ENCYCLOPEDIA OF AGROPHYSICS

About the Editors:

Em. Prof. Jan Gliński, soil scientist, is a full member of the Polish Academy of Sciences. He was Director of the Institute of Agrophysics in Lublin from 1982 to 2003. He was one of the initiators and an active promoter of scientific cooperation between many universities and institutes in Poland and abroad, and organized many international conferences on agrophysics. He has been a member of the ISSS since 1961 and was vice-chairman of the Commission I (Soil Physics) of the ISSS in the period 1986–1990. He is the author or co-author of numerous papers, books, monographs, patents and multilingual dictionaries in the field of agrophysics. He participated actively in eight World ISSS Congresses (1960, 1964, 1974, 1978, 1986, 1990, 1994, and 1998). He serves as the Editor-in-Chief of the journal International Agrophysics (since 1992).

Józef Horabik is Director of the Institute of Agrophysics, Polish Academy of Sciences, in Lublin, Poland. He holds a M.Sc. degree in physics, a Ph.D. in agricultural engineering, and is a professor of Agronomy. He is the Editor-in-Chief of Acta Agrophysica, an Associate Editor of International Agrophysics, and a member of the Editorial Board of the Polish Journal of Soil Science. He works together with over 20 scientific institutions in Poland and abroad. Over 260 scientific publications have been published to which he has contributed. His scientific interests are: applied physics, agrophysics, physical properties of agromaterials, modelling of mechanics of granular solids and food powders.

Jerzy Lipiec is a Professor of Soil Science and Plant Relations at the Institute of Agrophysics of the Polish Academy of Sciences in Lublin, Poland. He received his M.Sc. (1969), Ph.D. (1977) and D.Sc. (1983) in Soil Science from the Agricultural University of Lublin. He contributed widely in research activities in various European countries, Japan, US and international projects. He serves on the advisory boards of several scientific journals and has published over 250 scientific papers. He is author or co-author of several chapters in books, including works as *Soil Physical Conditions and Plant Roots* (CRC Press).

Aims of the Series

The *Encyclopedia of Earth Sciences Series* provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists.

These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students. See the dust jacket of this volume for a current list of titles in the *Encyclopedia of Earth Sciences Series*. Go to <http://www.springerlink.com/reference-works/> to visit the "Earth Sciences Series" on-line.

About the Series Editor

Professor Charles W. Finkl has edited and/or contributed to more than eight volumes in the Encyclopedia of Earth Sciences Series. For the past 25 years he has been the Executive Director of the Coastal Education & Research Foundation and Editor-in-Chief of the international *Journal of Coastal Research*. In addition to these duties, he is Research Professor at Florida Atlantic University in Boca Raton, Florida, USA. He is a graduate of the University of Western Australia (Perth) and previously worked for a wholly owned Australian subsidiary of the International Nickel Company of Canada (INCO). During his career, he acquired field experience in Australia; the Caribbean; South America; SW Pacific islands; southern Africa; Western Europe; and the Pacific Northwest, Midwest, and Southeast USA.

Founding Series Editor

Professor Rhodes W. Fairbridge (deceased) has edited more than 24 Encyclopedias in the Earth Sciences Series. During his career he has worked as a petroleum geologist in the Middle East, been a WW II intelligence officer in the SW Pacific and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil and New Guinea. He was Emeritus Professor of Geology at Columbia University and was affiliated with the Goddard Institute for Space Studies.

Contents

Contributors	xxi	After Harvest Technology	14
Preface	xlv	Aggregate Stability	14
Absorption	1	Aggregation Indices	14
Absorptivity	1	Agricultural Products	14
Acoustic Emission	1	Agricultural Raw Materials	14
Acoustic Tomography	1	Agriculture and Food Machinery, Application of Physics for Improving	14
Adaptable Tillage	1	<i>Leszek Mieszkalski</i>	
Adhesion	1	Agroforestry Systems, Effects on Water Balance in Cropping Zone	26
Adsorption	1	<i>Andrzej Kędziora</i>	
Adsorption Complex	2	Agrogeology <i>Ward Chesworth</i>	29
Adsorption Energy and Surface Heterogeneity in Soils	2	Agrophysical Objects (Soils, Plants, Agricultural Products, and Foods)	34
<i>Zofia Sokołowska and Stefan Sokołowski</i>		<i>Jan Gliński</i>	
Adsorption Energy of Water on Biological Materials	5	Agrophysical Properties and Processes	35
<i>Jiří Bláhovec</i>		<i>Jan Gliński, Józef Horabik and Jerzy Lipiec</i>	
Advection	7	Agrophysics: Physics Applied to Agriculture	35
Aeration of Agricultural Products	7	<i>Jan Gliński, Józef Horabik and Jerzy Lipiec</i>	
<i>Marek Molenda</i>		Air Entry Value	48
Aeration of Soils and Plants	8	Air Flux (Resistance) in Plants and Agricultural Products	48
<i>Witold Stępniewski</i>		<i>Agnieszka Kaleta and Krzysztof Górnicki</i>	
Aerodynamics	13		

vi	CONTENTS		
Air Humidity	49	Biofilms in Soil <i>Mette Burmølle, Annelise Kjøller and Søren J. Sørensen</i>	70
Air Porosity	49		
Algae, the Potential Source of Energy <i>Magdalena Frąc</i>	49	Biofilms in the Food Environment <i>Katarzyna Czaczyk and Kamila Myszka</i>	75
Alkalinity, Physical Effects on Soils <i>Lajos Blaskó</i>	49	Biogas	78
Alternative Sources of Energy from Agriculture Biomass – A European Perspective <i>Piotr Kowalik</i>	52	Biomass	78
Alumino-Silicate Clay Minerals	55	Biomass as an Environmentally Benign Energy Source <i>Keith Openshaw</i>	78
Anaerobiosis	55	Biomechanics	88
Angle of Repose	55	Biomes	88
Anion Exchange Capacity	55	Biospeckle <i>Artur Zdunek</i>	88
Anisotropy of Soil Physical Properties <i>Xinhua Peng</i>	55	Biota	89
Anoxia and Hypoxia	57	Biotechnology, Physical and Chemical Aspects <i>Zdzisław Targoński</i>	89
Anthric Saturation	57	Bound Water	90
Arable Land Use	57	Boussinesq Equation	90
Attenuation	57	Bowen Ratio	91
Atterberg Limits	57	Bragg's Law	91
Available Water (Capacity)	57	Breads: Physical Properties <i>Renata Różyło and Janusz Laskowski</i>	91
Backscattering <i>Bogusław Usowicz</i>	59	Brightness Temperature in Monitoring of Soil Wetness <i>Jerzy Usowicz</i>	93
Bedrock	60	Bruise	94
Bending Properties of Plants <i>Jiří Blahovec</i>	60	Buffer Capacity of Soils <i>Mieczysław Hajnos</i>	94
Bernoulli's Principal	62	Bulk Density of Soils and Impact on Their Hydraulic Properties <i>Shmuel Assouline</i>	95
Binding Force (Plants)	62	Burrow	100
Biochemical Responses to Soil Management Practices <i>Jan Koper and Małgorzata Brzezińska</i>	62	Bypass Flow in Soil <i>Horst H. Gerke</i>	100
Biocolloids: Transport and Retention in Soils <i>Tammo S. Steenhuis, Verónica L. Morales, M. Ekrem Cakmak, Anthony E. Salvucci and Wei Zhang</i>	66		

