.e., greater cone index values), while decreasing the diameter of its base will have the opposite effect. If one desires to make comparisons between treatments or soil conditions, it is important that the same type of penetrometer is used.

Soil Penetrometers and Penetrability, Figure 1 Soil penetrometer dimensions and examples of two common designs: (a) using a load-cell for force data measurement and, (b) a manual design with a dial gauge. Adapted from ASAE, 1999a.

Cone index and insertion speed

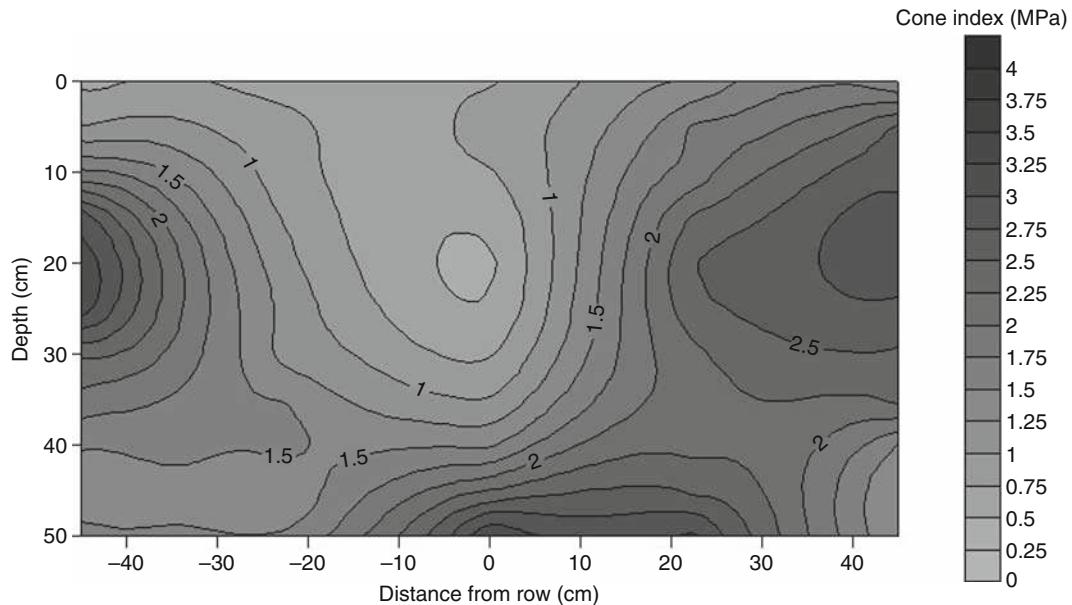

Penetrability measurements taken with a soil penetrometer can be expressed as the force required to push the cone into the ground. This force is typically referred to as the cone index and is defined as the force per unit base area (ASAE, 1999b). Further, it is recommended that a constant insertion rate of 30 mm/s be used when acquiring data with a soil penetrometer (ASAE, 1999b). However, it is noted that lower insertion rates would not introduce significant error to the measurement. In any case, it is important for the penetrometer rod to be pushed at a constant rate to avoid artificial spikes in the data.

Uses of soil penetrometers

Soil penetrometer designs also vary in the manner they record cone index and in the manner they are pushed. The most common and simple soil penetrometers are pushed into the soil manually by the user and measure cone index with either a dial or spring gauge. The main information that can be obtained with this type of device is the maximum cone index value and depth of the maximum value. This would be useful to determine the presence of hardpans and depth of subsoiling required to alleviate this condition. Cone index values >2 MPa are often considered to be root restricting (Taylor and Gardner, 1963; Raper et al., 1994).

Soil penetrometers used for most research purposes are designed to allow for the recording of the cone index data digitally as the rod/tip is pushed into the soil/material, as

well as the soil depth associated with the reading. This provides the user with a picture of the penetrability of a given soil profile. The force is typically measured with a load cell and the depth with a sonic depth indicator, an encoder, or a potentiometer. Various commercially available models rely on human power to push the device into the soil. However, Lowery (1986) developed a portable soil penetrometer that fits between crop rows and can be electrically driven into the soil at a constant speed, improving the quality of data collected compared to a manually pushed penetrometer. Other soil penetrometers have been designed to be driven hydraulically, thus allowing for constant insertion rates. Raper et al. (1999) developed a multi-probe soil penetrometer consisting of an array of five rods, each one with its own independent load-cell. This setup provides cone index data at five locations simultaneously and can be used to create contour plots of penetrability for soil profiles (Figure 2). Others have used soil penetrometers to map soil variability in agricultural landscapes since penetrometers can measure differences in penetrability between soil layers and depth to these layers (Grunwald et al., 2000, 2001). Arriaga and Lowery (2005) developed a three-dimensional (3-D) map of an eroded landscape with data collected with a soil penetrometer and used this and other information to estimate the total amount of soil organic carbon stored in various soil horizons. Other penetrometer designs have incorporated simultaneous determination of soil water content with some success (Morrison et al., 2000; Young et al., 2000).

Soil Penetrometers and Penetrability, Figure 2 Contour plot of cone index data collected with a multiple cone soil penetrometer for a soil profile in the autumn. Notice the area with lower cone index values is associated with the location of a bent-leg subsoiling operation conducted in the spring, and the area to the right with greater cone index values relates to the traffic middle. (Unpublished data)

Soil properties that affect penetrability

Penetrability is a function of several soil properties including soil water content and bulk density. Typically, penetrability and cone index values are directly correlated with soil bulk density (Lowery and Schuler, 1994; Grunwald et al., 2001). However, soil particle size distribution also affects penetrability, particularly clay content. The manner in which clay content affects cone index values is affected by soil moisture. Also, past tillage and traffic practices often cause increased bulk density in wheel tracks. Differences in cone index due to inherent soil conditions are sometimes difficult to determine due to differences caused by tillage and traffic events. Therefore, it is difficult to develop so-called pedo-transfer functions that would predict clay content, bulk density, or soil moisture from cone index values alone. Additionally, it is recommended to take data with soil penetrometers as close as possible to field capacity conditions (i.e., after a significant rainfall event) to minimize differences between treatments that might be caused by soil water content during soil investigations.

Summary

Soil penetrometers are useful tools that measure the penetrability, or strength, of a soil. They can be as simple as a rod or shaft with a blunt or sharp end, or complicated mechanically driven instruments with digital data collection systems. Regardless of their design, soil penetrometers measure soil penetrability and can detect differences in soil strength within a soil profile. Traditionally,

penetrometers in agriculture have been used to detect soil compaction issues and depth to compacted soil layers. However, with advances in electronics and computing power, several researchers have created innovative uses for soil penetrometers such as the development of pedotransfer functions and 3-D mapping of soil landscapes from cone index data. With the advent of new technologies and coupling of other sensors, soil penetrometers will continue to be important useful tools in agrophysics.

SOIL PHASES

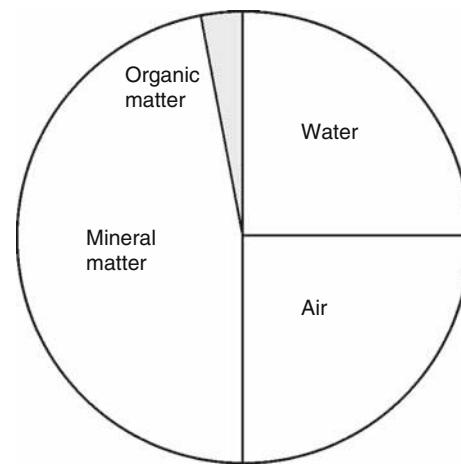

Jan Gliński
Institute of Agrophysics, Polish Academy of Sciences,
Lublin, Poland

Soil phase is a portion of a mixture that has: (1) differing properties from the contiguous material and (2) definite bounding surfaces (Fredlund and Rahardjo 1993).

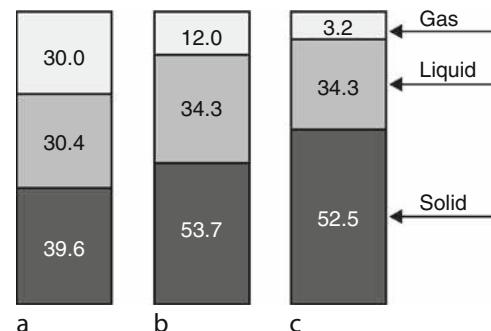

Soil is a heterogeneous, multiphase, disperse, and porous system. It is built of four phases: solid, liquid, gaseous, and living phase composed of organisms that participate in soil metabolism. In unsaturated soils, additionally, the air-water interface as an independent phase (or contractile skin) is distinguished (Fredlund and Rahardjo 1993). Phases play a significant role in formation soil, physical properties, and processes. A typical example of the proportion of phases in mineral soils is shown in Figure 1. In organic soils, which are in minority (about 1.2% of the world land area), these proportions are other, to the advantage of organic matter (at least 30%).

The distribution of solid, gaseous, and liquid phases within soil profile creates soil structure (soil architecture). When soil is dry, only solid particles and air within the pores are present, creating two-phase composition.

Phases have own volume and weight (except air phase), and they are not evenly distributed within the soil.

Soil Phases, Figure 1 Approximate proportions of phases in mineral soils (From Lal and Shukla, 2004; changed).

Soil Phases, Figure 2 Changes of a three-phasic system (in volumetric percent) of an upper layer of loess soil (acc. to Turski et al., 1997, changed), (a) after ploughing (soil density $1.06 \times 10^3 \text{ kg m}^{-3}$), (b) after wheat harvest (soil density $1.40 \times 10^3 \text{ kg m}^{-3}$), and (c) shortly after compaction by tractor (soil density $1.69 \times 10^3 \text{ kg m}^{-3}$).

The relative proportion of the phase change strongly depends on soil management practices. An example of such change due to soil compaction is shown in [Figure 2](#).

To determine numerous soil ecological functions, such as transport processes, buffering and transformation capacities, biological habitat, production of biomass (Blum, 2008), drainage and irrigation practices, phase diagram, and phase relationships based on ratios of the volume and mass are useful (Lal and Shukla, 2004).

The term *soil phase* is also used as a “subdivision of a soil type of other unit of classification having characteristics that affect the use and management of the soil, but which do not vary sufficiently to differentiate it as a separate soil type. A variation in a property of characteristic (e.g., degree of slope, degree of erosion, stone content)” (Gregorich et al., 2002).

SOIL PHYSICAL DEGRADATION: ASSESSMENT WITH THE USE OF REMOTE SENSING AND GIS

Stanisław Białousz

Department of Photogrammetry, Remote Sensing and GIS, Warsaw University of Technology, Warsaw, Poland

Synonyms

Information systems; Satellite images; Soil degradation; Soil harms; Soil threats

Definitions and introduction

Soil physical degradation is involved in more general notion “soil degradation.” In common understanding, soil degradation is defined as “the general process by which

soil gradually declines in quality and is thus made less fit for a specific purpose, such as crop production” (Soil Science Glossary Terms Committee, 2008).

“Remote sensing (fr. télédétection) means combination of techniques and methods to recognize, identify and investigate objects (e.g., soils) and phenomena (e.g., temperature) from a distance, i.e., without contact with those.” Remote sensing offers also the possibility to study the relationship between objects and phenomena as well as the study of development in their properties” (Białousz, 1999, 511).

In many books and dictionaries different definitions of remote sensing could be found. For example, Sabins (1997) defines it as: “The term remote sensing refers to methods that employ electromagnetic energy, such as light, heat, and radio waves, as the means of detecting and measuring target characteristics.... The science of remote sensing excludes geophysical methods such as electrical, magnetic and gravity surveys that measure force fields rather than electromagnetic radiation.”

“A geographic information system (GIS) is the combination of skilled persons, spatial and descriptive data, analytic methods, and computer software and hardware-all organized to automate, manage, and deliver information through geographic presentation” (Zeiler, 1999, 46). GIS provides the tools to collect, manage, and display geographic data very efficiently and effectively (Longley et al., 2005, 438). Recently acronym GIS is developed also as Geographic Information Science. “GIScience is the set of fundamental issues (scale, accuracy, relationship between humans and computers) arising from the use of geographic information systems” (Longley et al., 2005, 438).

Many interdependent processes occur in soil at the same time, but only some of them, fortunately, lead to soil degradation. According to scientific research methods and based on them indicators of degradation, one can talk about the degradation of biological, chemical, or physical properties of soil and caused by them the degradation of soil functions. In this text we examine the types of physical soil degradation and their influence on the degradation of soil functions and the methods of their study.

In the ultimate approach, soil physical degradation could be also understood as the total destruction of the soil as a biologically active body, creating a medium for plant growth and food production. Total physical degradation means total disappearance of the soil (e.g., by erosion of river or sea, or open mining of minerals) or change in the function of the biological substrate of the living soil environment for plant development platform (the base) on which the road or buildings are constructed.

Many countries and international organizations direct their attention to soil degradation, analysis of the causes of this processes, methods of preventing degradation, and methods of degraded soils’ rehabilitation. In the USA there is a Soil Conservation Service, while in the European Union ongoing work leads to establishment of Soil Protection Strategy (EC Proposal for a Directive, 2006).

Studies on soil degradation take into account all elements of the cause and effect relationship. There is a reason (cause), which causes processes (acting factors). The receptor of these processes is the soil, in which harms occur.

Analyzing the causes and processes of degradation and knowing the properties of soil and surrounding environment, areas vulnerable to degradation could be delineated and the intensity of degradation could be predicted. Such studies require a lot of time and resource; therefore, they often examine the effects of degradation processes (harms). Harms are expressed by, among other things, a deterioration of soil physical properties (increasing of density – compaction, reduced permeability, reduced water holding capacity, deterioration of structure, crusting, cracking, loss of organic matter), reducing the depth of active soil layer by water and wind erosion, creeping, solifluction, landslides, and in extreme cases by soil erosion leading to the point where soil is biologically inactive until the rocks or soil are covered with a layer of asphalt or concrete.

Currently, new approach that it is cheaper and better to anticipate risks and prevent them, than to remedy their consequences later is creating. Thus, development of methods that allow the delineation of priority areas for soil risk is begun. European Soil Bureau Network formed a special working group for this purpose. Notion of priority areas for soil risk correspond with notion of soil threats. The concept of strategy for soil protection contained in the European Soil Framework Directive (EC Proposal for a Directive, 2006) distinguishes eight major threats of soils:

- Erosion, loss of organic matter, contamination, salinization, compaction, decrease in biodiversity in the soil, sealing, landslides, and floods.

All these risks and their effects, regardless of their position in the cause and effect chain, could be studied using three different approaches (Eckelman et al., 2006):

1. Qualitative approach, based on expert knowledge
2. Quantitative approach, based on measured data
3. Model approach, based on prediction of the extent of soil degradation from modeling, considering site factors and soil management

Remote sensing and GIS for soil degradation survey: general information

In examining both the risk of degradation, degradation processes, as well as its effects, methods that utilize GIS and remote sensing are useful. Soil as a continuous layer on the Earth surface and the processes occurring in it are interesting subjects to investigate using remote sensing methods, but also difficult because it is a three-dimensional layer, mostly covered by plants which hinder observation from the air. Therefore, three main elements of remote sensing technology must be carefully utilized:

acquiring, processing, and interpreting image and related data obtained from aircraft and satellites that record the interaction between soil and electromagnetic radiation.

Technology of data acquisition uses different ranges of electromagnetic spectrum (UV, visible, infrared, microwave) and recording equipment adapted to these needs: analog (photographic) and digital cameras, multispectral scanners, radars, radiometers and image radiometers. Now available are images recorded almost entirely digitally. Therefore, their processing and interpretation are quite easy. It should be kept in mind, however, that for comparative researches, for example, for studies of progression or regression of soil degradation, which also use photos that are 20–50 years old, require ability to work with pictures taken with photographic cameras.