	CONTENTS	vii	
Caking	107	Coagulation	138
Caliche (Lime-Pan)	107	Cohesion	138
Canopy Structure	107	Colloids	138
Capillarity	107	Color Composite (Multiband Photography)	138
Capillary Fringe	107	Color in Food Evaluation <i>Seong Pal Kang</i>	138
Carbon Losses Under Dryland Conditions, Tillage Effects <i>Félix Moreno, José M. Murillo and Engracia Madejón</i>	108	Color Indices, Relationship with Soil Characteristics <i>Manuel Sánchez-Marañón</i>	141
Carbon Nanotube	110	Compactibility	145
Catchment (Catchment Basin)	110	Compaction of Soil	145
Cation Exchange Capacity	110	Compensatory Uptake	145
Cementation	110	Compressibility	145
Cereals, Evaluation of Utility Values <i>Dariusz Dziki and Janusz Laskowski</i>	110	Compression Index	145
Chemical Imaging in Agriculture <i>Adam Paweł Kuczyński</i>	113	Compression Point	145
Chemical Time Bomb, Relation to Soil Physical Conditions <i>Halina Smal</i>	116	Compression Test, Triaxial Conditioners, Effect on Soil Physical Properties <i>Ryszard Dębicki</i>	145
Chisel	117	Conductivity	148
Clay Minerals and Organo-Mineral Associates <i>Tatiana Victorovna Alekseeva</i>	117	Cone Index	148
Claypan and its Environmental Effects <i>Stephen H. Anderson</i>	122	Confined Compression Test	148
Cleavage Plane	125	Consistency	148
Climate Change: Environmental Effects <i>Miroslav Kutilek</i>	125	Consolidation	148
Climate Risk	135	Contact Area of Agricultural Tyres, Estimation <i>Etienne Diserens and Abdallah Alaoui</i>	148
Climate Stress Mitigation Tillage	135	Continuity Equation	153
Clod	135	Contour-Furrow Irrigation	153
Clusters in Soils <i>David L. Pinskiy</i>	135	Controlled Traffic Farming <i>Thomas Anken and Martin Holpp</i>	153
	135	Conventional Tillage	155
	135	Coulomb's Law	155

viii	CONTENTS	
Coupled Heat and Water Transfer in Soil <i>Joshua L. Heitman and Robert Horton</i>	155	Denitrification 200
Cracking in Soils <i>Pascal Boivin</i>	162	Density 200
Crop Emergence, the Impact of Mechanical Impedance <i>W. R. Whalley and W. E. Finch-Savage</i>	163	Desertification: Indicators and Thresholds 200 <i>Max Kuderna and Adam Zsolnay</i>
Crop Responses to Soil Physical Conditions <i>Jerzy Lipiec, Artur Nosalewicz and Jacek Pietrusiewicz</i>	167	Detachment 207
Crop Rotation	176	Deterministic Model 207
Crop Water Use Efficiency	176	Dew Point 207
Crop Yield Losses Reduction at Harvest, from Research to Adoption <i>Bogusław Szot, Mieczysław Szpryngiel and Jerzy Tys</i>	176	Dielectric Loss Tangent 207
Cropping Systems, Effects on Soil Physical Properties <i>Stephen H. Anderson</i>	180	Dielectric Properties of Agricultural Products 207 <i>Stuart O. Nelson and Samir Trabelsi</i>
Crushing Strength	184	Diffuse Double Layer (DDL) 213 <i>Md. Abdul Mojid</i>
Crust	184	Diffusion in Soils 214 <i>Witold Stępniewski, Henryk Sobczuk and Marcin Widomski</i>
Cultivation Under Screens, Aerodynamics of Boundary Layers <i>Josef Tanny</i>	185	Dilatancy 220
Cumulative Infiltration	187	Discharge 220
Cutan	187	Dispersion 220
Cyclic Compressibility	187	Dispersivity 220
Darcy's Law	189	Diurnal Strains in Plants 220 <i>Pawel Kojas and Tomasz Rusin</i>
Databases on Physical Properties of Plants and Agricultural Products <i>Agnieszka Kaleta and Krzysztof Górnicki</i>	189	DNA in Soils: Mobility by Capillarity 224 <i>Maria Teresa Ceccherini and Giacomo Pietramellara</i>
Databases of Soil Physical and Hydraulic Properties <i>Attila Nemes</i>	194	Double Layer 228
Deflation	200	Drainage 228
Deflocculation	194	Drip Irrigation 228
Degradation of Soil	200	Drought 228
	200	Drought Stress, Effect on Soil Mechanical Impedance and Root (Crop) Growth 228 <i>W. R. Whalley and L. J. Clark</i>
	200	Drying of Agricultural Products 231 <i>Digvir S. Jayas and Chandra B. Singh</i>
	200	Duripan 232

	CONTENTS	ix
Dynamic Load	232	Empirical Model
Earthworms as Ecosystem Engineers <i>Patrick Lavelle</i>	233	Energetically Homogenous (Heterogenous) Surface
Ecohydrology <i>Maciej Zalewski</i>	235	Energy Balance of Ecosystems <i>Andrzej Kędziora</i>
Ecosystem	237	Energy Balance of a Field
Effective Rainfall	237	Enthalpy
Elasticity	237	Entropy
Elastoplasticity	237	Environmental Conserving Tillage
Electrical Conductivity	237	Enzyme
Electrical Double Layer (Diffuse Layer, Double Layer)	237	Enzymes in Soils <i>Małgorzata Brzezińska</i>
Electrical Permeability	237	Erodibility of Soil
Electrical Properties of Agricultural Products <i>Zuzana Hlaváčová</i>	237	Erosion
Electrical Properties of Soils <i>Shmulik P. Friedman</i>	242	Erosivity
Electrical Resistivity	255	Estimation of Quartz Content in Mineral Soils <i>Vlodek R. Tarnawski, Toshihiko Momose, Wey H. Leong and David J. W. Piper</i>
Electrical Resistivity to Assess Soil Properties <i>Guy Richard, Maud Séger, Arlène Besson and Isabelle Cousin</i>	256	Evaporation
Electrical Susceptibility	260	Evapotranspiration
Electrochemical Measurements in Soils <i>Andrzej Bieganowski and Jolanta Cieśla</i>	260	<i>Viliam Novák</i>
Electrokinetic (Zeta) Potential of Soils <i>Mieczysław Hajnos and Jolanta Cieśla</i>	264	Exchange Complex
Electromagnetic Field	267	Exchangeable Ions
Electromagnetic Fields, Impact on Seed Germination and Plant Growth <i>Stanisław Pietruszewski</i>	267	Extrusion, Effect on Physical and Chemical Properties <i>Leszek Mościcki</i>
Elutriation	269	Exudate, Root
Eluviation	270	Fabric
Emissivity	270	Failure
		Fatigue Strength
		Fats: Rheological Characteristics <i>Fernanda Peyronel, Thamara Laredo and Alejandro G. Marangoni</i>

x	CONTENTS	
Fertilizers (Mineral, Organic), Effect on Soil Physical Properties <i>Kuntal Hati and Kalikinkar Bandyopadhyay</i>	296	Funnel Flow 321 Furrow 321
Fick's Law	299	Furrow Erosion 321
Field Water Capacity <i>Karl Vanderlinden and Juan V. Giráldez</i>	299	Furrow Irrigation 321 Gas Exchange In Soils 323
Fingering	300	Gases Sink 323
Firmness	300	Geologic Erosion 323
Fissures	300	Geostatistics 323
Flexural Strength	301	Gibbs Free Energy 323
Flocculation and Dispersion Phenomena in Soils <i>Emil Chibowski</i>	301	Grain Physics 323 <i>Stanisław Gründas, Agnieszka Nawrocka and Josef Pecen</i>
Flooding, Effects on Soil Structure <i>Miguel A. Taboada, Patricia L. Fernández and María F. Varela</i>	304	Grains, Aerodynamic and Geometric Features 327 <i>Bronisława Barbara Kram</i>
Flow	308	Grass Fibers, Physical Properties 333 <i>Majda Sfiligoj Smole and Silvo Hribenik</i>
Flowability	308	Gravimetric Water Content 334
Fluvial Erosion	308	Gravitational Potential 334
Flux	308	Gravity Head (Gravity Potential) 334
Food Freezing	308	Grazing-Induced Changes of Soil Mechanical and Hydraulic Properties 334 <i>Julia Krümmelbein</i>
Food Machinery	308	Greenhouse, Climate Control 338 <i>Istvan Farkas</i>
Fourier's Law	308	Greenhouse Effect 339
Fractal Analysis in Agrophysics <i>Yakov Pachepsky, Fernando San José Martínez and Miguel Angel Martin</i>	309	Greenhouse Gas Fluxes: Effects of Physical Conditions 339 <i>Ryusuke Hatano</i>
Fracture	315	Greenhouse Gases Sink in Soils 351 <i>Teresa Włodarczyk</i>
Fragipan	315	Ground-Penetrating Radar, Soil Exploration 354 <i>Jim Doolittle</i>
Friction	316	Groundwater 355
Friction Phenomena in Soils <i>Rainer Horn</i>	316	Gully (Linear) Erosion 355
Frozen Foods	318	Hardening 357
Fruits, Mechanical Properties and Bruise Susceptibility <i>Margarita Ruiz-Altisent and Guillermo P. Moreira</i>	318	

CONTENTS			xi
Hardpan	357	Hydrophobicity of Soil <i>Paul D. Hallett, Jörg Bachmann, Henryk Czachor, Emilia Urbanek and Bin Zhang</i>	378
Hardpan Soils: Management <i>Warren J. Busscher</i>	357	Hypobaric Storage	384
Hardsetting Soils: Physical Properties <i>Neyde Fabíola Balarezo Giarola, Herdjania Veras de Lima and Alvaro Pires da Silva</i>	360	Hysteresis in Foods <i>Matthew Caurie</i>	384
Harvest Technology	364	Hysteresis in Soil <i>Cezary Ślawiński</i>	385
Heat Advection	364	Ice Erosion (Glacial Erosion, Thermal Erosion)	387
Heat Balance	364	Illuviation	387
Heat Capacity	364	Image Analysis in Agrophysics <i>Magnus Persson</i>	387
Heat Diffusion	364	Imbibition	390
Heat of Condensation	364	Indicator Plants	390

Preface

Agrophysics is the science that studies physical processes and properties affecting plant production. The fundaments of agrophysical investigations are mass (water, air, nutrients) and energy (light, heat) transport in the soil–plant–atmosphere and soil–plant–machine–agricultural products–foods continuums and way of their regulation to acquire biomass of high quantity and quality with sustainability to the environment. Agrophysics has been developing dynamically over the past decades, filling the gap between disciplines like agrochemistry, agrobiology, agroecology, agroclimatology and linking them together. Unlike physics of individual objects like soils, plants, agricultural products and food, agrophysics provides a physical basis to better understand interrelations between the objects.

Understanding physical processes in the agrophysical objects is a pre-requisite for applying new technologies in sustainable land use and environment management, and in the production of healthy agricultural products and food. The recognition of physical phenomena in the agricultural environment allows more efficient use of water and chemicals in agriculture and decreasing biomass losses during harvest, transport, storage and processing. These result in a growing interest in the application of physics for improving the quality of the above mentioned objects. It is therefore considered timely to produce a key resource across the discipline providing a clear explanation of present knowledge in modern agrophysics interfacing with the physical sciences and environmental and food sciences.

The roots of agrophysics are based in Saint Petersburg (Russia) where A.F. Ioffe (1880–1960) founded the principles of a new branch of natural and agricultural sciences and was the founder in 1932 of the Institute of Physics and Agriculture, later called the Institute of Agrophysics. Subsequently, the Institute of Agrophysics of the Polish Academy of Sciences was created in 1968 in Lublin (Poland)

by B. Dobrzański (1908–1987), whose idea was to extend the application of physics not only to soils, but also to agricultural plants and products. Initially the Institute played an important role in the coordination of agrophysical research in Poland and in European countries, and later the cooperation was broadened to numerous scientific institutions worldwide.

The *Encyclopedia of Agrophysics* has been written to portray the agrophysical objects in terms of physical processes and physical properties characterising them. Interactions between the objects are also included. As agrophysical issues become more and more complicated, so will the knowledge and vocabulary required for their clear understanding, discussion and study be extended. Due to the dynamic and rapid growth of agrophysical knowledge, the Encyclopedia considers many new research methods and terms that did not even exist a decade ago.

The Encyclopedia can be helpful in evaluating and improving the quality of soils and agricultural products as well as the technological processes. Moreover, agrophysical terminology can be applied to soil science, agronomy, biophysics, agroecology, agricultural engineering, horticulture, plant science, food science, environmental science, landscape ecology and geography, and thereby it can help collaboration and the flow of information between the disciplines. The Encyclopedia can serve as a reference document for researchers, students of various levels, librarians, policy- and decision-makers, and interested societies working and studying in a range of disciplines related to agrophysics.

The *Encyclopedia of Agrophysics* encloses 261 articles and 400 glossary terms that are arranged in alphabetical order. Each article includes “cross-references” that direct the reader to one or more other articles that may shed more light on the topic.

The *Encyclopedia of Agrophysics* is a result of the efforts of many contributors from throughout the world.

The Editors are very obliged to all Authors who kindly accepted the invitation to contribute and who have inspired the Encyclopedia with their informative contributions.

We appreciate the assistance of the many friends and colleagues who have suggested new issues and terms, helped with definitions as well as provided valuable criticism. Particular thanks go to the Editorial Board of the Encyclopedia and to the anonymous reviewers for many helpful

advice and comments. We are indebted to the Publishing Editors of Springer for many suggestions and kind cooperation.

Józef Horabik
Jerzy Lipiec
(Editors-in-Chief)

A

ABSORPTION

The process by which one substance, such as solid or liquid, takes up another substance, such as liquid or gas, through minute pores or spaces between its molecules. Clay minerals can take water and ions by absorption.

ABSORPTIVITY

Absorbed part of incoming radiation/total incoming radiation.

ACOUSTIC EMISSION

The phenomenon of transient elastic-wave generation due to a rapid release of strain energy caused by a structural alteration in a solid material. Also known as stress-wave emission.

Bibliography

McGraw-Hill Dictionary of Scientific & Technical Terms, 6E,
Copyright © 2003 by The McGraw-Hill Companies, Inc.

ACOUSTIC TOMOGRAPHY

A form of tomography in which information is collected from beams of acoustic radiation that have passed through an object (e.g., soil). One can speak of thermo-acoustic tomography when the heating is realized by means of microwaves, and of photo-acoustic tomography when optical heating is used.

Cross-references

ADAPTABLE TILLAGE

See [Tillage, Impacts on Soil and Environment](#)

ADHESION

The attraction between different substances, acting at surfaces of contact between the substances e.g., water and solid, water films and organo-mineral surfaces, soil and the metal cutting surface.

ADSORPTION

A phenomenon occurring at the boundary between phases, where cohesive and adhesive forces cause the concentration or density of a substance to be greater or smaller than in the interior of the separate phases.

Generalities

The potential energy of interaction of a single adsorbate molecule with a solid adsorbent can be described by the function $U(R)$, where $\{R\}$ is a set of coordinates necessary to define the position of the adsorbate molecule. Assuming that the adsorbate molecule is a sphere of diameter σ , its position is given by the Cartesian coordinates of its center, $R = r = (x, y, z)$. For molecules composed of several atoms, one needs to specify a multidimensional vector $\{R\}$ that determines the coordinates of all the atoms (or groups of atoms) building a given molecule. Formally, according to the classical statistical thermodynamics $U(R)$ is the sum of the interactions of N_a interaction centers located within a given adsorbate molecule, with N_s interaction centers located within a solid,

$$U(R) = \sum_{i \in N_s} \sum_{j \in N_a} u(r_{ij}), \quad (1)$$

where r_{ij} is the distance between the interacting centers. Of course, when quantum-mechanical treatment is employed, $U(R)$ is the difference of ground state energies between the molecule at the position $\{R\}$ and the ground state of a separated molecule.

For a selected adsorbate molecule, say a spherical molecule, the potential $U(r)$ can be used to characterize the surface. For a given set of coordinates x, y in the plane parallel (or tangential) to the solid the minimum of the function $U(r)$ with respect to the third coordinate, z , is often called “the adsorption energy,” ε_{ad} . If ε_{ad} is independent of x, y , the corresponding surface is energetically uniform (or homogeneous). For crystalline surfaces ε_{ad} (and, of course, $U(r)$) is a periodic function of x, y . However, there exists a variety of surfaces that are neither uniform nor crystalline. In those cases, $\varepsilon_{ad}(x, y)$ may vary in a quite complicated manner with x, y and we call such surfaces energetically heterogeneous.

Energetically heterogeneous surfaces can be next classified into several groups, among which we can distinguish patchwise and random surfaces. In the case of random surfaces $\varepsilon_{ad}(x, y)$ varies quite randomly with x, y ; for patchwise surfaces $\varepsilon_{ad}(x, y) = \text{constant}$ for x, y within consecutive regions Δ_i . Both random and patchwise surfaces are two limiting cases of surface topography that is defined by spatial correlations between the points x_i, y_i with given values of the energy $\varepsilon_{ad,i}$. We can distinguish correlations between pairs of sites, triples of sites, and so on (Bulnes et al., 2001).

The variation of the energy of adsorption results from several factors: the presence of different atoms or groups of atoms on the surface; geometrical irregularities including the presence of pores of different shape and dimensions, and so on. Of course, geometrical and energetic nonuniformities are correlated and the former is one of principal sources of energetic heterogeneity. Moreover, a given adsorbent may be a quite complex mixture of several interacting chemical species. Both energetic and geometric heterogeneities have a great impact on the adsorption process.

Description of adsorption on energetically heterogeneous surfaces

Accurate modeling adsorption on geometrically nonuniform surfaces is difficult and only in some cases it is possible to construct an adequate model for a solid. When it is possible, then computer simulations can be employed. However, the structure of great majority of environmental adsorbents, and soils in particular (see [Clay Minerals and Organo-Mineral Associates](#); [Organic Matter, Effects on Soil Physical Properties and Processes](#); [Parent Material and Soil Physical Properties](#); [Soil Phases](#)) is extremely complex due to diversified mineral, organic, and ionic composition. Therefore, the application of approximate approaches is necessary. The most widely used methods are based on the so-called integral adsorption isotherm equation.