Remote sensing data for study and modeling of soil degradation should satisfy several conditions. First of all, they should be recorded in the spectral ranges, and in those seasons in which environmental elements affecting the degradation and their effects are most visible (Bonn, 1996; Białousz, 1999; Girard and Girard, 1999). These conditions, though theoretically known, are very difficult to satisfy because of cloud cover, and availability and cost of equipment (satellite images programmed on a specific date are much more expensive). Only in a few research projects such registrations were feasible. Thus, in most cases the study of soil degradation makes use of images recorded for other purposes (map updating, cadastre, LPIS for Common Agricultural Policy) and images taken during current satellite missions. For that reason the digital processing of such data must be handled in a manner that eliminates image features, which obscure the effects of soil degradation, and when interpreting the results, using many elements of deductive reasoning and the available knowledge bases (Mulders, 1987; Białousz, 1999).

Remote sensing methods used in soil study utilize differentiation behavior of electromagnetic radiation in contact with the soil as it reaches the soil surface. This differentiation lies in the fact that the soil, depending on its state and its properties, absorbs and reflects in different spectral ranges of various amounts of radiation falling on it from the Sun, or from a radar antenna, and radiates different amounts of energy depending on properties, especially humidity. Differences between the soils can be detected and then interpreted, when the differences of their characteristics or properties cause measurable differences of energy reflected or radiated by the soil.

The identification of soil in images registered in the optical band utilize the knowledge that soils with higher organic matter content, wetter, and cloudy reflect less solar energy and appear darker in photographs, while soils with low organic matter content, drier, and with smooth surfaces, or that contain carbonates in the surface layer reflect more energy, and hence appear brighter in the pictures. There are many examples, where the boundaries of soils with different organic matter content or with differences in humidity are very clearly visible on aerial

photographs and satellite images (Soil Atlas of Europe, 2005). A large amount of research has been performed to determine the relationship between organic matter content, soil moisture, carbonate content, soil pigments and spectral characteristics of soils, and associated soil images in photographs (Baumgardner et al., 1970; Escadafal and Girard, 1988; Białousz, 1999). Based on these correlations, attempts at automatic mapping of organic matter and soil moisture have been made. Due to the complexity of these relationships, only few attempts have been successful.

A number of models describing the relationships between the geometry of the structural aggregates on the soil surface, the position of the Sun as a source of radiation, the position of the observing sensor, and the spectral characteristics of soils have been developed (Cieriewski and Verbrugghe, 1997; Cieriewski et al., 2004).

Methods of remote sensing studies of soil degradation

General research on the recognition and interpretation of soils in aerial and satellite images have provided a basis to analyze whether, and if so how remote sensing methods can be used to study soil degradation. The logic of these methods is, as it follows:

1. To determine the risk of degradation:
 - (a) For each type of threats to determine the set of internal factors, arising from the soil characteristics and external factors (climate, relief, land cover, anthropopressure) causing danger of degradation and its intensity
 - (b) Specify remote sensing data; what methods of their processing and interpretation will provide data to the model simulating the threat, or will immediately (without model) predict these risks and determine their spatial extent
2. To study the effects of degradation (degraded soil inventory)
 - (a) To determine how degradation processes influenced physical and chemical properties of surface soil layers: loss of organic matter, deterioration or loss of crumb structure, increasing compaction, worsening air, and water properties. These cases are generally known from studies on physical properties of soil
 - (b) To determine how changes in these properties affect the spectral characteristics of the soils, on soil temperature, the density and intensity of vegetation cover
 - (c) To determine how it will effect on the radiometric value of remote sensing images and on the images of soils obtained from various digital processing of initial data
 - (d) To determine whether the resulting differences in images of soil (or vegetation cover) are sufficient to detect the occurrence of soil degradation and

their delineation, according to the types of degradation

In both cases (1 and 2) the final goal of application of remote sensing methods is assessment of the risk of degradation or a statement regarding degradation already present. It is a broader approach than a simple one informing that the change of physical properties.

Remote sensing data can often be understood as a radiometric value of pixels being still subject to digital processing as well as data recorded during satellite missions brought for radiometric and geometric correction of images. For environmental research, including soil, not only are used radiometric values of pixels, but also derived products such as DTM and land cover maps.

For the study of different types of degradation, it is recommended that various types of remote sensing data and different methods of processing and interpretation are used. Source data and methods must also take into account the territorial scope of research: on a scale of one field, micro regional, and regional. We will perform such an analysis for the most important types of soil threats.

Soil erosion

“Soil erosion is the wearing away of the land surface by physical forces such as rainfall, flooding water, wind, ice, temperature change, gravity or other natural or anthropogenic agents that abrade, detach or remove soil or geological material from one point on the earth’s surface to be deposited elsewhere” (Soil Science Glossary Terms Committee, 2008). The result of erosion caused by rain and melting water is the loss of soil mass in the upper parts of the terrain and its deposition at the foot of the slopes, at the water reservoirs and transfer by rivers to seas and oceans. Measurable effect of erosion is a lowering of the surface of the eroded area. With the reference to the morphology of the soil profile the result of erosion is reduced thickness of humus horizon, its total removal and the exposure of the deeper horizons, or even the mother rock (parent material). The most common indicator of the intensity of the erosion is the amount of eroded soil expressed in tones per hectare per year. It is obtained from measurements in the field or from modeling.

Remote sensing and photogrammetric methods can be used both to measure the effects of erosion (small area) and to assess the risks of erosion through modeling. For small areas, parameters calculated with use of remote sensing data, useful to estimate the effects of erosion are: value slope angle, slope length, elevation, the area of land occupied by ravines (gullies) and rills and their volume, surface covered by permanent and annual vegetation, the area without vegetation during the greatest threat of erosion.

Many of these data can be obtained from large-scale aerial photographs (altitude, slope angle, slope length,

area and volume of gullies and rills) and from periodic registration of LIDAR.

The utility of remote sensing data to model the risks of erosion depends on the type of model, namely, the parameters used in the model. The most commonly used parameters are: slope angle, slope length, class of land cover, type of agriculture, terrain dissection by hydrography network, and density of road networks. All these parameters can be determined from the DTM and satellite imagery of high (Landsat ETM, SPOT, IRS), and very high (IKONOS, Quick Bird, WorldView) spatial resolution (Białousz and Baritz, 2006).

Beside the measurement, the real effects of erosion performed on small plots of experimental fields the erosion hazard modeling an inventory of the larger areas already affected by erosion of varying intensity are carried out.

Traditional methods of photointerpretation (the interpretation of stereoscopic aerial photographs), computer-assisted interpretation of digital aerial photographs or satellite images classification, and an object-oriented approach can be used. In each of the methods a relationship between the effects of erosion and soil eroded images is used. It is assumed in general that woodland soils and permanent meadows are not affected by erosion. Pastures, because of the possibility of overgrazing, too early or too late season of grazing can be affected by erosion.

In the early stages of erosion, when there is still a preserved (though shallower) humus horizon, eroded soils (in the upper parts of the slopes) are lighter, while in the foothills in the deluvial accumulation zone they are darker. They also have a distinctive texture image composed of bright streaks of fine material, stretching along the slope line.

In subsequent phases, when on the surface deeper horizons of soil or rock appear, the color of eroded sites may also be light, if lighter soils horizons (E) or bright rocks (limestone, sandstone) where exposed or dark, when on the surface is illuvial horizon, clay parent material, or other dark rock.

Advanced erosion of the loess areas is visible through the dendrites of ravines (gullies) with a depth of several meters. The intenseness of erosion at such sites can be expressed by the density of the network of ravines. This is readily calculated almost automatically using the appropriate functions of GIS software. The ravines are very clearly visible on all types of aerial and satellite images.

GIS technologies allow connecting satellite and aerial images with different thematic layers, such as: soil types, texture, geology, geomorphology, land cover, slopes, aspect and others. This allows by modeling or by a simple visual analysis to delineate eroded areas and the intenseness of erosion. Results of both, modeling and visual analysis require verification in the field.

Delimitation of eroded areas is easier if specially processed image (enhancement of clear tones, maps of brightness indices) is overlayed on a three-dimensional

image derived from a DTM that has been magnified vertically.

Landslides

Landslide is defined as “the movement of a mass of rock, debris, artificial fill or earth down a slope, under the force of gravity, causing a deterioration or loss of one or more soil functions” (Huber et al., 2009). There are two types of landslides: slow moving landslides and fast moving landslides.

As in the case of erosion there is the possibility:

1. Of inventory of landslide activity occurrence with estimation of volume of displaced material
2. To assess landslide hazard
3. To create a system for landslide control measures

In all of these cases the role of remote sensing and GIS technology could be meaningful.

During the mapping, where landslides have occurred, facts observed on the ground are taken into consideration (they can be marked on a map or their coordinates measured using GPS) as well as specific terrain microforms identifiable in stereoscopic aerial photographs, or satellite imagery complemented by a DTM. In recent years, to identify these forms satellite radar interferometry and three-dimensional images generated from LIDAR have also been used.

For landslide hazard assessment models, the following key parameters are used: slope angle, slope length, land cover, drainage network and road network (as GIS layers), parent material (texture, aggregate stability, sequence of permeable and impermeable layers, depth of impermeable layers) climatic date, and current site of identified landslides.

The parameters for the slopes and forms of the terrain (convex, concave, flat) can be obtained from the DTM. The DTM should have a spatial resolution from 15 to 20 m. and a vertical precision of 30–50 cm. It should therefore be created from aerial photographs, or from aerial LIDAR registration. DTMs created from aerial photographs for the LPIS require careful checking before using it for such purposes. Classes of land use can be obtained from high resolution satellite images, or from orthophotomaps performed for LPIS.

Layers of parent material can be obtained from maps (databases) of soil, geological, or geomorphological maps at scales of 1:25,000 and larger.

System for landslide control measures should include fixed points for field measurements (analogous to the geodetic measurements of displacement), a base for terrain registration by LIDAR and reference points for processing LIDAR aerial images. Analysis of all mentioned data should take into account also data on rainfall (seasonal distribution and extreme values), snow cover, and freezing depth of soil to obtain information making possible to predict what amount of rainfall in a given area can cause landslides to occur.

Floods

Three kinds of applications of remote sensing and GIS technology can be identified:

1. To delineate the areas flooded by the flood waters. Theoretically, aerial infrared photographs are the best, but clouding associated with flooding causes the limitation to their implementation as well as for registration of satellite images in the optical band. Cloudless skies usually appear a few days following the peak flood wave, so the images do not register all the flooded areas. Radar images can be taken regardless of the weather and often they are the only documents that show all the flooded areas. There is an international agreement in effect by which the owners of remote sensing systems may at the request of interested countries pass along, as soon as possible transfer (usually for the next day), images recorded for flooded areas. This facilitates the tracking of the flood wave propagation as well as organizational measures for rescue operations. Such images of the Vistula River Valley were registered on 11 May 2010 by the TerraSAR-X system during the floods of May 2010. Images registering flooded areas make it easy to assess the damage and work on removing the effects of floods.
2. To control the state of flood banks. Levees along rivers in some countries are tens of thousands of kilometers in length. Current monitoring of their condition directly in the field requires much time and ample manpower. Aerial photographs taken for other purposes can be used to analyze levees and their environs. On enlarged and processed images, results of damage to the ramparts are visible, often due to damage by people and cattle in areas outside the paved passages, losses caused by animals by the river zone, and leakages of water. The best for these purposes are infrared images taken in early spring at high water levels in the river, but this kind of pictures is not always available.
3. To model flood risk. This pertains to two kinds of models. Models predicting the status (height) of water in the river and models of risk of land flooding. For the first type of models, data for the whole catchment are necessary, and for the second type of models, only data for the valley in the range of potential flooding.

In both cases, essential data are: land cover classes, DMT, and hydrography network. Land cover classes and their area could be determined with precision satisfying modeling by classification of multispectral satellite images or by visual interpretation of color composite

images obtained from multispectral images. They should register one or two infrared spectral bands and have pixel of 5 m or less.

Land cover classes are used to determine terrain roughness indices necessary to calculate speed of flood wave and to estimate soil retention ability. Images should be registered when it is the easiest to identify land cover classes, which affect terrain roughness: arable land, meadows and pastures, bushes, forests, and built-up areas. Consequently, in temperate zone the best time for it is May, second half of August, and September. Lately, new attempts to determine terrain roughness indices have been made with LIDAR, but there is no need for such high accuracy in modeling.

DTM should have vertical accuracy around 20–30 cm. Only direct measurement in the terrain (too costly), large-scale aerial images or LIDAR images can provide such precision. The same large-scale aerial images used to create DTM might be useful to perform land cover maps, but such procedure takes significantly more time and funds, than based on satellite images.

Land cover maps or color composite images from satellite images supply data not only to determine terrain roughness indices, but are proved to be useful to assign polders and storage reservoirs location as well as to planning valley monitoring or to carrying out rescue action. Nevertheless, those are commonly overlooked, as liable services prefer using maps.

Loss of organic matter

Loss of organic matter in common language means the loss of organic matter in the topsoil. It is a process that naturally occurs in all arable soils and in drained organic soils. In a good agrotechnical situation, these losses on mineral soils are offset by organic fertilization and crop rotation. When can a loss of organic matter be considered as soil degradation? This is difficult to determine, because the thresholds may be different depending on climate zone and soil use. It is understood that in Europe under conditions where the soil has less than 1% of soil organic carbon, and without organic fertilization deficit of mineral nitrogen may occur, which leads to a reduction in biomass production and to a decrease in soil organic matter (SOM) content (Soil biodiversity, 2010).

Remote sensing and GIS technologies can help in analysis of soil organic matter diminution in arable land. As with other phenomena, the SOM inventory and delineation, the areas with a greater risk of loss of SOM should be differentiated. In the case of inventory the mentioned earlier relationship, that soils with higher organic matter content are darker and reflect less solar energy (below 10%) in each of the ranges of visible and near infrared band is used. This leads to darker tones of these soils (dark gray, black) on aerial photographs and to lower radiometric values of pixels in the digital images.

Several attempts have been made to determine the quantitative correlation between the amount of reflected

solar energy, the optical density of aerial photographs, radiometric values of pixels, and the content of SOM. A set of indices has been used, among others: brightness indices, image enhancement, contrast stretching, and other digital image processing to increase the strength of correlation. The aim of these studies was to elaborate and test automated methods of delineation of soil boundaries according to content of SOM. However, results have been modest, because the appearance of soil on remote sensing images also depends on other soil properties as well as external factors. Practically it is possible to delineate the areas with a similar SOM content. The amount of SOM for each area should be measured by laboratory methods. Remote sensing data thus should be recommended as supporting material (Baumgardner et al., 1970; Białousz, 1999; Girard and Girard, 1999).

For analyzing loss of SOM multi-temporal remote sensing data could be useful. They may show diminution of the surface of soils rich in SOM as a result of artificial drainage or erosion. The second case is observed in the chernozems of Central and Eastern Europe formed on loess, particularly in countries where large-area state farms are operated.

Remote sensing methods can also be useful to investigate the loss of SOM in organic soils as a result of their drainage and tillage, because interpretation of images helps delineation of areas that are in intensive cultivation. Also, in particular cases make possible to detect differentiation of soil cover by differences of soil temperature and humidity, which are calculated on the basis of data registered in the thermal and microwave band. In connection with ground-based surveys, areas with different diminution of SOM could be detected and delineated.

In advanced studies, performed in the framework of the global balance of CO₂, remote-sensing data from the optical, thermal, and microwave bands are used to calculate LAI, biomass, evapotranspiration, moisture, soil temperature, and other indices. These parameters together with land cover data are implemented to the models that allow to calculate the ecosystem's CO₂ balance (Hese et al., 2005; Calvet et al., 2005). Positive balance of CO₂ (CO₂ released more than assimilated by plants) means a degradation of SOM. Studies of this type were designed and partially executed in the USA and Europe (CarboEurope, Geoland 2 programs).

Soil surface sealing

Soil surface sealing in the broader sense includes "all land development for human settlement-related activities by which previously undeveloped land is urbanized, i.e., agricultural, forest or natural land are turned into built-up areas" (Jones et al., 2008). It is also called as a land consumption. In more specific form, "soil sealing means the destruction or covering of soil for buildings, constructions, and layers or other bodies of artificial material that may very slowly permeable to water causing a deterioration or loss of one or more soil functions" (EC Proposal for a Directive, 2006).

Indicator of soil surface sealing may be the absolute area of sealed soils, the rate of sealed soils such as per 1 km², or per capita (Huber et al., 2009). Experience has shown that remote sensing data and GIS technology are indeed useful for the determination of these indicators. It would seem that the surface of sealed soils can be quickly calculated from cadastral data. However, the cadastral data do not include all surfaces that are sealed. Because the problem concerns mainly urban areas and their surroundings, the full data for those areas can be obtained from the base maps in scales of 1:500 or 1:1,000, but this requires a lot of work, even when the maps are already in digital form.

Each country protecting soils draws up an annual soil balance, which shows how much new agricultural and forested land has been converted to urban areas. Such data is available in each country's cadastral and statistics offices, urban planning and environmental organizations. But national or regional registers of sealed soils do not exist. Some cities in Europe calculated the surface of sealed soils, to estimate how much water flowing to the sewage treatment plant comes from households, and how much from the roofs of buildings and concrete-covered spaces. Some cities have introduced a so-called roof tax.

However, this is not the most important reason to know how large the surface of sealed soils is. Equally important is the impact of those areas on the city's microclimate. At the time of the writing of this text, it was 32°C out of the building. Some windows of the room are overlooking the garden (non-sealed soil), and the others the street with asphalt and concrete (sealed soil). Even without any measurements, impact of sealed soils on microclimate of the room and on the mood of the writer was perceptible. Sealed soils cause also a rapid runoff of rainwater into rivers and increase the risk of high water flooding.

The quickest way to calculate the area of sealed soils is to use large-scale digital maps showing buildings, concrete-covered surfaces, bitumen, and green areas as well as orthophotomaps generated from aerial photographs or from satellite images with a size of pixel around 1 m. In the first step homogeneous areas in terms of development intensity are delimited on orthophotomaps. In each homogenous area test zones are determined (randomly or systematically). For which test zone the surface of sealed soils is calculated using the detailed digital maps. Then, using the orthophotomaps, sealed surfaces and the various indicators are calculated for homogeneous areas and for the whole city. Calculations made by this method for Warsaw (Białousz, 2008) showed that in the district with the nineteenth century buildings, sealed soils occupy 96% of the total area and, respectively, 52% in the zone of big blocks, 26% in residential zone, and 20% in urban green areas. On average, sealed soils cover 47% of the built-up areas and 22% of the area within the administrative borders of Warsaw. The rate per inhabitant amounted to 66 m².

Surfaces of sealed soils and new urban areas (land consumption) will be calculated quickly after the creation of

CORINE Land Cover (CLC) database based on satellite images of very high spatial resolution (pixel 1 m and less). Reference zones will be needed, however, because part of the terrain is covered by trees and bushes; therefore the real surfaces of these terrains are not visible on orthophotomaps.

Salinization

Soil salinization is defined as “accumulation of water soluble salts in the soil, causing a deterioration or loss of one or more soil functions. The accumulated salts include sodium, potassium, magnesium and calcium chlorides, sulphates, carbonates and bicarbonates” (Huber et al., 2009).

Soil salinization causes salt efflorescence on the surface of soil, the disappearance of crumb structures, susceptibility to dispersion of the surface layer at a higher moisture content, the creation of superficial crust when dry, and less dense vegetation causing smaller biomass. For the delimitation of extent and intensity of the salty soil direct features could be used: increasing the brightness of the soil surface, and indirect features: lower density of vegetation and diminished plant vigor. Under natural conditions, meadows and pastures salted soils give rise to specific distinctive vegetation of a darker color than of vegetation on salt-free soils, which is visible on the images.

Many studies proved the usefulness of aerial photographs and satellite images later in the inventory of saline soils (USA, India, Pakistan, Iraq, Egypt, the European Mediterranean area, regions around the Caspian Sea, and other areas of semidry zone). Apart from satellite images, GIS thematic layers that provide data on irrigation systems, groundwater depth, and the parameters characterizing the soil and water for irrigation are commonly used. With such a multifactorial analysis the relationship between groundwater depth and salinity of the surface layer in the Nile Delta has been found as well as salinity and the efficiency of drainage system in the delta of the Rhone. GIS technology together with satellite images and historical data makes modeling of salinization risks a lot easier.

Compaction

“Soil compaction occurs when soil is subject to mechanical stress often through the use of heavy machinery or overgrazing, especially in wet soils conditions. Compaction reduces the coarse pore space between soil particles, thereby increasing the bulk density with the result that the soil partially or fully loses its capacity to absorb water. Compaction also affects subsoil layers” (Eckelman et al., 2006).

Application of remote sensing data and GIS technology to inventory the areas affected by the soil compaction and to threat's modeling is more difficult than to other types of soil degradation. Soil compaction causes changes in certain soil properties, which can be recognized by remote sensing methods, that is, deterioration of soil structure, restriction of root growth, decrease in water storage

capacity, fertility, and biological activity, thus reducing the density of vegetation and biomass. Rainwater periodically stagnant on the soil surface may be supplementary feature characterizing compacted soils. Detection of these features directly on the surface of bare soil or indirectly by the vegetation lead to identification of this type of degradation.

Because of the repetition of passages of heavy machinery by the same places (zones near the edges of plots, area of relapses, strips between the trees in the orchards), the intensity of soil compaction in these places is higher than in other parts of the field. For that reason a minimum and maximum values within the field, rather than one average value, should be shown.

At the scale of one field it is recommended to determine soil compaction on the basis of direct field measurements (analysis of the soil profile and soil density measurements with penetrometer). For larger areas, aerial photographs or satellite images can be used to determine the sample plots and to extrapolate the results obtained on the sample plots, and GIS technologies to take into account other factors contributing to soil compaction. Modeling based on soil texture, slope value, CEC, water regime, and economical data (type of farming, saturation by heavy machinery, frequency and periods of use of fertilizers and pesticides, etc.) can separate the zones with different susceptibility to soil compaction. According to the simplified model, for example, such zones have been separated for the southwestern Poland with an accuracy corresponding to a map at the scale of 1:250,000 (Białousz and Rozycki, 2006).

This type of soil degradation, which so far mainly has been studied in laboratory-scale and in a single field scale, has an impact not only on the yield of plants, but like soil sealing accelerate also runoff of rainwater into the rivers, therefore increase the risk of flooding. More accurate models to determine the areas already affected by the soil compaction, and delimitation areas that can be potentially affected are not yet completely tested.

Contamination

This type of degradation is the hardest to investigate using remote sensing and GIS methods. Such analysis, as well as on the other types of degradation use the physical properties of soil changes and vegetation cover changes caused by the contamination of soils. These changes (properties of soil and vegetation) depend on the type of contamination. If it is, for example, fallout dust from the cement plant, they will lighten the soil surface and reduce the acidity, which will affect the structure of the surface layer. Both of these changes, as well as the impact of emission from the chimneys of other types of industrial plants influence weekly on the differentiation of soils in the images. However, there are spectacular examples. Few days after precipitation of snow the darker area around the chimney of industrial plants was visible on the satellite images. Contamination, like soil compaction generally impairs

soil biodiversity, soil fertility and consequently reduces the density and biomass crops (European Atlas of Soil Biodiversity, 2010).

There have been successful attempts carried already (Zawadzka, 2005) at exploring the correlation between soil contamination and the results of processing multispectral satellite images. Processing was supported by data input from GIS thematic layers. A significant correlation was found between the content of lead, zinc, and copper, and the weighted sum of the spectral channels of the ASTER system. Color composites generated from multispectral satellite images and GIS thematic layers can be fully used to design monitoring networks in the areas affected by contamination, primarily from industrial sources.

Desertification

Desertification is not only an ecological problem, but also a social and economical, and in some regions a political one. The term “desertification” is not about enlarging the area of deserts, but refers to a loss of productivity of the land due to farming practices in dryland areas.

Drylands are characterized by a precipitation/potential evaporation ratio of less than 0.65 (wiki/Desertification, 2010). Drylands called also as the hyperarid, arid, semi-arid, and dry subhumid zones cover 35% of Earth land surface, and hosts a billion people in more than a hundred countries (Middleton and Thomas, 1997). The largest areas of degraded drylands are in sub-Saharan Africa, in Asia, and Latin America. The consequences of desertification are visible also in Mediterranean zone, in Central and Eastern Europe (Toth et al., 2008; Soil Atlas of Europe, 2005).

Problem of desertification is so serious that many international organizations, governments of majority of countries, and also scientific institutions have intensively taken care of it. The United Nations has formulated in 1994 Convention to Combat Desertification (UNCCD). It has been ratified by 184 institutions and governments, 38 European governments among this number. According to this Convention, “Desertification means land degradation in arid, semi-arid and dry sub-humid areas resulting from various factors, including climatic variations and human activities”.

The main factors causing this kind of degradation are: overgrazing, cutting trees and bushes for fuel, overexploitation of water and lowering of groundwater table caused by this, and cultivation of the terrain that should be protected by permanent vegetation. Visible results of desertification are: soil erosion, vegetation disappearance, and dunes transgression. That is why the effects of desertification are very well visible in aerial and satellite images. Rare appearance of clouds in dry and semidry zones facilitates registration of images.

Analogically to the investigation of the results of desertification, one can observe extent and efficiency of remediation actions, such as plantation of trees and bushes

bands, protecting soils against wind and erosion, fixation of the structure of topsoil layer, irrigation infrastructure and its extent. Actually there are many kinds of remote sensing data and it is easy to choose images of adequate spatial resolution, acquisition date, and spectral bands; so we do not enumerate the preferred images. Even simple color compositions generated from multispectral Landsat images are very useful for these purposes. One can use also images from systems dedicated to vegetation analysis, ex. SPOT Vegetation or from meteorological satellites. Images registered by ground penetrating radar can give information on presence and depth of groundwater table.

Very important advantage of remote sensing and GIS methods is that satellite images give synoptic view of terrain, facilitating connection of analyzed phenomena with landscape. GIS thematic layers and DTM provide data for analysis of causes and also for designing of remediation.

In Internet, conference proceedings, and journals one can find thousands of articles about desertification, remediation methods, and examples of successes and failures. World Atlas of Desertification has been also published (Middleton and Thomas, 1997). Research results show that it is easier to solve technical and ecological problems of desertification, than problems resulting from poverty, local traditions, lack of initiative of local governments.

Soil drought is an intermediary state between desertification and normal conditions for vegetation growth. Soil drought means that during the vegetation period there are weeks or even months of deficit of water available for plants. This deficit decreases yield, even 30% and more, but they do not cause a visible degradation of soil besides the loss of organic matter.

Areas touched by soil drought, like desertification, are investigated with use of satellite images and field measurements. The most frequently calculated indices in consecutive decades of vegetation periods are: NDVI, plant moisture and temperature, soil moisture in roots layer. In many countries maps of spatial distribution of these indices and maps of soil drought are published regularly. Besides cognitive goals, these maps are also useful for models of yield prediction with use of remote sensing methods.

Conclusion

Soil degradation causes changes in the appearance of the surface layer of soil: usually brightens it, reduces water capacity, alters thermal emissivity, and changes dielectric properties. Some of these changes can be measured by remote sensing methods, which facilitates the detection and delimitation of areas with degraded soil. From satellite and aerial images and from GIS thematic layers one can generate data like: morphometric parameters of the terrain, land cover classes, biomass, temperature and humidity of the surface layer, which implemented to models, make possible to predict risk of various types of degradation, its range, and intensity.

Soil physical health

Definition

Soil Physical Quality is the ability of a given soil to meet plant and ecosystem requirements for water, aeration, and strength over time and to resist and recover from processes that might diminish that ability. Concepts of soil physical quality can be applied to individual soil horizons, profiles, or areas classified to a common soil type.

Introduction

Soil physical quality is determined by a combination of soil texture, structure, and morphology and relates to the capacity of a soil to function (Karlen et al., 1997). Soil texture, the relative proportions of sand, silt, and clay in the soil and soil structure, the arrangement of these mineral components with soil organic matter, are described elsewhere (see [Soil Phases](#)). Soil morphology describes how soil looks, is handled, and behaves in the field. Morphology is usually determined through soil survey taking into account soil depth, stoniness, and the presence and depth of various horizons and other soil layers.

Soil properties that limit or lead to improved crop yields have been identified and are often taken as standards (Tisdall and Adem, 1988; Reynolds et al., 2008). An example is that a soil with a penetrometer resistance of greater than 2 MPa will decrease root elongation by more than 50% (Gregory, 2006). More detailed explanations of this example can be found elsewhere (see [Root Responses to Soil Physical Limitations](#)). The standards may apply to an individual plant species, a crop or plant community in a managed ecosystem, or may relate to a process of root growth. Standards for root, plant, or crop growth quantify soil characteristics that may decrease crop yield. By comparison of specific soil properties with the standards for root growth, soil management may be identified to improve deficient soil characteristics (Tisdall and Adem, 1988). Measurements associated with different standards can be combined and indicators that provide relative

measures or indexes of soil physical quality developed. Pedotransfer functions (see [Pedotransfer Functions](#)) have been used (da Silva and Kay, 1997) to predict one soil characteristic from one or more other characteristics. This estimation may enable faster or cheaper estimation of soil physical quality.

The physical characteristics of the soil, such as soil water, infiltration, soil aeration, soil temperature, and mechanical resistance, are considered individually elsewhere (see [Soil Water Flow](#); [Aeration of Soils and Plants](#); [Temperature Effects in Soil](#)). Here, the combination of the physical characteristics is related to soil physical quality and the ability of the soil to be used for particular purposes, particularly plant growth. When limiting nutrients, water, aeration, temperature or mechanical resistance can impair seedling emergence and root growth. A productive soil environment requires coordination of these soil physical characteristics. The structure of the soil does not directly affect plant growth but does affect the supply of water and gases, temperature and mechanical resistance that directly influence plant growth (Letey, 1985; Boone, 1988). The magnitude of the soil physical characteristics differs with time and position in the soil profile, especially in relationship to rainfall and irrigation. Values for soil physical characteristics that allow a balance for optimum plant growth need to be understood, because different crops may have different responses. Rice (*Oryza sativa* L.) grown as paddy (i.e., under waterlogged condition) is the basis of feeding a large proportion of the world's population. Other cereals would not be productive if grown under the same conditions. Similarly, if only one soil characteristic were considered, the overall growth of the plant may be limited by another (Letey, 1985). The relationship between water and aeration is opposite to that between water and soil strength. If the water content increases toward a waterlogged condition, aeration decreases and may impair root growth. An increase in water content also decreases mechanical resistance and allows penetration of roots and emergence of seedlings. Thus, soil physical quality needs to be properly defined, understood, and managed.

Because soil physical quality can, to varying degrees, be manipulated by soil management, several indexes or scales have been, and are being, developed to specifically quantify soil physical quality. In some cases, these scales are being linked to soil survey techniques and to the visual assessment of soil structure (see [Soil Structure, Visual Assessment](#)).

Soil survey and the assessment of soil physical quality

The definition of soil physical quality above includes "of a given soil." It is thus necessary to define what is meant, in this context, by a given soil. Soil survey is "the systematic examination, description, classification and mapping of soils in an area" (Soil Science Society of America, 2001). A given soil, sometimes termed the soil type,

whether taken as a sample or in situ, has properties that can be measured, estimated, or inferred. There may be variation around a mean for any given property of a soil type, but that variation cannot be sufficiently extreme as to prevent the classification as a type.