Suppose we know the function $\theta_l(p, \varepsilon)$ that describes the isotherm (surface coverage) on a uniform surface with the adsorption energy ε . Then, the isotherm on a heterogeneous surface can be approximated as

$$\theta(p) = N_m \int_{\varepsilon_{min}}^{\varepsilon_{max}} \theta_l(p, \varepsilon) \chi(\varepsilon) d\varepsilon, \quad (2)$$

where p is the pressure, $\theta(p, \varepsilon)$ is the global (measured) adsorption isotherm, N_m is the monolayer capacity, and $\chi(\varepsilon)$ is the energy distribution function that yields a fraction of the surface characterized by the adsorption energy ε . The latter function satisfies the normalization condition

$$\int_{\varepsilon_{min}}^{\varepsilon_{max}} d\varepsilon = 1, \quad (3)$$

where $[\varepsilon_{min}, \varepsilon_{max}]$ are the lower and upper integration limits. In many cases, these limits are assumed to be $[\varepsilon_0, \infty)$, where ε_0 is the liquefaction energy of the adsorbate. [Equation 2](#) states that the total adsorption is just a weighted average of the isotherms on model, homogeneous surfaces, characterized by different values of ε . However, it means that the adsorption on each homogeneous surface occurs independently of the adsorption on other surfaces. The last assumption is satisfied only for a patchwise topography, or when the interactions between adsorbed particles are negligibly small. Despite of the above quoted limitations, [Equation 2](#) has been widely used to describe adsorption on heterogeneous surfaces. Note that a quite similar approach is usually used to describe adsorption by porous solids. In the latter case, the weight function is just the pore size distribution function.

If the local adsorption isotherm and the energy distribution function are given by analytical expressions, [Equation 2](#) can be integrated to yield an equation for the total adsorption isotherm. For example, if the local isotherm is just given by the Langmuir equation, $\theta_l(p, \varepsilon) = pK(\varepsilon)/[1 + pK(\varepsilon)]$, where $K(\varepsilon) = K_0 \exp[-\varepsilon/kT]$, k is the Boltzmann constant, T is the temperature, and K_0 is a constant, then one can show that the Temkin isotherm, $\theta(p) = \ln(1 + Kp)^\gamma$, corresponds to a constant energy distribution function; the Freundlich isotherm is associated with an exponential distribution and the Langmuir–Freundlich isotherm, $\theta(p) = Cp^\gamma/[1 + Cp^\gamma]$ – with a quasi-Gaussian distribution (Xia et al., 2006). In the above C , K and γ are constants. Numerous analytical expressions for the total adsorption isotherms obtained from [Equation 2](#) can be found in the monographs of Rudziński and Everett (1992) and Jaroniec and Madey (1988).

The above method of derivation of isotherm equations can be also extended to the case of a multilayer adsorption. The multilayer local adsorption isotherm on a homogeneous surface can be described by the Brunauer, Emmet and Teller (BET) equation (Brunauer et al., 1938)

$$\theta_l(p, \varepsilon) = \frac{1}{1 - x} \frac{c(\varepsilon)x}{1 + [c(\varepsilon) - 1]x}, \quad (4)$$

where $x = p/p_s$ is the relative vapor pressure, p_s is the saturated vapor pressure, and $c(\varepsilon) = \exp[-(\varepsilon - \varepsilon_0)/kT]$. For a quasi-Gaussian energy distribution, we obtain then the multilayer Langmuir–Freundlich isotherm of the form $\theta(x) = [1/(1 - x)\{\tilde{c}x^\gamma/[1 + \tilde{c}x^\gamma]\}]$ with $\tilde{c} = \exp[-(\varepsilon_{min} - \varepsilon_0)/kT]$ (Rudziński and Everett, 1992).

Evaluation of the energy distribution functions from the experimental adsorption isotherms

When the total adsorption $\theta(x)$ is measured experimentally and the local adsorption model is assumed, [Equation 2](#) can be solved (analytically or numerically) with respect to the distribution function $\chi(\varepsilon)$. The main difficulty in evaluating $\chi(\varepsilon)$ is the ill-posed nature of [Equation 2](#) for some of its kernels $\theta_l(p, \varepsilon)$. Therefore, if

meaningful results are to be obtained, special care and the quality of experimental data are required (Jaroniec and Bräuer, 1986). The easiest way to obtain an approximate solution of [Equation 2](#) goes through the so-called condensation approximation, according to which (Rudziński and Everett, 1992)

$$\chi(\varepsilon) = -\partial\theta[p(\varepsilon)]/\partial\varepsilon. \quad (5)$$

The condensation approximation replaces the local adsorption isotherm by a step function, i.e., every pressure is associated with the value of the adsorption energy, $p/p_0 = \exp(\varepsilon/kT)$, that corresponds to one half of the coverage of a given homotactic patch. The basic difficulty in this method is associated with an appropriate numerical differentiation of the total adsorption isotherm, $\theta[p(\varepsilon)]$. One of the methods that has been widely used for that purpose relies on the approximation of the experimental data by the so-called exponential adsorption isotherm (Jaroniec and Bräuer, 1986)

$$\theta(p) = \exp \left[\sum_{n=1}^N B_n (kT \ln(p/p_m))^n \right], \quad (6)$$

where $\{B_n\}$ are the coefficients and the pressure p_m is associated with the minimum adsorption energy via $\varepsilon_{min} = kT \ln(p_m)$. The distribution function resulting from [Equations 5](#) and [6](#) is

$$\chi(\varepsilon) = \left[\sum_{n=1}^N n B_n (\varepsilon - \varepsilon_m)^{n-1} \right] \exp \left[\sum_{n=1}^N B_n (\varepsilon - \varepsilon_m)^n \right]. \quad (7)$$

Approximation of the experimental data using [Equation 6](#) must be carried out under constraint that the function $\chi(\varepsilon)$ is nonnegative for the energies corresponding to the interval of pressures at which the isotherm was measured. Note that the above described method has been next extended to the case of adsorption on fractal surfaces (Sokołowska and Sokołowski, 2008).

The steps that lead to an appropriate solution of [Equation 2](#) must involve a correct choice of the local adsorption isotherm and initial analysis of experimental data with respect to elimination of systematic and random experimental errors. Several numerical procedures for the evaluation of $\chi(\varepsilon)$ from experimental adsorption data have been proposed; numerous of them have been outlined by Jaroniec and Bräuer (1986) and Jaroniec and Madey (1988). One of the most accurate methods is the so-called regularization method (von Szombathely et al., 1992). Note that a quite analogous method was also employed to calculate the pore size distribution from experimental adsorption isotherms (Kowalczyk et al., 2003). Another quite accurate and numerically simple method was developed by Stanley and Guiochon (1993), who employed an expectation–maximization method of parameter estimation to calculate adsorption energy distributions from

experimental adsorption isotherms. The method does not require any prior knowledge of the distribution function, or the analytical expression for the experimental isotherm, requires no smoothing of the isotherm data, and converges with high stability toward the maximum-likelihood estimate. The method is therefore robust and accurate at high iteration numbers. The test calculations carried out by Stanley and Guiochon proved that their method is more accurate than several previous approaches (Jaroniec and Madey, 1988).

One should also mention about an alternative theoretical approach to model adsorption by heterogeneous adsorbents that is based on the concept of quenched-annealed mixtures (Pizio, 2000). In the case of one-component adsorbate, the adsorption system is considered as a two-component mixture, in which one component (adsorbent) is frozen. The application of the so-called replica methodology (Pizio, 2000) allows them to calculate adsorption isotherms. Similarly, a planar heterogeneous surface can be modeled by “quenching” an imaginary “fluid of adsorbing centers” (Rzysko et al., 1999). This approach, although theoretically promising, has been not employed to model experimental data adsorption on environmental materials so far.