Soil survey traditionally uses a range of morphological measures to characterize the soil, allowing comparison between classes. These morphological measures are used to infer the characteristics of the soil that directly affect plant growth. These measures typically include color, texture, structure, and consistence of the material for each horizon (e.g., Kerry et al., 2009) and are at least in part related to the physical performance of the soil. A simple example is that the soil color may indicate the likelihood of waterlogging and poor aeration of the profile. Soil survey that adds soil chemical and biological criteria to soil physical analysis is often used to define potential land use. As some of the values that contribute to soil physical quality may be subjective, some authors (e.g., Bouma and Droogers, 1998) have considered quality in terms of the ability to meet requirements relative to a potential in the absence of other constraints.

The key feature of soil physical quality that soil survey reveals is the depth of soil available to fulfil a function. The depth of the soil available is determined by the depth of horizons above weathering bedrock (usually taken as the A and B horizons). The amount of plant available water that can be stored in the profile is directly determined by the soil depth. Plant productivity can be directly linked to the depth of soil available for root development (Wheaton et al., 2008). In some cases, the proportion of the soil horizons that are occupied by stones or gravel must be subtracted from the soil depth as these components prevent soil function. For example, Chow et al. (2007) report some detrimental impacts of coarse fragment content on soil properties and potato production.

Traditional concepts of soil physical quality

Water intake and delivery

A key concept that underlies most indexes of soil physical quality is that of plant available water. Plants cannot grow without access to water. The ability of a soil to store water in a manner that is available to the plant roots is thus the most important single function of the soil (see *Root Water Uptake: Toward 3-D Functional Approaches*). Traditionally, water that is held in soil between the energy states of field capacity and permanent wilting point is described as the plant available water (White, 2006). Field capacity is defined simply as the amount of water that is held within a soil after the soil has been saturated and allowed to drain freely for 2 days (Kirkham, 2005). While there may be some local variations in the value ascribed to field capacity, it is, for this purpose, usually taken as equivalent to a matric suction of -10 kPa . Similarly, $-1,500\text{ kPa}$ is usually taken as the energy state of soil water at which it can no longer be extracted by plant roots.

The volume of plant available water held by a soil can be related to precipitation by the depth of soil as in a water budget (see *Water Budget in Soil*). The root depth determines the plant available water (Boone, 1988). The full relationship between the amount of water in a soil and its energy state is described by a water retention curve. Explanations of terms such as field capacity, permanent wilting point, matric suction, and water retention curve can be found in standard soil physics texts such as Hillel, (1998) or Marshall et al. (1996). Traditionally, the pores holding water between the limits of field capacity and permanent wilting point have been described as mid-range or mesopores. A soil with greater plant available water is generally regarded as having better soil physical quality.

In addition to storing water, a functioning soil must be able to accept rainfall or irrigation and transmit and distribute that water. The movement of water through the soil depends on the number, size distribution, and orientation of pores that conduct water. Various authors have suggested values for the functions of infiltration and hydraulic conductivity. These are sometimes related to particular plant types, e.g., Cass et al. (1993) suggested for adequate root growth of a tree or vine, the infiltration rate of the soil needs to be greater than 0.5 m day^{-1} . Others have suggested more general values such as Dexter (1988), who concluded that the minimum hydraulic conductivity of the bulk soil must be in the range $0.1\text{--}0.01\text{ m day}^{-1}$ if water supply is not to restrict plant development.

Aeration

Aeration is the process of gas exchange between life in the soil, particularly plant roots and the atmosphere. As noted in the introduction, with the exceptions of certain hydrophytes, oxygen is required from the soil for root growth and is supplied by diffusion to the respiration site. The delivery of oxygen to roots and the removal of carbon dioxide to the atmosphere are thus essential functions of the soil physical structure. Because gas diffuses through water at only $1/10^4$ that of diffusion through air, the air-filled porosity of the soil has been used as an indicator of the soils' ability to function. Diffusion of air through the soil profile is related to air-filled pore space and hence is connected to soil water retention. Moldrup et al. (2000) have developed gas diffusion models based on as few as two points from a soil water retention curve, provided that one of the points corresponded to a matric suction of -10 kPa (the value often used for field capacity). Values of air-filled porosity below which the soil cannot adequately support root growth have been variously suggested as at between 10% and 15% (Cockroft and Olsson, 1997). Dexter (1988) suggested that 10% of the soil volume is needed to comprise gas-filled pores and for at least 10% of the gas to be oxygen for supply to roots to be adequate. Macropores, defined as those pores that are air-filled when the soil is at field capacity, are often taken as an indicator of the ability of the soil to deliver

its aeration function. A macroporosity of 10% may be viewed as a critical limit for soil physical quality. Czyż (2004), in a study of barley (*Hordeum vulgare*) growth found that increased soil density and the associated loss of macroporosity resulted in decreased oxygen diffusion rates through the soil and suggested that this contributed to decreased crop yield.

Mechanical impedance

For a plant to achieve its genetic potential, it must access water and nutrients from the soil. Expressing this alternatively, the root system must explore a sufficient volume of soil to meet the requirements of the plant for water and nutrients. To explore the soil, roots must either grow along existing pore spaces or create pores by pushing soil from their path. The mechanical impedance of the soil is the force that plant roots and shoots must generate to deform the soil and allow growth. If a plant root cannot generate a force greater than the soil strength, the root is not able to elongate (Gregory, 2006). The mechanical impedance of the soil affects the volume of rooted soil, the distribution of roots in this volume, the extent to which crop emergence is mechanically impeded, and the mechanical stability of the plant.

The volume of soil occupied by large pores is less in a dense soil, and hence dense or compacted soils have smaller volumes through which roots can grow. Roots in loose soil move through continuous cracks, large pores, and planes of weakness. The roots move through the easiest path, i.e., those with minimal resistance. Roots are unable to decrease in diameter to enter rigid soil pores. Roots may be able to penetrate the soil by expanding the pores, but this depends on the strength of the soil which in turn is determined by factors including the nature and extent of the solid material and the soil water content. When dense layers appear in soil, either naturally at textural changes or as a result of compaction by traffic roots, they may be deflected and may not grow through the compacted layer. Roots accumulate above soil layers with greater mechanical impedance and plants growing with confined roots are at greater risk of drought and other stresses. Definitions and understanding of soil physical quality need to reflect the risks to crops associated with dense soil layers or horizons.

Each plant species has a mechanical resistance that it is able to overcome. The turgor pressure that roots can exert is limited, with all reliably reported values less than 1 MPa (Clark et al., 2003). These can be related to critical values for easily measured penetrometer resistance at which root growth is inhibited. Penetrometer resistances of 1 MPa slow root growth with all elongation ceasing by 3–4 MPa (Kirkegaard et al., 1992). Because penetrometers can quickly assess soil strength conditions and the results are related to root growth, many measures of soil physical quality incorporate penetrometer data (see also *Soil Penetrometers and Penetrability* and *Root Responses to Soil Physical Limitations*).

Temperature

Metabolic processes are temperature dependent; therefore soil temperature is important in crop production (Letey, 1985) (see *Temperature Effects in Soil*). The temperature regime in a soil is a function of many factors including surface radiation, reflection, absorption, and emission characteristics; aerodynamic roughness and subsurface soil thermal properties influence the heat flux. These factors can be changed by management, e.g., irrigation of dry soil increases the heat stored in the soil and thus may decrease the risk of frosts detrimental to crop production. Similarly, metabolic processes that lead to greenhouse gas emissions from soil depend on temperature, and as such, the soil thermal regime is linked to the function of ecosystems both above and below ground.

The degree to which the soil temperature varies depends on the soil surface properties. Mulch diminishes the variation in soil surface temperature. A well-drained, loose, finely crumbed seedbed dries out earlier and increases the variation in temperature of the soil surface (Boone, 1988). Soil temperature influences plant growth rates, and interacts with other soil physical properties including water relations (Licht and Al-Kaisi, 2005).

Soil structure and stability

The definition of soil physical quality given above acknowledges that soil is subject to external and internal forces over a wide range of time scales. The ability of the soil to resist, and recover from, processes that might diminish the ability to function is inherent in its quality and so the stability of the soil in response to stress, particularly stresses related to water and mechanical loading have been included in traditional thinking about soil quality (see *Soil Aggregates, Structure, and Stability*).

Soils consist of primary particles that may be combined to form secondary particles, called aggregates. Oades and Waters (1991) describe a porosity exclusion principle in which larger aggregates have a greater porosity (contain more pores of all size ranges) than do smaller aggregates. Thus, smaller aggregates are more dense and likely to be stronger than larger aggregates, as described by Utomo and Dexter (1981). The size distribution of pores within a soil is thus governed by the extent of aggregation.

Aggregates and pores are formed by a range of processes including:

- (a) Coagulation and flocculation
- (b) Soil fauna which ingest and excrete soil and organic matter
- (c) The movement of soil fauna and roots through the soil profile
- (d) The physical process of wetting and drying, and freezing and thawing (Oades, 1993)

Changes in the water status of the soil, freezing, thawing, and tillage cause shrinkage and swelling. All these processes thus change the soil structure. The ability of a soil to maintain coherence under external forces, particularly

forces associated with water has been used to understand mechanisms underlying the soil quality (Tisdall and Oades, 1982) and to assess the suitability of soil for crop production (Vance et al., 2002).

Assembling the components of soil physical quality into indexes

The soil is the environment for root growth. Soil properties can be manipulated to maximize root growth and hence the soil physical quality can be changed. A simple example is that the addition of farm yard manure changes aggregation of soil particles, leading to improved soil water relations and crop productivity (Singh et al., 2007). Manipulation of soil to change soil structure is costly but can be justified by increased production or by changes to the soils' ability to resist or recover from threats such as erosion or salinization. It is therefore important to quantify changes in soil physical quality, and to have quantitative relationships between soil structure and plant or crop production. To this end, there have been several attempts to unify the various aspects of the traditional descriptors of soil physical quality, provided above, into individual indexes.

Many of the traditional concepts discussed above rely on the soil structure and explicitly the degree of aggregation, generating a wide range of pore sizes (see *Pore Morphology and Soil Functions*). Pores of different sizes deliver different functions, e.g., macropores controlling aeration, mesopores controlling water storage, and micropores influencing the material strength. The nature and extent of these pores can be influenced by soil management. Macroporosity can be increased by cultivation or the activity of soil fauna, mesoporosity can be changed by organic amendments or root growth and exudation, and microporosity can be changed by changing cation concentrations by adding calcium or other salts. For this reason, many of the indexes of soil quality that have been developed have sought to reflect the degree of aggregation and the stability thereof, or the diversity of pore sizes. The indexes or specific measures of soil quality that follow are not a complete list. Rather they are some of the more common examples which can be and are being widely used.

Friability

Aggregates are assemblages of primary particles that cohere into structural units. Friability (see *Soil Tilt: What Every Farmer Understands but No Researcher Can Define*) was defined by Bodman (1949) as the propensity of a soil to crumble and break down into smaller fragments or aggregates under a given load. This concept was used as a basis for an index of soil physical quality by Utomo and Dexter (1981) and has been modified by Watts and Dexter (1998) to indicate the coefficient of variation in soil tensile strength. The measurement of friability involves assessing the strength, by brittle fracture, of multiple aggregates from a soil. Thus, friability cannot be determined on soils with no aggregation. The aggregatory need to be crushed

at the same water content, usually air-dry or oven-dry. For this reason, the assessment of friability is a laboratory-based method.

Tensile strength depends on the microstructure of the soil within the aggregate. The strength is limited by the largest flaw, usually the largest pore within the aggregate. From multiple crushed aggregates, a distribution of the extent of flaws within aggregates from that soil is assembled and from this the statistical coefficient of variation can be obtained. For aggregates of a given size, this coefficient of variation is a measure of the friability. Alternatively, aggregates of different sizes can be crushed. By the porosity exclusion principle, larger aggregates contain larger flaws, and thus are weaker than are smaller aggregates. The slope of a plot of the natural log of the aggregate strength against the natural log of the aggregate volume is similarly a measure of the soil friability. The relative methods of calculating soil friability have been assessed by Watts and Dexter (1998).

Because friability depends on the distribution of cracks within soil aggregates, factors that influence soil microstructure change friability. Natural processes, such as swelling and shrinking in response to water content, changes throughout a season, generate cracking within aggregates and hence change the friability. Processes that homogenize soil and remove large pore spaces, e.g., soil compaction by machinery, result in decreased friability. Agricultural management and changes in land use from continuous cropping to grassland can result in improved friability (Munkholm and Kay, 2002).

Aggregate stability in water

As aggregates are assemblages, their ability to resist change that will be detrimental to their integrity is a measure of their quality (see *Soil Aggregates, Structure, and Stability*). The ability of aggregates to resist abrasion when dry has been used to assess the risk of wind erosion (Chepil, 1962), but this is a specific use, and for the purposes of this review, beyond the scope of general measures of soil physical quality. In a similar manner to the friability measure, just described, the ability of aggregates to remain coherent after exposure to water has been used as a measure of soil quality. Aggregates collected from the field are brought to the laboratory. Depending on the severity of the test required, the aggregates may be dried, or other pretreatments imposed. The distribution of aggregate sizes may be determined prior to testing for later comparison (Six et al., 2000a). Known weights of aggregates are placed on sieves with different apertures and the soil and sieve oscillated in water for a fixed time interval. The amount of soil remaining on each sieve is determined after drying. From the amount of soil that remains on the different sieves, a mean weight diameter of stable soil can be calculated and used as a measure of soil quality.

The processes that lead to the breakdown of aggregates in water can be described as slaking and dispersion. Slaking is the rapid wetting of dry aggregates, and the ability to

withstand this rapid wetting is a measure of the manner in which aggregates typically larger than 100 mm are held together. The coherence of aggregates of this size is determined by the nature of organic matter in the soil and by other biologically-induced mechanisms. Dispersion is the separation of aggregates into their primary particles and can be seen as the reverse of coagulation. Dispersion is influenced by the mineralogy of the primary mineral particles and the salts offsetting the associated changes.

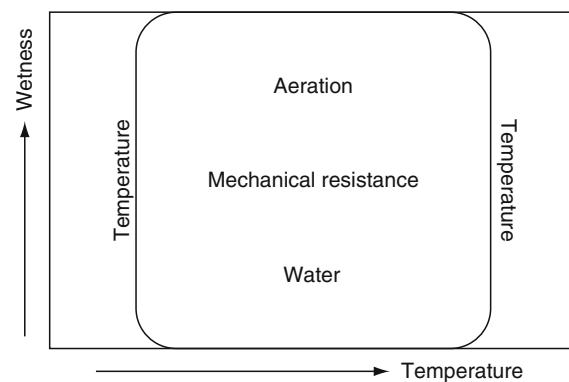

Because of the different mechanisms involved in the stability of aggregates in water changes, in that stability can reflect management and thus seen as a measure of soil physical quality. By comparison with initial aggregate size distribution, an index can be determined (Six et al., 2000b).

Least limiting water range

Letey (1985) introduced the non-limiting water range (NLWR) to link the separate effects that water, aeration, and mechanical resistance have on root growth. The NLWR is a single parameter that defines a range of water contents at which available water, aeration, and mechanical resistance do not restrict root growth (Letey, 1985). Values of soil aeration and mechanical resistance that limit root growth have been reported by various researchers (see *Root Responses to Soil Physical Limitations*). As the water content of the soil changes, mechanical resistance and aeration change and may exceed limiting values for root growth. The limits of available water are between the matric suction at wilting point (1,500 kPa), where plant roots are unable to access water required for growth and the matric suction at field capacity (10 kPa). The NLWR is the range where root growth is not limited by available water, aeration, or mechanical resistance. The maximum water content is the drier of field capacity, or the water content at which root growth is limited by aeration. The minimum water content is the wetter of wilting point or the water content at which mechanical resistance limits root growth.

The NLWR has since been termed the least limiting water range (LLWR) by da Silva et al. (1994), and has continued to be used by researchers (da Silva and Kay, 1996, 1997; Tormena et al., 1999; Leao et al., 2006). The change was made because plant growth occurs continuously in response to changes in available water, aeration, and mechanical resistance and may be limited, although the growth not totally prevented. Inside the range, growth is least limited, while outside the range, growth is most limited (da Silva et al., 1994). da Silva and Kay (1997) defined the LLWR as “the range in soil water content after rapid drainage has ceased within which limitations to plant growth associated with water potential, aeration and mechanical resistance to root penetration are minimal.”

Soil physical characteristics are linked. In Figure 1, adapted from Boone (1988), soil water content and soil temperature are independent variables. At very low or very high temperatures, root growth is limited. When the

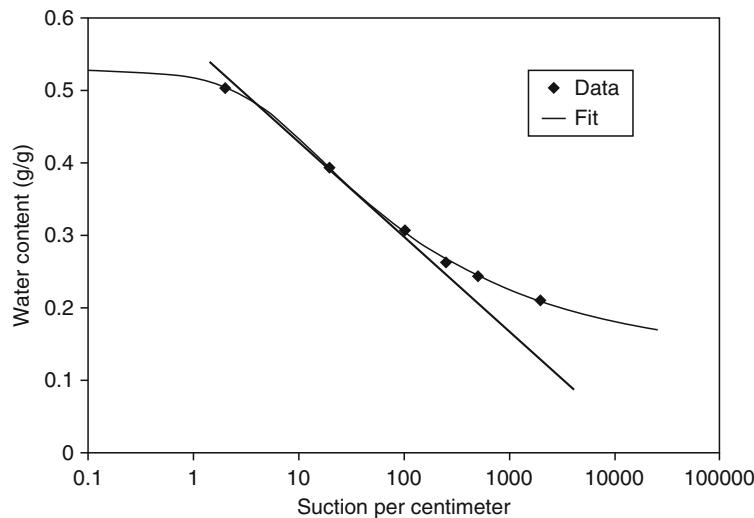

Soil Physical Quality, Figure 1 Representation of the least limiting water range (LLWR) after Boone (1988).

soil temperature is non-limiting and the soil is very wet, aeration is limiting. As the soil dries, water becomes limiting and high mechanical resistance restricts root growth, which also limits crop water availability. Boone et al. (1986) investigated the relationship between soil water and soil structure (Figure 1) to determine the limits of soil aeration and soil mechanical resistance. With combined limits of soil mechanical resistance with soil water and soil structure and limits of soil aeration with soil water and soil structure, it can be determined at what soil water contents root growth and function are not limited (Boone, 1988).

The period of least-limited root growth is when neither mechanical resistance nor aeration is limiting. To these two parameters, the water contents associated with plant available water are added as limits, the matric suctions of field capacity, and wilting point. The LLWR is then calculated from the water content values associated with the values of mechanical resistance and aeration that limit root growth and matric suctions of wilting point and field capacity. It is possible to have a negative LLWR, which da Silva et al. (1994) considered as zero.

S-theory or S-index

Dexter (2004a, b) describes an index, S, as representing soil physical quality. The S-value represents the slope of the water retention curve at its point of inflection when the curve has been plotted as gravimetric water content against the natural logarithm of the pore water suction. Figure 2 shows a soil water retention curve. Typical raw data are presented and the curve, fitted to the van Genuchten (1980) parameters, follows these points. The slope at the point of inflection is shown as a straight line. The slope at the point of inflection is not arbitrary but has been related to physical management of soil, e.g., it has been suggested that the water content at the point of inflection is the optimum condition for soil manipulation through tillage (Dexter and Bird, 2001). Because the water retention curve is a measure of the pore-size distribution, an increase in slope at the point of inflection indicates

Soil Physical Quality, Figure 2 Water retention curve showing data and fitted curve with the slope at the point of inflection as a line.

greater pore diversity. The larger pore classes, the often-termed structural pores, are responsive to soil management, while pores that result from texture are less sensitive to management. So when the different pore types are connected, the S-index can be changed by management. Typical values of the S-index are >0.05 for a soil with very good structural quality, while a value <0.02 classes it as a degraded soil or one with very poor quality. While the vast majority of soils exhibit a single inflection point, the approach is more difficult in soils with more than one inflection point.

There is currently an increasing use of the S-index approach to assess soil physical quality. Keller et al. (2007) connected the optimum water content for conducting tillage operations with the S-index of the soil. They found that the optimum water content for tillage was close to the point of inflection on the water retention curve, and that tillage operations when the soil was in this state produced a better seedbed with fewer large clods. Similarly, Cavalieri et al. (2009) have found the S-index sensitive to small increases in the bulk density of particular layers within a given soil and by inference suggested that it is a good measure of soil physical quality.

Resistance and resilience

The indexes described in the text above are based on the state of the soil as it exists at a given time. They are responsive to management; values increase under conditions that improve crop performance and decrease when the soil is compacted or has decreased concentrations of organic matter. However, the indexes may not reflect the ability of a soil to resist change by poor management or other stress and do not explicitly reveal how rapidly, if at all, the soil will recover from being degraded. Lal (1993) introduced the idea that, implicit in the concept of soil quality a soil needs to be able to resist degradation and

that, rapid recovery to the preexisting state (not to an inferior state) was part of the concept of soil quality. Gregory et al. (2007) defined resilience as the ability of a soil to recover its original property, capacity, or function when an applied stress is removed. While the stresses can be physical (e.g., compaction), chemical (e.g., toxic elements), or biological (e.g., pathogens), the risks of compaction in modern agriculture make physical resilience a key parameter. A soil deemed to have good soil physical quality will show rapid and total recovery. Gregory et al. (2007) suggest that self-mulching surface soils as described by Grant et al. (1995) provide an example of this good quality (see *Shrinkage and Swelling Phenomena in Soils*). Griffiths et al. (2005) studied several measures of soil condition in response to amendments with heavy-metal contaminated sewage sludge. They suggested that the recovery or resilience of the soil to imposed physical stresses resulting from compaction and long-term waterlogging and stresses, on the biological function resulting from heat or contamination, were linked. Strong interconnection between the physics, chemistry, and biology of soil are well known. The concepts of resistance and resilience may provide opportunities to unify them for measures of soil quality.

Soil physical quality: the future

There is clearly a need for more practical, rigorous testing of the current indexes of soil physical quality. This should include comparisons between the different approaches to test how they perform relative to each other and how they might be connected. Because the soil physical quality is not isolated from chemical fertility or biological function, the opportunity to unite approaches from different disciplines needs to be explored. It will not be simple to combine different ways of thinking, but to place an environmental as well as an economic value on soil, dialog

between the disciplines is needed. One novel approach is to supplement physical measurement with expert or stakeholder knowledge (e.g., Kaufmann et al., 2009) through expert systems. Mixing human experience with multi-criteria scientific analysis of soil quality is being tested to develop approaches for soil monitoring (Aalders et al., 2009). Whether this can be used to quantify the ability of a given soil to meet plant and ecosystem requirements for water, aeration, and strength over time remains to be seen.

SOIL SEPARATES

Mineral particles, <2.0 mm in equivalent diameter, ranging between specified size limits. The names and size limits of separates recognized in the USA are: *very coarse sand* (Prior to 1947 this separate was called “fine gravel;” now fine gravel includes particles between 2.0 mm and about 12.5 mm in diameter), 2.0 to 1.0 mm; *coarse sand*, 1.0 to 0.5 mm; *medium sand*, 0.5 to 0.25 mm; *fine sand*, 0.25 to 0.10 mm; *very fine sand*, 0.10 to 0.05 mm; *silt*, 0.05 to 0.002 mm; and *clay* (Prior to 1937, “clay” included particles <0.005 mm in diameter, and “silt,” those particles from 0.05 to 0.005 mm) <0.002 mm. The separates recognized by the International Society of Soil Science are: (i) *coarse sand*, 2.0 to 0.2 mm; (ii) *fine sand*, 0.2 to 0.02 mm; (iii) *silt*, 0.02 to 0.002 mm; and (iv) *clay*, <0.002 mm.

SOIL STRUCTURE AND MECHANICAL STRENGTH

Rainer Horn, Heiner Fleige

Institute for Plant Nutrition and Soil Science, Christian-Albrechts-University zu Kiel, Kiel, Germany

Definition

Soil strength is typically referred to the maximum amount of stress a solid material can stand before it fails, thus exceeding soil strength results in soil failure or yield.

Stress is defined as force per area within a solid body. Stress can be induced by external or internal forces which lead, if the body is nonrigid, to a change in the body's volume and/or shape expressed as deformations or strains. The mechanical behavior of a soil can therefore be characterized by its stress-strain relationships. The transition from the recompression to the virgin compression state is defined as precompression stress.

Introduction

The determination of soil strength always coincides with a link to physical soil properties like hydraulic conductivity, pore size distribution, and pore continuity, and is also linked with plant growth and yield, climate change aspects as well as groundwater recharge, and water quality.

The determination of soil and/or aggregate strength has always to be subdivided into (1) mechanically, hydraulically, or chemically prestressed and (2) virgin conditions, which also ultimately affect the predictability of physical properties. These general ideas have been described in greater detail by Hartge (1965), Toll (1995), Baumgartl and Horn (1999), Groenevelt and Grant (2002), Grant et al. (2002), Horn et al. (2000, 2006), and Horn and Fleige (2003).

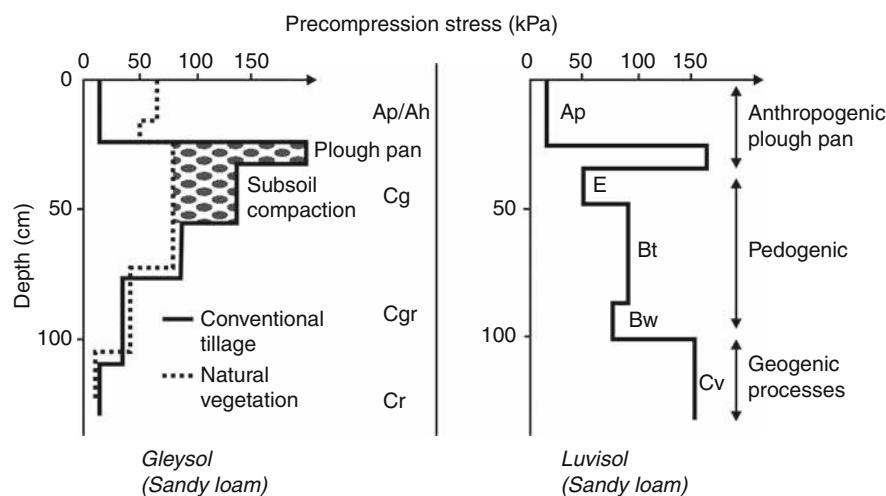

Mechanical strength of structured soils

The mechanical strength of structured soils depends on aggregation and history of hydraulic stresses (degree of maximum pre-drying), as well as the shape and internal arrangement of particles, micro-aggregates, and voids. At comparable grain size distribution, bulk density, and pore water pressure, soil strength increases with aggregation (i.e., coherent < prismatic < blocky < subangular blocky < crumbly). In the case of a platy structure, the strength depends on the direction of shear forces relative to the preferred orientation of the particles. In the direction of the elongated axes of aligned particles, shear strength is lower than perpendicular to it. This means that not only mechanical stresses are anisotropic but also strength properties which in turn are a function of aggregation. However, both the magnitude of previous hydraulic stresses (pre-drying intensity) and their dynamic changes determine soil strength. Therefore, mechanical properties also depend on the frequency of swell/shrink and wet/dry events and on the actual pore water pressure at the time

of loading. Soils become stronger when re-dried and rewetted and when pore water pressure gradients over longer distances promote particle movement and rearrangement until entropy is minimized (Semmel et al., 1990). The effect of pore water pressure on strength itself is governed by the theory of effective stresses in unsaturated soils (e.g., BISHOP's effective stress equation). The χ factor in this equation quantifies the water-filled pores in soils relative to water saturation (=1) and complete dryness (=0). Thus, if the relative reduction in water-filled pores is smaller than the actual decrease in pore water pressure (more negative matric potential), soil strength increases. Conversely, drier soils become weaker when the effective surface of water menisci decreases above average ($\chi \rightarrow 0$).

In principle, soil strength is promoted by two different mechanisms: (1) the increase in strength results from an increase in the total number of contact points between single particles (i.e., an increase in effective stress) and (2) the increase in shear resistance per contact point (Hartge and Horn, 1984). Therefore, even if soil bulk densities are similar, strength properties may be quite different. Also freezing and thawing affects soil strength, because aggregates become denser or are destroyed by ice lens formation during freezing. Aggregates may act as rigid bodies which allow exfoliation processes to start from the outer skin due to ice lens formation. Both effects are called soil curing but result in completely different strength values and physical properties of the bulk soil (Horn, 1985; Kay, 1990).

Pedogenic effects on natural soil mechanical strength are illustrated in Figure 1. A Gleysol derived from marine sediments can be defined as very loose, linked with a high air capacity and plant available water capacity as well as high values for hydraulic conductivity, which can be also linked to the high biological activity. This soil also shows a pronounced effect of natural drying intensity and

Soil Structure and Mechanical Strength, Figure 1 Precompression stress values for two soil profiles under various land use and geological origin (marin sediments, weichselian glacial till) at an initial soil matric potential $\Psi_m = -6$ kPa.

aggregate formation with increasing distance to the groundwater table as well as of land use. Under natural vegetation, soil strength (defined as precompression stress P_c) increases from coherent (=weak) structure (C_r horizon) to prismatic structure ($C_{gr\ hor.}$) and blocky structure ($C_g\ hor.$) due to a more often and more intense swelling and shrinkage and drying intensity. If these natural soils are wheeled and ploughed, a more compressed, dense, and more rigid plow pan layer is created, which can also be detected by the increased P_c value at this depth. Additionally, the soil deformation alters the soil properties over depth as can be derived from the higher P_c values which only fade off at depths >50 cm.

Soils derived from glacial till are characterized both by their geological origin and soil genetic processes. The latter can be derived for the Luvisol from the effect of clay illuviation, which results in strength decrease in the E-horizon and an increase in the Bt-horizon due to aggregation based on the improved swell shrink behavior of the clay. In general, the parent material (C-horiz.) is weakest as long as it was deposited as an aeolian or fluvial sediment. If, however, the geological origin (glacial pressure) dominates, then the former higher strength caused by, e.g., 150 m of (weichselian) glacier height in northwest Germany and the long-term backward and forward shearing movement of the glacier can be still detected and quantified even after more than 10,000 years of postglacial soil development.

Anthropogenic processes such as annual plowing and wheeling create very strong plow pan layers with P_c values similar to the contact pressure of a tractor tire or even higher (up to 300%) due to lug effects, while the loosened Ap horizon has been mostly homogenized and consequently weakened by the reduction of the contact points between particles, a height increase of the soil horizon. Thus, the strength decreases in the Ap-horizon due to plowing and, seedbed preparation can be observed until texture-dependent values are reached. Pronounced strength decreases are also found in soil profiles which have been deep loosened or deep plowed (up to 60 cm) or loosened and/or mixed with other soil material. In the case of a partial deep loosening by a trenching slit plow (Blackwell et al., 1989; Horn, 1994), traffic must be restricted by use of smaller and lighter machinery or controlled tracks perpendicular to the homogenized soil volume.

Soils with a well-developed vertical pore system are stronger than those with randomized or horizontal pore arrangements since elongated pores are more stable with their symmetry axis oriented in the direction of the major principle stress (σ_1) than perpendicular to it. Therefore, vertical (bio-) pores are less prone to compression than horizontally oriented pores and, thus, untilled or minimum tilled soils are stronger than conventionally tilled ones (Horn, 1986, 2004).