Energetic heterogeneity of soils

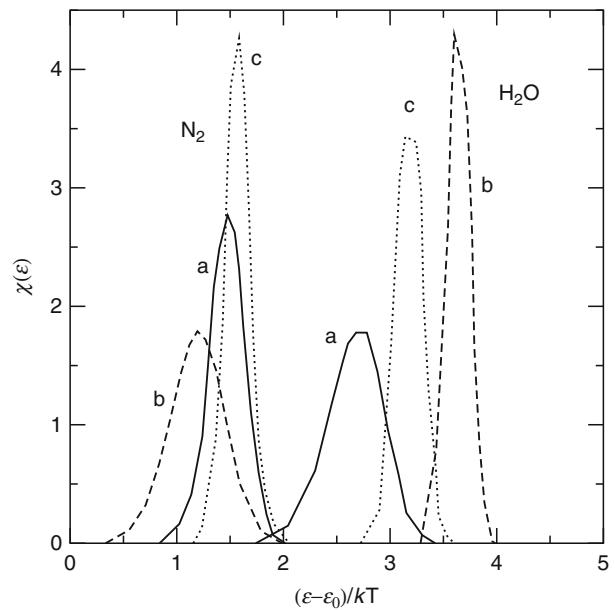

The concepts of adsorbent heterogeneity and the integral adsorption equation in particular have been widely used to study adsorption of vapors by soils (Bottero et al., 1993; Pachepsky et al., 1995; Józefaciuk and Bowanko, 2002; Sokołowska et al., 1999; 2002; Villiéras et al., 2002). The energy distribution functions and the average values of the energy of adsorption, $\langle \varepsilon \rangle$,

$$\langle \varepsilon \rangle = \int d\varepsilon \chi(\varepsilon) \quad (8)$$

obtained from experimental adsorption isotherms have been proved to be useful while discussing the mechanism of adsorption, the role played by selected constituents of soils and soil minerals in the adsorption process, to get insights into the changes in the soils caused by chemical and/or treatment, and so on.

Figure 1 shows exemplary energy distribution functions obtained from the numerical solution of **Equation 2** applied experimental data of nitrogen and water vapor adsorption on alluvial soils (for details see Sokołowska et al., 2002). Of course, the energy of interaction of a single adsorbate particle with adsorbing surface depends on its chemical nature. Consequently, the results for both adsorbates are different. However, the energy distribution functions for nitrogen, as well as for water are described by narrow, Gaussian-like peaks. Such peaks indicate the existence of one major kind of adsorbing centers.

The energy distribution functions and their changes due to the changes or modifications of soils depend on the individual soil properties, but one should remember that function $\chi(\varepsilon)$ provides only a global energetic

Adsorption Energy and Surface Heterogeneity in Soils,

(2002). Labels (a), (b), and (c) denote horizons. (Reprinted from Sokołowska et al. (2002). Copyright (2002), with permission from Elsevier).

characteristic of a given surface. In order to associate its particular peaks to really existing adsorption centers, additional studies, e.g., spectroscopic measurements of adsorbed molecules, are necessary.

ADSORPTION ENERGY OF WATER ON BIOLOGICAL MATERIALS

Jiří Blahovec
 Department of Physics, Czech University of Life Sciences, Prague 6-Suchdol, Czech Republic

Synonyms

Adsorption enthalpy; Adsorption heat; Isosteric heat of sorption

Definition

Adsorption energy (heat) represents the difference between the heat of evaporation the unit quantity of a substance from the product and the heat of evaporation the unit quantity substance from the pure liquid state in the same conditions (temperature, external pressure, product composition, etc.). The SI unit of adsorption energy is $\text{J}\cdot\text{mol}^{-1}$.

The adsorption energy (heat) of water is usually calculated at constant moisture content (isosteric heat of adsorption).

Introduction

The biological materials are not simple substances and/or simple mixtures. Substances in biological materials form aggregates in which they bond one to the other ([Physical Properties of Raw Materials and Agricultural Products](#)). The consequence is that molecules of the individual substances have lower energy in the aggregates than in pure substance. These interactions of the individual substances in the aggregate are described by the chemical potentials ([Daniels and Albery, 1961](#)).

For biological materials, the most important component is water (See also [Water Effects on Physical Properties of Raw Materials and Foods](#); [Water in Forming Agricultural Products](#); [Drying of Agricultural Products](#)) and that is why we deal here only with the adsorption of water. Water vapor in the surrounding air depends on the state of water inside the material. Water from the material can evaporate into the surrounding air or water can condense on the surface of the material. Both processes, evaporation and condensation, lead to equilibrium after some time. In this state, the properties of water inside a material can be described by the properties of water vapor. This equilibrium is related only to the “surface,” most available water being in contact with water vapor; the product usually contains more water that is not in contact with the vapor. This water is usually more bond than the above mentioned more available “surface” water. Different mechanisms of water bonding in biological materials were observed. The most important are participation in solution, adsorption on surfaces (internal and external), adsorption in biological cells, and pore adsorption. Adsorption is not usually very strong when chemical adsorption is excluded.

The state of internal water can be expressed by the relative chemical potential that is termed water potential ([Oertli, 1976](#); [Moore, 1972](#)). This term is in direct relation to the adsorption enthalpy. The state of water vapor in the surrounding air is well described by the relative pressure that is termed water activity ([Daniels and Albery, 1961](#)).

Water potential: adsorption enthalpy

Water potential (Ψ) is directly given by the difference between the chemical potential of water in the material (μ_m) and the chemical potential of pure water (μ_0) in the same conditions:

$$\Psi = \mu_m - \mu_0 \quad (1)$$

The water potential can be expressed either in the usual SI units ($\text{J}\cdot\text{mol}^{-1}$) or it could be recalculated into another SI expression, frequently into pressure (in Pa). The chemical potential is the relative Gibbs potential so that its value represents also the adsorption enthalpy in conditions that the difference between entropy of water in the material and entropy of water in the pure state can be omitted (Daniels and Alberty, 1961). Water potential is frequently used to describe the status of water in living organisms (See *Water Effects on Physical Properties of Raw Materials and Foods*) (Oertli, 1976) and in soil (Blahovec, 2008). Binding of water in the product is expressed by the negative value of water potential.

Water activity

Dimensionless term, water activity (a_w) of water solutions can be simply estimated by the formula (Daniels and Alberty, 1961)

$$a_w = e^{\frac{\Psi}{RT}} \quad (2)$$

where R is the universal gas constant ($8.3145 \text{ J.K}^{-1} \text{ mol}^{-1}$) and T absolute temperature. Water activity then changes from 0 to 1 for water potentials from $-\infty$ to 0. In more complicated materials, water activity can be simply expressed as the ratio of fugacities of the material water (f_m) and pure water (f_0):

$$a_w = \frac{f_m}{f_0} \approx \frac{p_m}{p_0} \quad (3)$$

that could be approximated by the ratio of the partial water vapor pressures (p_m and p_0) above the corresponding water states (Daniels and Alberty, 1961). The definition of water activity by the pressure ratio is fully correct for water vapor described as an ideal gas; the water activity of the material is then given directly by the air humidity being in equilibrium with the material. The difference between water activity based on the fugacity and on the pressure increases with deviations of the water vapor properties from properties of the ideal gas, for example, with increasing moisture content of the material.

Water activity is a crucial parameter for the living activity of agroproducts and the activity of their components (enzymes, microorganisms, etc. – see Karel, 1975b, Fennema, 1976). This is very important for storage of agricultural products (See also *Physical Phenomena and Properties Important for Storage of Agricultural Products; Physical Properties as Indicators of Food Quality*).

Sorption isotherm

The vapor pressure of the solvent in a solution can be expressed by Raoult's Law (Daniels and Alberty, 1961; Karel, 1975a, Moore, 1972) and the relation between moisture content and water activity can be estimated on this base. In real water solutions and/or more complex

materials, this relation is more complicated. It can be obtained experimentally at constant temperature in the form of a sorption isotherm that is the plot of moisture content (usually on dry basis) versus water activity at equilibrium and constant temperature. In most cases, the material is in solid and/or semisolid state (*Rheology in Agricultural Products and Foods*); in this case, the adsorption of water is understood and theoretically analyzed as a surface controlled process, that is, process based on water deposition on the (internal surface) of the material. Van den Berg and Bruin (1981) gave 77 types of different equations that can be used to describe water sorption isotherms in foodstuffs; more than 22 of them are theoretically based on water surface sorption. The most frequent are the Langmuir's isotherm, BET isotherm, and GAB isotherm.

The most frequent way to obtain the sorption isotherm at a sample consists in finding individual points of the sorption isotherm. Each point is obtained by determining the moisture content of a sample (by a gravimetric method) that was kept for long time, up to equilibrium, at constant temperature close to an oversaturated water solution of known water activity (Karel, 1975b).

Isosteric heat of sorption

A set of sorption isotherms obtained at different temperatures is the usual basis for determining the isosteric heat of sorption ΔH , that is, the difference between the heat of evaporation unit quantity of water from the product and the heat of evaporation of a unit quantity of water from the pure water in the same conditions. Isosteric heat of sorption of water is given by formula (Daniels and Alberty, 1961, Blahovec, 2008)

$$\Delta H = \left(R \frac{d(\ln a_w)}{d(\frac{1}{T})} \right)_{MC} \quad (4)$$

where MC denotes that the derivative is calculated at constant moisture content. The experimental values of water activity are usually well given by an exponential function of reciprocal absolute temperature (see Equation 2) so that the isosteric heat of sorption is nearly independent of temperature.