However, each soil deformation affects air-filled pore space and continuous coarse pores because each settlement requires a reduction in coarse pores and a hydraulic

conductivity which allows during compression to drain off excess pore water. The smaller the hydraulic conductivity, the hydraulic potential gradient, and the pore continuity, the more stable is the soil especially during short-term loading. It is often described with termini-like aquaplaning or the waterskiing effects. In sandy soils, this effect is small and the initial settlement equals the total strain. With increasing clay content, however, the proportion of initial to primary and secondary consolidation is reduced and the time-dependent soil settlement becomes more important (Horn, 1988). This results in an increase of P_c for short-term loading due to an increase in the pore water pressure-related soil strength that dissipates only slowly depending on the local hydraulic conductivity. Consequently, it is to be expected in mainly fine-textured soils (sand < silt < clay) with increasing bulk density, with mostly minor aggregation, higher degree of soil disturbance, e.g., by plowing, and less continuous pores. More detailed information is given in Horn: Management Effects on Soil Properties and Functions.

Conclusions

Soil strength depends on the kind and arrangement of aggregates as well as on the pore geometry and rigidity. The coupled mechanical and hydraulic processes affect the time-dependent soil strain and the alteration of the pore functioning, e.g., aeration and water fluxes.

Geogenic, pedogenic, and anthropogenic processes can be differentiated by the parameter precompression stress and can therefore also be used to define the actual internal soil strength as a function of matric potential.

SOIL STRUCTURE, INTERSECTING SURFACE APPROACH, AND ITS APPLICATIONS

Victor Yakov Chertkov

Division of Environmental, Water, and Agricultural Engineering, Technion – Israel Institute of Technology, Haifa, Israel

Definitions

Soil structure. The arrangement and organization of the different soil particles in a soil.

Intersecting surfaces approach (ISA). The physical approach to soil (and rock) structure and properties description and prediction that originates from the obvious presence and superposition in any (sufficiently large) soil

volume of the enormous number of natural intersecting surfaces having a different scale and physical nature and meeting several simple geometrical conditions.

Applications of ISA. The physical derivation of such geometrical characteristics of soil structure underlying any soil properties and processes, as (1) interconnected size and shape distributions of soil solids and voids between them; and (2) porosity, connectedness, and tortuosity relating to the voids.

Development history

Initially, the prototype of the ISA only related to multiple cracking of rocks and their corresponding fragmentation, natural- and explosion-induced (Chertkov, 1985; Chertkov, 1986; Chertkov, 1991). The prototype model is based on a concentration criterion of crack accumulation and connection (Zhurkov et al., 1981) and effective independence of cracks in the case of multiple cracking (Hudson and Priest, 1979). In the case of the natural blockiness of a rock mass (this is interesting for the extension to soils), the model is in good agreement with the following principal observations: (1) the ratio of the maximum size of a structural block of rock mass to the average size is approximately equal to 4 (Hudson and Priest, 1979); (2) severe, but incomplete disintegration is observed in rock masses due to natural cracks; (3) the average number of faces on a fragment, at randomly oriented cracking, is approximately equal to 8 (Curran et al., 1977); (4) the observed size distributions of structural blocks for deposits of granite, diorite, and diabase (Azovtsev, 1984); (5) the shape characteristics of rock blocks – average ratios of the second and third fragment sizes to the first one (Repin, 1978).

The prototype of the ISA was applied to multiple cracking ([Cracking in Soils](#)) and fragmentation of swelling soils as they dry and shrink ([Shrinkage and Swelling Phenomena in Soils](#)) (Chertkov, 1995; Chertkov and Ravina, 1998; Chertkov and Ravina, 1999). Comparison between the model prediction (Chertkov, 1995) and data (Guidi et al., 1978) for two-dimensional fragmentation showed good agreement. The model of multiple cracking considers cracks to be surfaces (without openings). For this reason, in the three-dimensional case the model gives parameters of the crack network itself – crack spacing and depth – as functions of soil depth. Crack opening and volume are found by accounting for the soil shrinkage. Comparison between predicted parameters of crack networks (Chertkov and Ravina, 1998; Chertkov and Ravina, 1999) and available observations for different clay soils from Yaalon and Kalmar (1984), Zein el Abedine and Robinson (1971), and Dasog et al. (1988) showed good agreement.

After application of the multiple cracking and fragmentation model to rocks and soils, in which the crack network develops (for different reasons), it was realized that the geometrical entity of the model, that is, the division of a volume by a surface system meeting some conditions,

can likely be relevant to many geometrically similar issues of soil structure with another physical nature of the dividing surfaces. Before formulation of ISA, such an approach (“by analogy”), inspired by the multiple cracking model, was used to describe the pore structure of a clay matrix as applied to the physical modeling of clay shrinkage (Chertkov, 2000; Chertkov, 2003). With that, clay particles meeting some conditions played the part of surfaces (instead of cracks) dividing the space into the clay matrix pores (in place of soil or rock fragments). The comparison between prediction and data from Bruand and Prost (1987) and Tessier and Pedro (1984) was promising. There is a review of the prehistory of ISA (Chertkov and Ravina, 2004).

Major concepts of ISA

S- and V-objects

Geometrically, soils consist of volume-like objects (V-objects – blocks, fragments, aggregates, silt and sand grains, and 3D pores) ([Soil Aggregates, Structure, and Stability](#)) and surface-like objects (S-objects – boundaries of V-objects as well as cracks, and clay particles). S-objects have limited sizes and random orientations in space. The ratio of connected S-objects to the total number of S-objects defines the so-called connectedness of their system, $0 < C \leq 1$. S-objects do not stick together at their surfaces. Connections of S-objects of close sizes, $\sim x$, lead to the development of an S-object of a larger scale $\sim (K+1)x$ according to the concentration criterion at $K \cong 5$ (Zhurkov et al., 1981). The condition of the effective independence of S-objects: the spacing x between neighboring intersections of the S-objects with a straight line is distributed as $\exp(-x/d)$ where d is an average value (Hudson and Priest, 1979 – data for rocks; Scott et al., 1986 – data for soils). The condition of V-object formation at S-object connection: at least part of the S-objects outline V-objects totally or nearly so. The V-objects have sizes in the range, $x_{\min} \leq x \leq x_m$ (x_{\min} and x_m being the minimum and maximum sizes) and constitute a volume fraction $P \leq 1$ of the soil (rock) volume where P is a function of connectedness C (see below).

ISA distributions

If the S-objects fulfill the above geometrical conditions, the physical size distribution of V-objects originates from the division of a volume by a large number of intersecting S-objects. The elementary ISA distribution of V-objects of a given type, $F(x)$ (a volume fraction of V-objects of size $< x$ of their total volume) is given as (Chertkov, 2005):

$$F(x) = \left[1 - (1 - P)^{I(\xi(x))/8.4} \right] / P, \quad x_{\min} \leq x \leq x_m \quad (1)$$

where $I(\xi) = \ln(K+1)(4\xi)^4 \exp(-4\xi)$, ($K=5$); $\xi \equiv (x-x_{\min})/(x_m-x_{\min})$; and P is a volume fraction of V-objects (of the total volume). P is coupled with connectedness C as $P \cong 1 - \exp(-8.4C)$. Thus, the V-object size

distribution is characterized by the P , x_{\min} , and x_m parameters.

If the soil contains two different types of V-objects, for example, inter-aggregate pores with volume fraction $P = P_p$ ([Pore Size Distribution](#)) and aggregates with volume fraction $P = P_a = 1 - P_p$, the above distribution $F(x)$ can be separately written for the pores ($F(x) = F_p(x)$, $P = P_p$, $x_{\min} = x_{\min p}$, $x_m = x_{\max p}$) and aggregates ($F(x) = F_a(x)$, $P = P_a$, $x_{\min} = x_{\min a}$, $x_m = x_{\max a}$). In the general case of more than two different V-object types, the sum of all volume fractions P_j ($j = 1, \dots, J$) should be equal to unity.

The size distribution of the mixture of V-objects of a given type (e.g., I modes of pores) can be presented as the sum of I terms of corresponding elementary ISA distributions multiplied by the weights $P_i / \sum_{i=1}^I P_i$ (P_i is the porosity of the i th pore mode; $i = 1, \dots, I$) as (Chertkov, 2005):

$$F(x) = \sum_{i=1}^I \left[1 - (1 - P_i)^{I(\xi_i(x))/8.4} \right] / \sum_{i=1}^I P_i, \quad x_{\min 1} \leq x \leq x_{\max I} (x_{\min 1} < x_{\min 2} < \dots < x_{\max I}) \quad (2)$$

where $\xi_i \equiv (x-x_{\min i})/(x_{\max i}-x_{\min i})$, ($i = 1, \dots, I$). The case of $I=1$ corresponds to the elementary ISA distribution. If the $F(x)$ function gives a [Pore Size Distribution](#), $P = \sum_{i=1}^I P_i$ is the total porosity, and P_i is the volume fraction of pores of the i -th mode (of the soil volume). If the $F(x)$ function gives a solids-size distribution (e.g., for several sand-grain modes) $\sum_{i=1}^I P_i = 1 - P$ where P again is the total porosity, and P_i is the volume fraction of solids of the i -th mode (of the soil volume). The above generalized ISA distribution was checked (Chertkov, 2005) in the case of two modes ($I=2$) of sand pores (data from Day and Luthin, 1956), aggregates (data from Wittmuss and Mazurak, 1958), and silty fine sand (data from Mualem, 1976).

The presentation of [Equations 1](#) and [2](#) is relevant to both rigid and nonrigid soil matrices. However, in the case of the clay of a shrink-swell matrix the soil parameters P_i , $x_{\min i}$, and $x_{\max i}$ (for pore modes or aggregate modes) become functions of the water content (for a clay porosity example, see Chertkov, 2004).

Features of ISA

1. The ISA distribution of V-objects that fulfills the abovementioned geometrical conditions is a universal function of V-object size, x . The view of the function ([Equations 1](#) and [2](#)) does not depend on V-object type, for example, soil (rock) fragments, clay matrix pores or soil aggregates, and their methods of preparation. Materials and methods can only influence values of the P , x_{\min} , and x_m parameters (universality).

2. Except for the size distributions, ISA allows one to estimate the tortuosity of the connected S-objects (Chertkov and Ravina, 1999; Chertkov, 2005) (tortuosity estimation).
3. In connection with the soil heterogeneity and variability of a different type, the P , x_{\min} , and x_m parameters become functions of spatial coordinates and time (locality).
4. The approach enables consideration of an actual soil as a superposition of S-objects of different physical nature, for example, clay particles and cracks, and different scales, such as cracks of essentially different sizes (superposition of different S-object systems).
5. One can also estimate any shape characteristic of V-objects (Chertkov, 2005).
6. Part of the actual S-objects (cracks, slits, and clay particles) has small, but finite (nonzero) thickness (or aperture) and volume. The small thickness of such S-objects is found by independent means from physical conditions of a task.

Recent applications and perspectives

The recent physical explanation and prediction of soil shrinkage (Chertkov, 2007a, b; Chertkov, 2008a, b) essentially relies on ISA concepts in the estimation of the relevant size distributions of pores and aggregates. Without a doubt, the similar use of ISA will be needed in future physical approaches to soil swelling, residual cracking (after soil wetting), [Hydraulic Properties of Unsaturated Soils](#), and water flow.

Summary

ISA leads to the scale invariant fragment and [Pore Size Distribution](#) and permits one to take into account the superposition of S-objects of a different physical nature and scale, the connectedness and tortuosity of the S-objects, the shape characteristics, and the swelling-shrinkage of the corresponding V-objects.

SOIL STRUCTURE, VISUAL ASSESSMENT

Lothar Müller

Leibniz – Centre for Agricultural Landscape Research (ZALF), Institute of Landscape Hydrology, Müncheberg, Germany

Definition

Visual assessment of soil structure is a procedure for obtaining and evaluating information on the feature and function of soils from macro-morphological characteristics of the soil structure.

Role and purpose

Soil structure is a soil property and a criterion of agricultural soil quality. Soil structure is vulnerable to change by management and degradation processes like

compaction and erosion, and its preservation is key to sustaining soil function. Visual soil structure refers to macro-morphological features of soil structure that can be detected and evaluated in the field. Soil structural features meet the farmers' perception of soil quality (Shepherd, 2000; Batey and McKenzie, 2006) and are correlated with measured data of physical soil quality (Shepherd, 2003; Lin et al., 2005) and crop yield (Mueller et al., 2009a). Visual assessment of soil structure may serve as a diagnostic tool for the recognition and evaluation of the morphological and functional status of soil. Structure features and function result from soil substratum and genetic and management factors. This offers the potential to provide semiquantitative information for use in extension and monitoring or even modeling (Roger-Estrade et al., 2009). Visual soil structure assessment may also serve as a research tool in conjunction with measurements and analyses of soils. Some methods identify layers and can provide useful guidance for locating further measurements. Visual soil structure evaluation plays a particularly important role in organic farming where good structure is vital to mineralize nutrients and where poor soil structure cannot be compensated by an extra input of agrochemicals in those systems (Munkholm et al., 2003). Visual soil structure assessment may explain only part of crop yield variability, as the influence of inherent soil properties and climate on crop yield is dominant, particularly over larger regions.

Soil Structure, Visual Assessment, Figure 1 Assessment of soil structure by the visual soil assessment (VSA) method of Shepherd (2009) (Photo: T. Graham Shepherd). (a) Good conditions, VS = 2: soil dominated by friable, fine aggregates with no significant clodding. Aggregates are generally sub-rounded and often quite porous. (b) Moderate conditions, VS = 1: soil contains significant proportions (50%) of both coarse clods and friable fine aggregates. The coarse clods are firm, sub-angular or angular in shape and have few or no pores. (c) Poor conditions, VS = 0: soil dominated by coarse clods with very few finer aggregates. The coarse clods are very firm, angular or sub-angular in shape and have very few or no pores.

Methods

Visual assessment of soil structure includes (1) recognition and description of soil structure and rooting features, visible to the naked eye; (2) classification, evaluation, and parameterization of visual soil structure, and sometimes (3) conclusions on the functional status of soil. Visual-tactile recognizable soil features like type, size, and hierarchy of aggregates, inter- and intra-aggregate porosity, and number and size of biogenic pores including earthworm casts may serve to evaluate and classify the quality of soil structure. Over the past decades, several methods have been evolved. Most of them differ in several important ways including depth of the soil under consideration, handling the soil prior to assessment, emphasis placed on particular features of soil structure, and application of size increments and direction of scoring scales. One of the most accepted methods is that of Peerlkamp (1967).

It has a conjoint scale referring to type and size of aggregates and pores. The main advantages of this method are speed and minor soil disturbance, providing comparative statistical analyses both in large fields and also in small plots of long-term trials. However, the scoring framework has potential for subjective errors. Methods like the “Le profil cultural” (Roger-Estrade et al., 2004), SOILpak (McKenzie, 2001), or the method of Werner and Thaemert (1989) or Munkholm et al. (2005) provide single scorings of different structure features. This is more time-consuming, a total assessment is sometimes difficult, and a total numerical score, though desirable, may not be part of the test. The New Zealand Visual Soil Assessment (VSA) method (Shepherd, 2000) is a multi-parameter technique based on scoring a spadeful of soil by different criteria. Disaggregation of soil after a drop-shatter test is a key criterion for assessing soil structure (Figure 1) and helps minimize

Structure quality	Ease of break up (moist soil)	Size and appearance of aggregates	Visible porosity	Roots	Appearance after break-up: various soils	Appearance after break-up: same soil different tillage	Distinguishing feature
Sq1 friable (tends to fall off the spade)	Aggregates readily crumble with fingers	Mostly <6 mm after crumbling	Highly porous	Roots throughout the soil			 Fine aggregates
Sq2 intact (most is retained on the spade)	Aggregates easy to break with one hand	A mixture of porous, rounded aggregates from 2 mm to 7 cm. No clods present	Most aggregates are porous	Roots throughout the soil			 High aggregate porosity
Sq3 firm	Most aggregates break with one hand	A mixture of porous aggregates from 2 mm to 10 cm; less than 30% are <1 cm. Some angular, non-porous aggregates (clods) may be present	Macropores and cracks present. Some porosity within aggregates shown as pores or roots.	Most roots are around aggregates			 Low aggregate porosity
Sq4 compact	Requires considerable effort to break aggregates with one hand	Mostly large >10 cm and sub-angular non-porous: horizontal/platy also possible; less than 30% are <7 cm	Few macropores and cracks	All roots are clustered in macropores and around aggregates			 Distinct macropores
Sq5 very compact	Difficult	Mostly large >10 cm, very few <7 cm, angular and non-porous	Very low; macropores may be present; may contain anaerobic zones	Few, if any, restricted to cracks			 Grey-blue colour

Soil Structure, Visual Assessment, Figure 2 Visual soil structure quality assessment by the revised Peerlkamp method (Ball et al., 2007). (Photo: Bruce C. Ball.)

the subjective handling of the soil prior to assessment. A quantitative comparison of some methods and their correlations with measured physical parameters after standardizing data revealed that many methods provided similar results (Mueller et al., 2009a). Types and sizes of aggregates and abundance of biological macropores were the most reliable criteria relating to measurement data and crop yields. Differences in soil management or effects of compaction may be detected by visual assessment of the soil (Batey and McKenzie, 2006; Mueller et al., 2009b). Unfavorable visual structure scores were associated with increased dry bulk density, higher soil strength, and lower infiltration rate but correlations were site specific. Visual soil structure assessments may form part of overall soil characterizations (FAO, 2006; WRB, 2006). Field data of this method may be parameterized by a simple coding scheme given by Mueller et al. (2009a). Overall soil and land quality rating schemes like the Muencheberg Soil Quality Rating (Mueller et al., 2007) include soil structure indicators.

Recommendation

Visual methods based on, or supplemented by illustrations, have clear advantages for the reliable assignment of a rating score based on visual diagnostic criteria. The latest development of the Peerlkamp method provided by Ball et al. (2007) (Figure 2) is well illustrated. Also, the New Zealand Visual Soil Assessment (VSA) (Shepherd, 2009) as an illustrated multi-criteria method, enabling reliable assessments of the soil structure status.

Summary

Methods of visual soil structure examination enable semi-quantitative information on the morphological and functional status of soil for use in extension, monitoring, modeling, and research. Type and size of aggregates and number and size of biogenic pores are reliable criteria.

Illustrated methods like the updated Peerlkamp method (Ball et al., 2007) and the Visual Soil Assessment (Shepherd, 2009) lead to ordinally scaled scores are easy to learn and use and are reliable in handling.

SOIL SURFACE SEALING AND CRUSTING

Shmuel Assouline

Environmental Physics and Irrigation, Institute of Soil, Water and Environmental Sciences, Agricultural Research Organization – Volcani Center, Bet Dagan, Israel

Definition

Often, the surface of bare soils is topped with a relatively thin and hard layer that tends to peal when it dries. This layer was named “crust,” and the process of its formation was addressed as “soil surface crusting.” Many different causes to its formation were identified: high-intensity rain-storm, fire, microbiological activity, mechanical compaction, or chemical treatments. In some cases, like during rainstorms for example, the formation of that particular layer on top of the soil profile occurs under wet conditions. In those cases, the term “crust” is replaced by the term “seal” to differentiate the layer during its formation from that obtained after drying. When rainfall is the cause to seal formation, structural seals generated by the impact of raindrops, and depositional seals resulting from the settling of suspended solids in runoff can be formed.

Presence of seals or crusts at the soil surface can induce severe agricultural, hydrological, and environmental hazards: decrease of the infiltration rate; reduction of the available water to plants; diminution of aquifers’ recharge; increase of runoff; and limitation of seedlings and crop yields. In semiarid regions, crust presence can enhance a vicious cycle that intensifies desertification by reducing vegetation cover, initiating overgrazing, and finally leaving the soil surface bare and prone to seal formation. On the other hand, it can be beneficial as it augments runoff and improves the efficiency of water harvesting installations.

Introduction

Soil surface sealing may result from different causes such as raindrop impacts, fire, biological activity, and mechanical or chemical treatments. This complex phenomenon has been studied through extensive laboratory and field experimental investigations and different conceptual and empirical models of seal formation were suggested.

Rainfall-induced seals, also called structural seals, form at the surface of bare soils exposed to the direct impact of raindrops. Their formation is dominated by a wide variety of factors involving soil properties, rainfall characteristics, and flow conditions. Different reviews on the subject are available (Mualem et al., 1990a; Bradford and Huang, 1992; Assouline, 2004).

Depositional seals are formed when water rich in suspended solids infiltrates into the soil. The nature, the composition, the thickness, and the hydraulic properties of such seal layers depend on soil clay mineralogy and the chemical conditions in the soil-water system

prevailing during their formation. Depositional seals reduce the hydraulic conductivity of the soil profile and therefore affect infiltration and evaporation processes. Detailed information can be found in Shainberg (1992), Lado et al. (2007), and Bhardwaj et al. (2009).

Biological, or microbiotic, crusts are composed of lichens, cyanobacteria, algae, mosses, and fungi. These components improve the binding of soil particles together, thereby increasing soil surface stability and resistance to water and wind erosion. They affect soil physicochemical properties and, consequently, soil wetting and drying processes. Detailed information on this topic could be found in Evans and Johansen (1999), Belnap (2003), Eldridge and Greene (1994), and Eldridge et al. (2000).

In the following lines, the methodology applied to characterize seal morphology and properties, formation, and effects on flow processes is presented through the study of structural crusts formed under high-kinetic energy rainfalls.

Morphology and properties of rainfall-induced crusts

Reviews on seal morphology and properties were presented by Mualem et al. (1990a), West et al. (1992), and Assouline (2004). Various methods were applied to determine crust morphology: examination of thin sections of the crusted soil surface by means of light microscope, electron microscope, or X-rays radiography and tomography; mechanical analysis of the upper soil layer; measurements of hydraulic head distribution in the upper soil layer; and analysis of data from infiltration tests. The characteristics of structural crusts appear to strongly relate to the conditions prevailing during their formation.

The two-layer structure of McIntyre (1958a, b), which consists of a 0.1-mm skin overlying a 2.0-mm washed-in layer, is the most widely adopted description of the crust (Tackett and Pearson, 1965; Onofio and Singer, 1984; Tarchitzky et al., 1984; Wakindiki and Ben-Hur, 2002). It is interesting to note that this two-layer structure resulted from visual examination of the crust. When different methods were applied, like porosity or bulk density measurements, the results showed that gradual changes of structure within the crust were more likely to exist (Epstein and Grant, 1973; Eigel and Moore, 1983; Roth, 1997; Fohrer et al., 1999; Bresson et al., 2004; Augeard et al., 2007).

The reported crust thickness based on laboratory experiments varied by two orders of magnitude, from 0.1 mm (Chen et al., 1980; Wakindiki and Ben-Hur, 2002) to 10.0 mm and more (Sharma et al., 1981; Bresson and Boiffin, 1990; Roth, 1997; Fohrer et al., 1999; Bresson et al., 2004). Under field conditions, larger thicknesses than those observed in the laboratory, up to 20.0 mm, were reported (Hadas and Frenkel, 1982). Similarly, the ratio between the saturated hydraulic conductivities of the seal and that of the undisturbed soil underneath presents a huge variability, from 20% (Tackett and Pearson,

1965) to 1% (Hadas and Frenkel, 1982; Simunek et al., 1998) and even to 0.1% or 0.01% (Morin et al., 1981; Perez et al., 1999). Crust saturated hydraulic conductivity also is related to the conditions prevailing during seal formation: Baumhardt et al. (1990) reported that the conductance of the upper 10 mm of a sealed soil profile ranges between 0.013 h⁻¹ and 0.071 h⁻¹, depending on the applied rainfall intensity.

The crust layer is more compacted than the undisturbed soil underneath. A gradual increase of the bulk density from a depth of 10 mm below soil surface to the crust surface was measured (Eigel and Moore, 1983; Roth, 1997; Fohrer et al., 1999; Bresson et al., 2004). Augeard et al. (2008) showed that this distribution depends on the flow conditions during seal formation.

Different conceptual models of the crust layer were proposed. Hillel and Gardner (1969, 1970) suggested the simplified model of a single uniform saturated layer of constant low permeability, generally assumed to be 5-mm thick. This model was widely adopted to study infiltration into sealed soils (Ahuja, 1983; Brakensiek and Rawls, 1983; Parlange et al., 1984; Vandevaere et al., 1998). Mualem and Assouline (1989) have proposed the model of a nonuniform layer where the bulk density, ρ_c , decreases exponentially with depth, h , to that of the undisturbed soil, ρ :

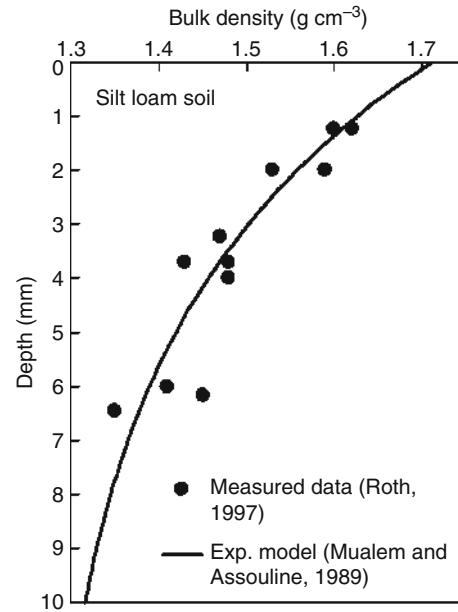

$$\rho_c(h) = \rho + \Delta\rho_o e^{-\gamma h}; \quad h = -Z \quad (1)$$

where Z is the elevation taken positive upward, $\Delta\rho_o$ is the maximum change in bulk density at the soil surface ($h = 0$), and γ is a characteristic parameter of the soil–rainfall interaction. This model was validated by the experimental results of Roth (1997), Bresson et al. (2004), and Augeard et al. (2008). Figure 1 depicts the distribution with depth of ρ_c measured by Roth (1997) in a crusted silt loam soil, and the fitted exponential model in Equation 1.

Formation of structural seals

During rainfall on a bare soil surface, transfer of kinetic energy from the raindrop to the surface and soil wetting occur simultaneously. Consequently, the processes involved in seal formation are (1) destruction of the soil aggregates exposed to the direct impact of the rain drops (Farres, 1978), (2) compaction (McIntyre, 1958a, b; Epstein and Grant, 1973; Bresson and Boiffin, 1990), (3) slaking (Moore, 1981b; Valentin and Ruiz Figueroa, 1987), (4) particle segregation (Eigel and Moore, 1983; Radcliffe et al., 1991), and (5) pore filling and clogging by wash-in of fine material (McIntyre, 1958a, b; Farres, 1978; Valentin and Bresson, 1992). Chemical dispersion resulting from the specific chemistry of the soil–rainfall system could play an additional significant role (Agassi et al., 1981). The relative importance of each of these processes depends upon the initial and boundary conditions that prevail during seal formation.

The study of seal formation addressed morphological aspects (Tackett and Pearson, 1965; Edwards and

Soil Surface Sealing and Crusting, Figure 1 Distribution with depth of ρ_c as measured by Roth (1997) in a crusted silt loam soil, and the fitted exponential model of Equation 1.

Larson, 1969; Farres, 1978; Bresson and Boiffin, 1990; Fohrer et al., 1999; Augeard et al., 2008) and impact on infiltration (Morin and Benyamin, 1977; Romkens et al., 1986; Baumhardt et al., 1990; Assouline and Mualem, 2000; 2001; Augeard et al., 2008). Modeling approaches for the different aspects of seal formation were suggested (Farres, 1978; Edwards and Larson, 1969; Baumhardt et al., 1990; Mualem et al., 1990b). In these models, the rainfall was represented by its duration, t (Moore, 1981b; Ahuja, 1983) or cumulative kinetic energy, E (Brakensiek and Rawls, 1983; Mualem et al., 1990b).

Assouline and Mualem (1997) proposed to model seal formation in terms of the temporal increase of the bulk density of the soil surface during the rainfall. This model relates the dynamics of the process to the initial soil mechanical and hydraulic properties as well as the physical characteristics of the regional rainfall. The bulk density increase at the soil surface, $\Delta\rho_o$, resulting from raindrop impact and wetting is related to rainfall intensity, I , and duration, t :

$$\Delta\rho_o(I, t) = \Delta\rho_o^*(1 - e^{-\xi t}) \quad (2)$$

where $\Delta\rho_o^*$ is the maximal change characterizing the final seal and the soil–rainfall characteristic, ξ , is defined by

$$\xi = \frac{6\omega kI}{d_{\max} \Delta\rho^* \tau(\rho_i, \psi_i)} \int_0^{d_{\max}} d^2 f(d, I) \delta d \quad (3)$$

where $f(d, I)$ is the raindrop size distribution, d_{\max} , the maximal drop diameter, k , a rainfall parameter

interrelating raindrop velocity and drop diameter d , ω , a fitting parameter, and $\tau(\rho_i, \psi_i)$, the initial soil shear strength. Figure 2 depicts the $\Delta\rho_o(t)$ relationship measured by Augeard et al. (2008) and the fitted dynamic model in Equations 2 and 3.

The theoretical analysis leading to Equation 3 indicated that rainfall cumulative kinetic energy, E , and intensity, I , determine the seal formation rate, in agreement with the result from the statistical analysis of Romkens et al. (1986).

Several physical, chemical, and mineralogical soil and rainfall properties were found to affect seal formation (Bradford and Huang, 1992; Shainberg, 1992). Rainfall intensity and kinetic energy were found to be decisive in determining the seal properties and the rate of seal formation (Morin and Benyamin, 1977; Romkens et al., 1986; Baumhardt et al., 1990). Soil properties affecting the cohesive power between the soil particles were found also to play a role in seal formation. These properties included soil mineralogy, texture, and structure (Mannering, 1967; Moldenhauer and Kemper, 1969; Farres, 1978; Tarchitzky et al., 1984; Freebairn et al., 1991; Bradford and Huang, 1993; Wakindiki and Ben-Hur, 2002); aggregate stability (Bryan, 1969; Le Bissonnais, 1996); initial bulk density and water content (Francis and Cruse, 1983; Luk, 1985; Le Bissonnais and Singer, 1992; Augeard et al., 2008); application of phosphogypsum or polymers to the upper soil layer (Helalia et al., 1988; Shainberg, 1992); slope (Poesen, 1987; Bradford and Huang, 1993; Fox et al., 1997); organic matter content (Le Bissonnais and Arrouays, 1997); soil exchangeable sodium percentage (ESP); and electrical conductivity (EC) of the applied water (Agassi et al., 1981; Hadas and Frenkel, 1982; Shainberg, 1992).