The isosteric heat of sorption in real biological materials increases with decreasing water activity (decreasing moisture content) similarly as the absolute value of the water potential in Equation 2 at least at moisture contents higher than approximately 10% w. b. At lower moisture contents, Equation 2 loses its validity for real biological materials:

$$\Delta H_R \approx -\Psi_R \prec \Delta H_T \approx -\Psi_T \quad (5)$$

where index R denotes water in real biological materials and index T denotes data based on water vapor as an ideal gas.

Direct and indirect methods for determination of the heat of adsorption

Direct methods for the determination of the heat of adsorption meet experimental difficulties when they are applied to biological experimental materials (Heiss, 1968). The biological materials are sensitive to changes of external parameters (temperature, pressure, see also [Stomatal Conductance, Photosynthesis, and Transpiration, Modeling](#)) that usually lead to changes of the physical state of the biological material. Hence, the direct experimental methods have only limited application in the determination of the heat of adsorption of biological materials.

Among indirect methods, the most frequent is the above mentioned method based on the sorption isotherms. From the others, the methods based on the determination of the points of melting and evaporation can be also applied (Daniels and Alberty, 1961; Heiss, 1968). New ways for studying water sorption in biological materials have been developed (e.g., Nelson and Trabelsi, 2005).

The highest values of the isosteric heat of adsorption ($20\text{--}30\text{ kJ}\cdot\text{mol}^{-1}$) are observed in biological materials at low moisture contents (lower than about 5% w.b.). These values are about one half of the heat of vaporization of water ([Water in Forming Agricultural Products](#); Blahovec, 2007; 2008).

Conclusion

The adsorption energy of water (AEW) on biological materials depends on the material moisture content. At higher moisture contents, AEW increases with decreasing moisture content in a similar manner as the absolute value of water potential increases with decreasing water activity. At the lowest moisture contents (less than 5%), the AEW reaches in many cases nearly constant values $20\text{--}30\text{ kJ}\cdot\text{mol}^{-1}$ that represent about half of the heat of evaporation of water.

The AEW is well described by isosteric heat of sorption that could be easily obtained from sorption isotherms measured at different temperatures. Direct methods for measurement of AEW are difficult to apply to AEW of biological materials. Application of physical chemistry to the calculation of AEW usually fails either due to the limited applicability of ideal gas conception or complicated aggregate structure of biological materials.

AERATION OF AGRICULTURAL PRODUCTS

Marek Molenda

Institute of Agrophysics, Polish Academy of Sciences,
Lublin, Poland

Definition

Aeration, that is, forced ventilation of ambient or refrigerated air through stored products is necessary to maintain their quality. The main purpose of aeration is to minimize a risk of storage losses through equalizing temperatures in a bedding in order to minimize moisture movement, to cool product for pest control, and to stop product heating.

Background

Certain biological reactions generate heat and often it is necessary to remove it, that is, to cool the product. Heating

and cooling (see [Heat Diffusion](#)) large amounts of biological material require energy and time so the knowledge about the process is necessary to optimize operations. Heating or cooling is not an uniform inside the volume of layer of material, rather heating or cooling front passes through the material. The velocity and thickness of the front are dependent on the air velocity (see [Air Flux \(Resistance\) in Plants and Agricultural Products](#)), the evaporation rate, the temperature difference, and the sizes of particles (see [Pore Size Distribution](#)). Usually, the air velocity is a crucial factor. In design of processes or equipment mathematical equations describing heating or cooling are used that are derived with necessary simplifying assumptions. Usually, the most important assumptions are as follows: the material is isotropic (see [Isotropy and Anisotropy in Agricultural Products and Foods](#)) in terms of thermal and mass diffusivity; the temperature, moisture content, and porosity of the layer are initially identical in the volume and porosity does not change during the process; the temperature of the moving air does not change observably, walls limiting the considered volume are isolated, and fluctuations of external temperature are negligible. Differential equations are formulated and solved numerically that allow to estimate movement of heat front.

Grain aeration

The process of aeration of grain will be described below as probably the most common at the farm. Grain is good insulator (see [Grain Physics](#)) and heat loss from it is relatively low as compared to other materials. Grain is usually placed in a storage silo in the fall and its portion near the center tends to remain near the temperature at which it came from the dryer or field. The grain near the silo wall tends to cool to near the average outside temperature. With a decrease in the ambient temperature, the difference between the temperature in the center and near the wall produces air currents inside the grain mass. The colder air near the wall is denser and tends to fall, while warmer air flows up through the center of grain mass. Warmer air contains more moisture and when it reaches top center of the silo fill it cools to a point at which it cannot hold all moisture it had absorbed. The excess moisture condenses at the top layer of grain and creates an environment enhancing mold and insect growth. The opposite situation occurs in warmer periods, the moisture condenses near the bottom center of grain mass.

The problem of air currents within the grain mass may be minimized by keeping the temperatures near the center close to the average temperature near the wall of the storage silo (Loewer et al., 1994). To accomplish this aeration fans may be used that pull air down through the grain until the temperature of grain mass is within 5°C of the average monthly temperature. Aeration air can move either up or down through the grain mass. Most fans have the ability to either push or pull, however, airflow volumes and power requirements will often change due to direction. It is not necessary to cool the grain mass below 5°C, because

the activity of typical storage fungi is very low below this temperature. In spring, warming of grain is necessary if extended storage (post June) is required or if the temperature of grain is below 0°C. Typical aeration airflow rates range from 1 to 2 L of air per second per cubic meter of grain (1–2 L/(s m³)). Higher rates should be used (2–6 L/(s m³)) if grain is stored at higher moisture levels or if a large variance in incoming moisture levels exist. An aeration system cannot be considered a drying (see [Drying of Agricultural Products](#)) system since natural air drying rates are at least 10 times longer.

Conclusion

Aeration and controlled atmosphere storage are still under development to elaborate efficient methods for control of temperature and moisture of product, as well as for elaboration of optimum strategies specific for crop, storage structure, and climatic conditions. Currently, investigations are conducted on characterization of bedding anisotropy and including this into strategies of aeration control (Navarro and Noyes, 2001).

AERATION OF SOILS AND PLANTS

Witold Stepniewski

Department of Land Surface Protection Engineering,
Lublin University of Technology, Lublin, Poland

Synonyms

Gas exchange in soils; Oxygenation of soils and plants;
Oxygenology of soils and plants

Definition

Aeration of soils and plants is a term used in wide sense as a name of complex issues related to air transport and distribution in soil and its effect on processes occurring in soil and plants. Sometimes it is used in a narrow sense to denote gas exchange between soil and atmosphere, or only

oxygen content in soil air or even as a name for a process of artificially forcing air into the soil (Gliński and Stepniewski, 1985).

Introduction

In soil medium intensive production, transformations, and consumption of a number of gases, which are transported to and from the atmosphere, take place. These processes are not only important for the production of plant biomass but also play an important environmental role.

The most important soil gasses are oxygen (indispensable for root respiration and important for microbial metabolism and for numerous biochemical and chemical processes) and carbon dioxide (product of oxic respiration of plant roots, microorganisms, and mezo- and macrofauna, as well as anoxic microbial respiration and fermentation). Nitrogen, important for its fixation by some microbes, draws less attention because it is considered as non-limiting due to its abundance.

Soil air contains, moreover, a number of gases occurring in trace amounts such as nitrous oxide (N_2O), nitrogen oxide (NO) and dioxide (NO_2), ethylene, ammonia (NH_3), and hydrogen sulfide (H_2S). An intermediate position occupies methane which under dryland conditions occurs in trace amounts but under wetland conditions and under landfill conditions can occupy a substantial fraction of the soil air. Dependently on the aeration status, the soil can be a source or a sink of greenhouse gasses such as CH_4 and N_2O .

Pathways of gas exchange

There are two essential pathways of the gas transport in the *soil-plant-atmosphere continuum* (see [Soil-Plant-Atmosphere Continuum](#)): the soil pathway and the internal pathway through the plant tissues ([Figure 1](#)). The first one prevails in soils cultivated under dryland conditions, while the plant pathway dominates in natural and constructed wetlands and paddy fields (e.g., Yan et al., 2000). If the soil

is without plants, the downward transport of gases practically ceases while the gases generated in the soil such as CO_2 and CH_4 are released to the atmosphere by ebullition.