Effect of soil sealing on flow processes

The complexity of the soil-sealing phenomenon requires the use of physically based quantitative models to study the

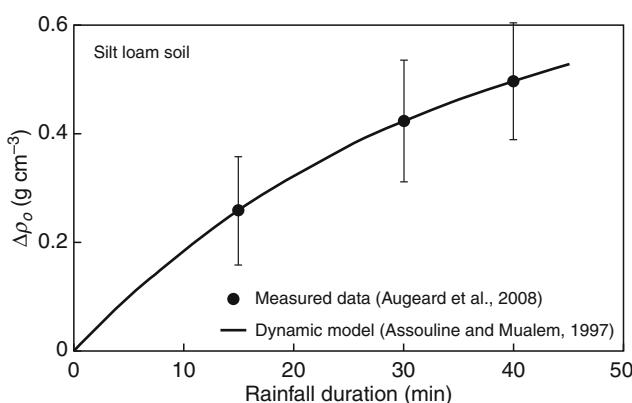

impact of seal formation on flow processes. Such models have to address two main aspects: the definition of the seal hydraulic properties and the simulation of the dynamics of seal formation.

The simplest model of the seal properties assumed a saturated soil layer with constant hydraulic conductivity and thickness (Hillel and Gardner, 1970; Ahuja and Swartzendruber, 1973). Although technically appropriate for simulating infiltration, it cannot simulate redistribution and drying processes, for which the entire hydraulic functions, i.e., water retention curve and hydraulic conductivity function, are needed. Approximated hydraulic properties were suggested by Moore (1981a), Philip (1998), Baumhardt et al. (1990), and Smith et al. (1999). Mualem and Assouline (1989) proposed a conceptual link between the hydraulic properties of the seal layer and those of the undisturbed seal underneath.

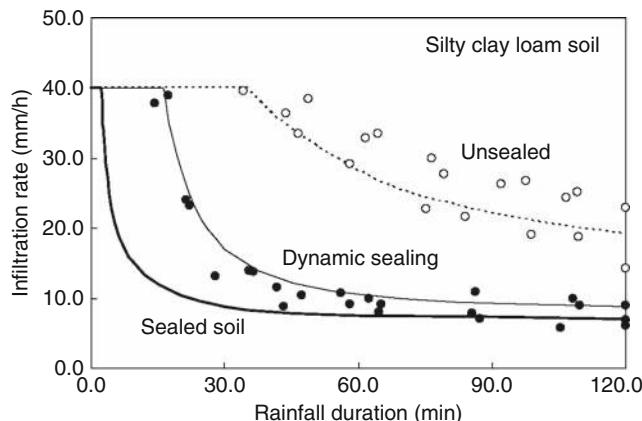

The first solution of infiltration into a sealed soil profile was proposed by Hillel and Gardner (1969, 1970), where the Green and Ampt (1911) approach was applied to a uniform soil profile capped with a saturated thin layer of low permeability and prescribed constant properties. This basic approach was adopted in a series of studies on infiltration through sealed soils with constant seal properties (Ahuja, 1983; Moore, 1981a; Parlange et al., 1984), or time-dependent ones (Farrell and Larson, 1972; Moore, 1981b; Ahuja, 1983; Brakensiek and Rawls, 1983; Vandevaere et al., 1998). The Green–Ampt approach was considered inappropriate to the simulation of infiltration into crusted soils sealed by Philip (1998), who preferred the flux-concentration method (Philip, 1973).

A different approach solving numerically the one-dimensional water flow equation was proposed by Baumhardt et al. (1990), Mualem et al. (1993), and Assouline and Mualem (1997). In these studies, the hydraulic properties of the seal layer are derived from the soil–rainfall system characteristics. This approach was extended to evaluate the combined effect of soil seal formation and areal heterogeneity of soil hydraulic properties on infiltration (Assouline and Mualem, 2002) and on runoff at the watershed scale (Assouline and Mualem, 2006). Figure 3 illustrates the effect of a completely formed seal and the effect of a seal under formation on infiltration compared to an undisturbed (mulched) soil for a constant rainfall intensity of 40 mm/h. The measured data were reported by Baumhardt (1985). The measured data were reported by Baumhardt (1985). The dashed curve results from the solution of the flow equations for the unsealed soil, the thin solid line corresponds to the calibrated dynamic model of Assouline and Mualem (1997), and the bold line is the predicted infiltration curve for a sealed soil profile following the model of Mualem and Assouline (1989).

Soil crusting affects also evaporation. Besides the fact that crust formation reduces water penetration and consequently, soil water content, it was shown to reduce evaporation directly (Bresler and Kemper, 1970; Jones et al., 1994). Assouline and Mualem (2003) have simulated the impact of constant evaporation on the water regime of

Soil Surface Sealing and Crusting, Figure 2 The change of ρ_c at the soil surface, $\Delta\rho_o$, during rainfall as measured by Augeard et al. (2008) and the fitted dynamic model of Assouline and Mualem (1997).

Soil Surface Sealing and Crusting, Figure 3 Infiltration through (1) a completely formed seal (bold line), (2) a seal under formation (thin solid line), and (3) an undisturbed silty clay loam soil (dashed line). The measured data (dots) are from Baumhardt (1985).

sealed soil profiles, showing that the sealed surface dries quicker than the undisturbed one, indicating that the seal surface acts as a barrier preventing further evaporation.

Summary

Bare soil surface can be prone to seal or crust formation. Different types of seals or crusts resulting from various processes are identified: structural seals resulting from high-intensity rainstorm; depositional seals or crusts resulting from the percolation of runoff water rich in suspended solids; post-fire crusts; biological or microbiotic crusts formed by nonvascular plants. Soil surface sealing can have severe agricultural, hydrological, and environmental effects. It decreases infiltration rate, reduces available water to plants, diminishes natural recharge of aquifers, increases runoff, and decreases crop yields. Seal formation is a complex phenomenon that involves several factors characterizing soil and rainfall physicochemical properties and flow initial and boundary conditions prevailing during the process. This entry presents the methodology applied to the investigation of rainfall-induced soil surface sealing, in terms of morphology, phenomenology, and modeling approaches to simulate the effect of on flow processes, as an illustrative case study of all the different seal types.

Particle size distribution

Definition

The percentage content of groups of particles with specific sizes in the soil is known as the *texture or the particle size distribution of the soil*. Soil texture determines the probability of finding a particle with a specific size in the set of all particles.

Introduction

The soil, also referred to as the pedosphere, is a natural formation of the upper layer of the earth crust, formed from weathered rock as a result of the effect of various factors changing over time (climate, biosphere, hydrosphere, relief, and human activity). The component elements of the soil are in the solid, liquid, and gaseous phases (see [Soil Phases](#)). The solid phase of the soil is made up mainly of mineral, organic, and organic-mineral particles with various degrees of fragmentation. The degree of their fragmentation has a significant effect on many of the properties of the soil. The percentage content of groups of particles with specific sizes in the soil is known as the texture or the particle size distribution of the soil. The size of soil particles and their packing affect the pore distribution (see [Pore Morphology and Soil Functions](#) and [Pore Size Distribution](#)) in the soil, and thus determine, among other things, the possibility of gas exchange (see [Aeration of Soils and Plants](#)), water retention, as well as the thermal and sorptive properties of the soil (see [Coupled Heat and Water Transfer in Soil](#)) and its content of mineral components. An important feature of the particle size distribution is its stability in time and relatively easy measurability, thanks to which it serves as a parameter for many models,

for example, for the estimation of water retention curves or hydraulic conductivity.

Sample dispersion

While analyzing the particle size distribution of soils, it should be kept in mind that it reflects the original properties of the soils only when the measurement is concerned with the “elementary” soil particles, that is, those properties that do not break up under the effect of various dispersing factors. Under natural conditions, every soil is characterized by specific aggregation; hence, for many years there has been a search for effective methods of soil sample dispersion in soil particle size distribution measurements. At present, the most frequently used methods of soil sample preparation for measurement include methods consisting in stirring, addition of suitable chemical agents, for example, calgon (solution of sodium hexametaphosphate and anhydrous sodium carbonate), or ultrasonic treatment (Day, 1965; Chappell, 1998; ISO 11277, 1998).

Mechanical methods

One of the oldest methods for the separation of substances with different particle sizes are the decantation and sieve methods, used already in the ancient Greece. However, documented sources give the year 1692 as the date of the first application of the decantation method for the separation of soil particles. It is accepted that the first described application of a sieve for the separation of sand fractions took place in 1704, while the term “mechanical analysis” itself was introduced in 1800 (Krumbein, 1932).

Sedimentation methods

Based on the fundamental laws of physics (and the Stokes law in particular), a succession of new methods for the determination of particle size distribution was created. Those methods can be classified into two categories – field and laboratory methods.

The sensory identification of soil type is highly useful in fieldwork when it is necessary to make an estimation of the content of particular soil particle fractions. The simplest of those is the so-called finger method, which permits the identification of soil composition on the basis of analysis of its behavior when rubbed between fingers in dry state, and after wetting. When analyzing a soil in the dry state, we estimate its coarseness or hardness and slipperiness. With wet soil, we can make an estimation of its viscosity, compaction, and capacity for rolling. Correct identification of soil type using the finger method requires a lot of experience. The method can only be used for preliminary classification of soils in field conditions.

The sieve method is used for the separation of the skeleton fractions (stones and gravel) from the earth fractions (sand, silt, and clay) of the soil, and for the determination of the coarser earth fractions. To be able to make comparison of results obtained with the sieve method one should

keep in mind that the result depends on the shape of apertures in the sieve; results obtained with sieves with square apertures will not be equivalent to results obtained with sieves with round holes. The probability of a particle passing through a given sieve during a given time of screening will depend both on the properties of the particle and on those of the sieve, as well as on the distribution of sizes and the number of particles on the sieve, on the physical properties of the particles (shape and type of surface), and on the method of sieve shaking. Analysis performed with the help of sieves consists in the selection of a suitable set of sieves. A specific weight of a soil sample is placed on the upper sieve, and then, after covering the upper sieve, the whole set of sieves is placed on the shaker. When the screening is over, the particles remaining on each of the sieves are weighed, and on this basis, the percentage share of a given fraction is determined as the ratio of the weight of the particles that remained on a given sieve to the weight of the whole soil sample.

The sedimentation methods are based on measurement of the settlement rate of soil particles in a water suspension. The basis for the sedimentation methods is the fact of balancing of forces acting on a particle suspended in a liquid, which causes it to settle to the bottom in a uniform motion. The forces that act on the particle are the following – the downward force of gravity F_g , the upward force of buoyant force F_w (resulting from the Archimedes law), and the force of friction F_t (resulting from the viscosity of the medium, expressed by the Stokes law). In measurements based on the sedimentation methods, the following assumptions are made:

- (a) The soil particles are hard and smooth spheres
- (b) The suspension has a Reynolds number below ca. 0.2, that is, it is a liquid in which particles settle with a laminar motion.
- (c) Soil particles in the suspension are at such a rate of dilution that none of them disturbs the settlement of any other.
- (d) There are no interactions between the particles and the liquid.
- (e) The diameter of the suspension column compared to particle diameter is large, that is, the fluid volume is “infinitely great.”
- (f) The soil particles have attained the terminal velocity.
- (g) The soil particles have the same specific density.

The most frequently applied sedimentation methods include the pipette method and the hydrometric method (in Poland, the latter method is mainly used in the Prószyński modification).

The pipette method consists in using a pipette to take a specific volume of water suspension of a soil. Samples are taken after a specific time from suspension stirring, at a specific depth, and using a pipette with known volume. Next, the samples taken are evaporated and dried to constant weight. Based on the sample weight after drying, the content of particles with a given diameter in the whole soil sample is determined (ISO 11277, 1998).

Another sedimentation method is the Casagrande hydrometer method (Day, 1965). In its classical form, the method consists in using a hydrometer to measure the density of water suspension of a soil at time intervals at which soil particle fractions with specific decreasing diameters settle at the bottom of the measurement cylinder. Obtaining results of measurements taken with the hydrometric method required the plotting of many graphs and making prior calculations. The modification of the method developed by Prószyński (Mocek et al., 2000) consisted in the application of a hydrometer of his own design and in the development of sedimentation tables, which permits direct determination of the percentage share of particles remaining in the suspension at the moment of measurement. Determination of particle size distribution with the Casagrande method in Prószyński modification (Mocek et al., 2000) requires a preliminary measurement to be made after ca. 10 min from the stirring of the suspension. That measurement permits the determination of approximate content of the fraction of <0.02 mm, and thus permits the selection of a suitable sedimentation table from which, depending on the ambient temperature, times are taken after which a reading should be taken on the hydrometer so as to calculate the content of a given fraction of particles in the soil tested (Mocek et al., 2000).

As in any other measurement, so also in the case of the sedimentation methods, one should remember the sources of uncertainty. One of the more important sources is the observed fact that thin blade-shaped particles settle much more slowly than the equivalent spheres adopted for them, which causes the obtainment of overestimated measurement results for such particles. In turn, for particles whose equivalent sphere diameter is less than 1 μm , the cause of measurement errors may be attributed to Brownian motions interfering with particles settling under the effect of gravity (Allen et al., 1996).

The standard ISO 11277 recommends that determinations of particle size distribution for air-dry soil samples can be done using the sieve–pipette method. Such an analysis should be performed as follows: particles that do not pass through sieve with 2-mm mesh are to be determined with the dry sieving method; particles passing through a 2-mm mesh sieve and retained on a sieve with mesh diameter of 0.063 mm are to be determined with the wet sieving method, while particles that have passed through the last sieve are to be determined with the sedimentation (pipette) method.

Laser diffraction method

A method that recently found an application in soil science is the laser diffraction method (Buurman et al., 1997). Diffraction is a phenomenon consisting in light being deflected when passing close to an obstacle, such as the edge of a slot. Diffraction takes place when the head of a light wave is partially stopped by an opaque object. Such a nontransparent object may be a particle that happens to be in the way of a light beam. Falling on that

particle the light beam is deflected. Measuring the angle of the deflection and the intensity of the deflected light we can obtain information about the size of the particle that caused the diffraction. The angle at which the laser light beam becomes deflected/scattered on the particle is inversely proportional to the particle size. Small particles deflect/scatter light at large angles, while large particles do so at small angles. Based on the angles of deflection/scattering of laser light beam calculation of particle sizes is made on the basis of the Fraunhofer or Mie theories. Contemporary apparatus for the determination of particle size distribution with the method commonly referred to as the laser diffraction method take into account four types of interactions between the electromagnetic wave (laser light) and the particle (ISO 13320, 1999), and namely:

- (a) Diffraction on the outer surface (contour) of the particle – Fraunhofer diffraction,
- (b) Reflection from particle surface (internal as well as external),
- (c) Refraction of laser light at the medium-particle and particle medium phase interface,
- (d) Absorption within the particle.

It takes two steps to obtain information about particle size distribution on the basis of analysis of deflected/scattered light falling onto detectors. The first step is the choice of mathematical model describing light deflection/scattering by the particles (the choice is between two possibilities – the Fraunhofer approximation and the Mie theory). The second step is to convert the information from the angular distribution of intensity of deflected/scattered light onto the size distribution of particles under analysis in accordance with the selected mathematical model. This step is realized automatically by the software supplied by the manufacturer of the apparatus. The growth of the computing power of computers that took place over the recent years permitted the application of the Mie theory for the determination of particle size distribution, as the Mie theory requires the solution of significantly more complex equations. The Mie theory treats the electromagnetic field in the space surrounding the particle as a superposition of the falling field and the scattered field.

The application of the Mie theory for the determination of particle size distribution requires the definition of the optical parameters of the particles, that is, the coefficient of light refraction and the coefficient of light absorption.

The Mie theory is recommended for the determination of size distribution of particles with dimensions below 25 μm in accordance with standard ISO 13320. However, application of the Mie theory with relation to a nonhomogeneous material such as soil, whose optical properties (refraction and absorption coefficients) for various particles are different, causes that it is hard to assume in prior which theory will be better. Especially as the determination of the optical parameters of the material studied may not only be costly and time consuming, but may also constitute a significant source of uncertainty in the determination of particle size distribution. All these inferences may lead to a situation

when the theoretically less precise Fraunhofer theory may have a better practical application for soil material, even taking into account the presence of smaller particles in the sample (Loizeau et al., 1994).

Summary