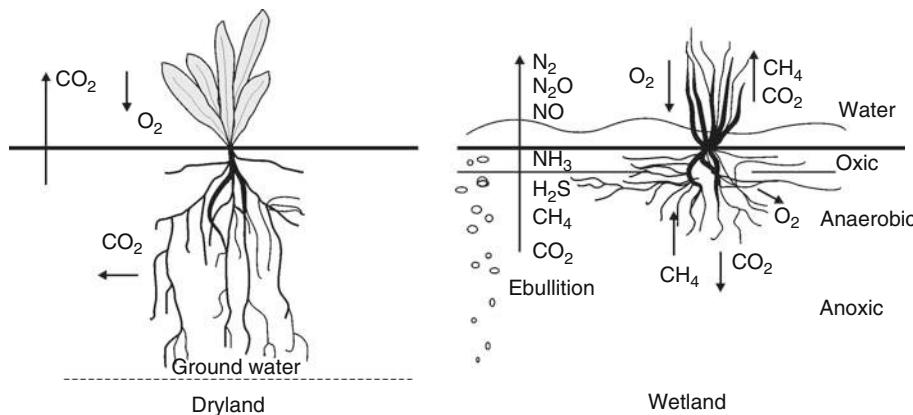

Between these two pathways, there are numerous intermediate situations with different contributions of soil- and plant-mediated transport of gases dependently on the land use and tillage influencing air-filled porosity, gas diffusion coefficient, and air permeability of soil (Stepniewski and Stepniewska, 2009). Agricultural land use is connected mainly with dryland conditions as wetland rice cultivation produces about 20% of food calories (IRRI, 2005). There are also examples of intermediate systems such as midseason drainage of paddy fields to prevent toxicity of sulfides (Kanno et al., 1997), combining cultivation of lowland rice with dry season crops (So and Ringrose-Voase, 2000) as well as so-called system of rice intensification characterized by change from permanent flooding to intermittent irrigation (Dobermann, 2004) to improve the oxygen supply to rice roots (Stoop et al., 2002).

Mechanism of gas exchange

There are two essential mechanisms of gas exchange in soil medium: mass flow or advection (convection) and molecular diffusion. Both these mechanisms can take place in soil pores as well as in plant tissues. The relative contribution of both mechanisms of gas exchange can vary within wide limits dependently on the conditions.

Mass flow

The driving force of mass flow is pressure gradients appearing within soil or plants due to fluctuations of atmospheric pressure, variability of temperature, changes of groundwater depth, infiltration of rainwater, as well as humidity-induced convection in leaves and Venturi convection caused by wind action (Armstrong et al., 1996). Of these drivers only fluctuations of atmospheric pressure may be of importance in the soils with very deep impervious layer.

Aeration of Soils and Plants, Figure 1 Model of the two pathways of gas exchange in the atmosphere-plant-soil continuum. Dryland conditions – oxygen is supplied to the plant roots via the soil. Wetland conditions – oxygen is transported through the tissues of the plant itself.

In case of *laminar flow* (see [Laminar Flow](#)) usually occurring in soil, when the Reynolds's number < 1 (Currie, 1970) the movement of gases is described by Darcy's equation:

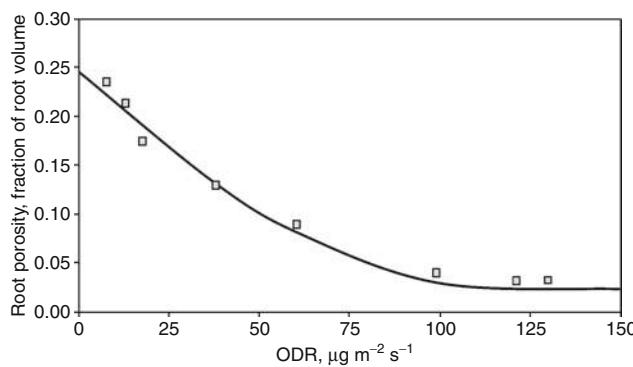

$$\frac{dV}{dt} = -A \frac{k}{\eta} \frac{dp}{dx} \quad (1)$$

where dV/dt is the volumetric rate of gas flow, $\text{m}^3 \text{s}^{-1}$, A is the cross-sectional area of the porous medium, m^2 ; η is the dynamic viscosity of the gas, $\text{kg m}^{-1} \text{s}^{-1}$; dp/dx is the pressure gradient, $\text{Pa m}^{-1} = \text{kg m}^{-2} \text{s}^{-2}$; and k is the air permeability, m^2 .

According to Gliński and Stepniewski (1985), the values of air permeability in soil are within the range of $0.01-500 \times 10^{-12} \text{ m}^2$. Air permeability depends in general terms on the quantity and quality of air-filled pores. The latter term relates to the pore size distribution, continuity, and tortuosity, which, in turn depend on the arrangement of soil particles, on soil bulk density, and water content. Advective gas flow depends on the fourth power of the pore size.

Morphological changes within plants are very important adaptation to flood conditions. They include development of a shallow root system, formation of adventitious roots of high porosity, formation of aerenchyma within roots (Gliński and Stepniewski, 1985), and development of aerial roots or pneumatophores (e.g., Purnobasuki and Suzuki, 2005).

The internal *air flux* ability of the plant tissues can be a permanent feature or it may become apparent or enhanced under oxygen deficiency conditions ([Figure 2](#)). Internal transport of oxygen via plant roots can cover not only oxygen demand of the plant roots, but also can protect the plants against Fe^{2+} and H_2S toxicity (Jayakumar et al., 2005). It should be emphasized that an increase of internal porosity of root tissues increases both air permeability as well as gas diffusion coefficient.

Aeration of Soils and Plants, Figure 2 The relationship between oxygen availability in soil medium as characterized by oxygen diffusion rate (ODR) and the internal porosity of rice roots. (Modified from Ghildyal [1982].)

Diffusion

The basic mechanism of gas exchange in the soil medium and within the plant tissues is the concentration diffusion induced by concentration gradients.

The diffusive flow f_x of a gas within a porous medium is described by the first Fick's law.

$$f_x = -D dC/dx \quad (2)$$

The above equation says that the uniaxial diffusion flow (f_x) of an agent through a unit cross-section, in a unit of time, is proportional to the concentration gradient (dC/dx) and to the diffusion coefficient D characterizing the mobility of the agent in a given medium.

Coefficient of gas diffusion in soil depends on the kind of gas, its temperature, and pressure, and also on the amount of air-filled pores, their continuity, and shape which depend on the spatial arrangement of soil particles and on distribution of water. The diffusive properties of a soil medium are usually characterized by the relative diffusion coefficient D/D_o , being the ratio of gas diffusion coefficient in soil D , to that of the same gas in atmospheric air D_o , under the same pressure and temperature conditions. The D/D_o value does not depend on the temperature, pressure, or the kind of the diffusing gas.

The influence of *soil bulk density* and soil moisture tension on D/D_o is presented in [Figure 3](#). The value of D/D_o in soil is usually below 0.2. It increases with soil moisture tension, and rapidly decreases with soil bulk density. It should be stressed out that gas diffusion coefficient in porous media does not depend on the size of the pores, as long as the pore diameters are greater than the mean free path of the molecules of the gas under consideration. (Gliński and Stepniewski, 1985). This limit is the pore diameter of $0.10 \mu\text{m}$. In the case of soil, pores of that size are emptied of water at soil moisture tension levels over 3 MPa ($\text{pF} > 4.5$), i.e., at moisture contents lower than the permanent wilting point. Thus, gas diffusion within macropores (above $30 \mu\text{m}$) as well in the mezopores ($30-0.2 \mu\text{m}$) containing usually plant available water does not depend on the pore size.

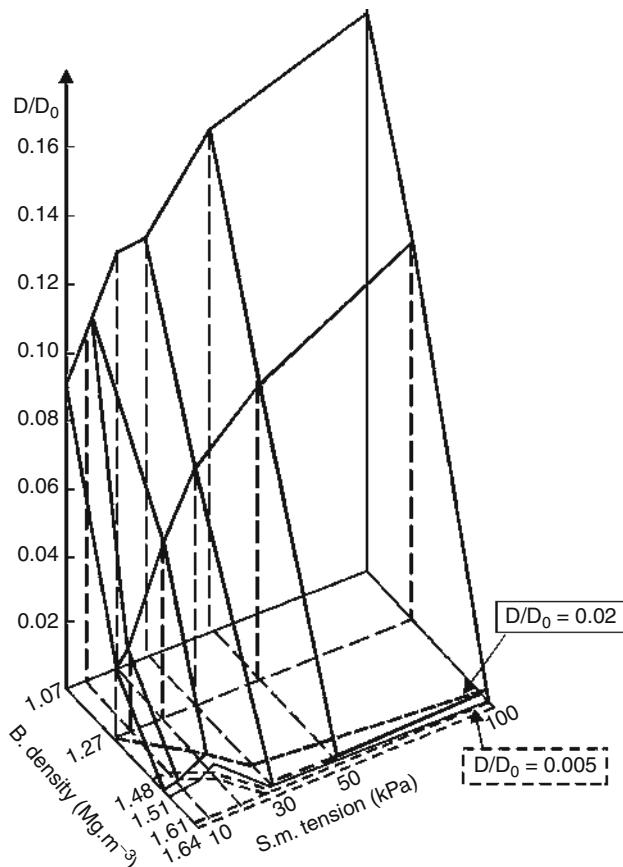

D/D_o usually shows a curvilinear relationship versus E_g , as shown in [Figure 4](#). It can be described by an empirical power model in the following form:

$$\frac{D}{D_o} = \gamma E_g^\mu \quad (3)$$

where γ and μ are empirical coefficients characterizing the porous material.

The author was unable to find literature data related to direct measurements of gas diffusion coefficients within living plant tissues.

It should be underlined that the composition of air within the intra-aggregate pores may differ from that in the inter-aggregate pores due to soil heterogeneity. The former pores contain less oxygen and more

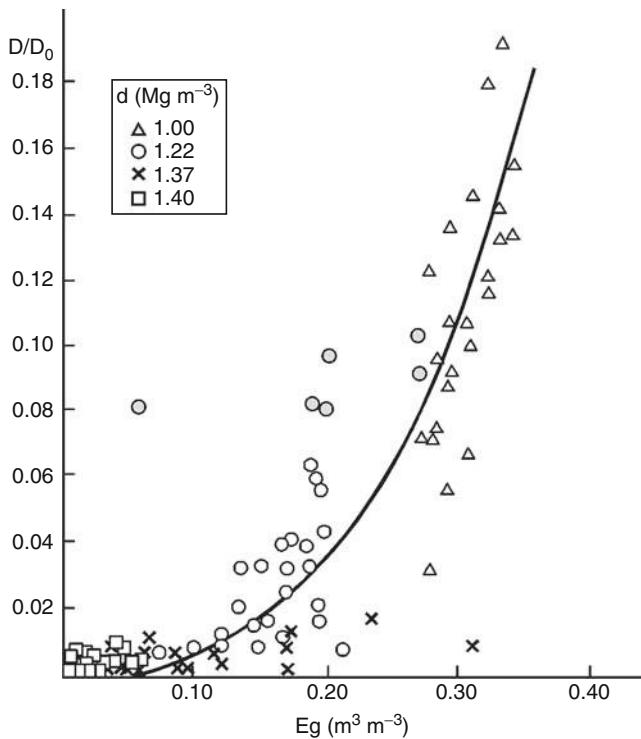

Aeration of Soils and Plants, Figure 3 Dependence of relative gas diffusion coefficient in a loamy textured Phaeozem (Kock, Poland) on soil moisture tension and bulk density. (Modified from Stępniewski [1981].)

carbon dioxide compared to the inter-aggregate pores (e.g., Zausig et al., 1993; Højberg et al., 1994; Horn, 1994; Horn and Smucker, 2005).

Oxygen

Oxygen is taken up by the soil due to respiration of microorganisms and plant roots. Respiration of soil microorganisms depends on the availability of oxygen, organic carbon, and nutrients as well on temperature and water content. The temperature interval for microbial growth ranges from -12°C to 110°C . Microorganisms with respect to their temperature requirements are divided into psychrophilic, mesophilic, and thermophilic (Paul and Clark, 1998). A new term “hyperthermophiles” denotes extreme thermophiles growing in the temperature range from 60°C to 110°C . Soil contains a mixture of different groups of microorganisms and its respiration rate increases two to three times with the increase of temperature by 10°C until the temperatures of break of metabolism (at about 60 – 70°C).

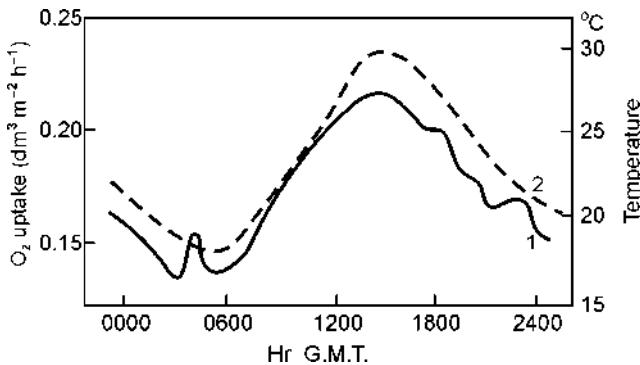

Aeration of Soils and Plants, Figure 4 Relationship of D/D_0 to air-filled porosity E_g of silt Fluvisol at different bulk densities d . (Modified from Stępniewski [1981].)

With respect to oxygen requirements, soil microbes are divided into obligate oxic, facultative anoxic, and obligate anoxic organisms (obligate anaerobes). A special group of microorganisms constitute microaerophiles characterized by oxygen optimum of order 2–10% by volume (Black, 1996). Oxic microorganisms utilize oxygen as a terminal electron acceptor from the cytochrome oxidase.

Soil microbial activity depends both on oxygen and carbon dioxide concentration, independently. Carbon dioxide is a carbon source for autotrophic microflora. Dommergues and Mangenot (1970) reported 2–14% CO_2 as the optimal range for the growth of these bacteria. For other microorganisms, carbon dioxide is an inhibitor of respiration and growth although some microorganisms display metabolic stimulation by low CO_2 concentration and inhibition above a certain CO_2 concentration (Dixon et al., 1998; Sierra and Renault, 1995).

The dependence of microbial respiration on water content shows a maximum corresponding to the range of optimal availability of oxygen and water. With respect to water requirements, the soil microorganisms are divided (Gliński and Stępniewski, 1985) into hydrophilic (disappearance of activity at pore water pressure > -7.1 MPa), mesophilic (disappearance of activity within the pore water pressure interval from -7.1 to -30 MPa), and xerophilic (disappearance of activity at pore water pressures < -30 MPa). Under field conditions, the rate of soil

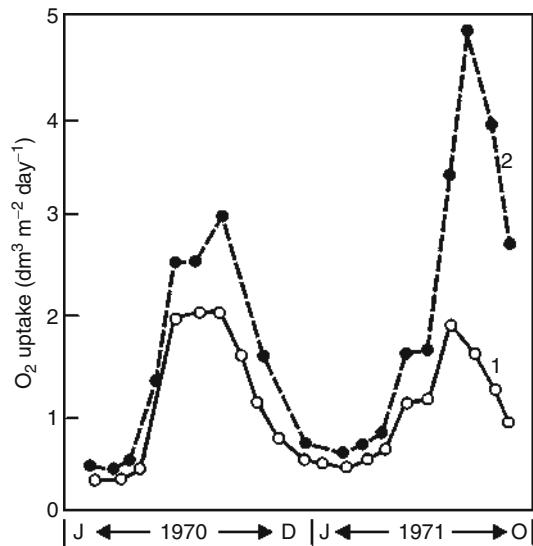

Aeration of Soils and Plants, Figure 5 Diurnal dynamics of soil respiration rate as measured by oxygen uptake and temperature. (Modified from Currie [1975].)

microbial respiration is usually within the range from 0.1 to 10 mg m⁻³s⁻¹ (Gliński and Stępniewski, 1985).

The root respiration rate depends on plant internal factors such as plant type and development stage, root mass distribution, dimensions, and physiological age of the tissue, as well as on external factors such as temperature and the availability of water and nutrients. It should be emphasized that soil microbial activity increases in the presence of plant roots due to production of root exudates being a source of easily available carbon for microorganisms. Respiration rate of the root tissues is about two orders of magnitude of that of the soil itself and ranges from 10 to 50 mg m⁻³s⁻¹ (Gliński and Stępniewski, 1985).

Oxygen uptake by a cropped field is a sum of microbial and root respiration and under field conditions is of order of several tons of oxygen per hectare and year (Gliński and Stępniewski, 1985). Soil respiration under field conditions (Figure 5) shows a maximum in the afternoon and minimum before sunrise. In the moderate climate zone, the annual dynamics of oxygen uptake under field conditions is characterized by a summer maximum (Figure 6). It should be emphasized that the presence of plants may elevate the oxygen uptake more than twice.

The oxygen deficiency in soil affects the plant performance directly by limitation of root respiration, of energy supply, and changing the metabolism in the root tissue itself, as well as indirectly by inducing chemical and biological changes in the surrounding soil (e.g., *oxidation-reduction reactions* (see *Oxidation-Reduction Reactions in the Environment*), accumulation of phytotoxic substances, changes of pH and ion exchange equilibria). Effects of deficient aeration can be manifested in plant roots in the form of ethanol and ethylene generation, reduced water permeability, growth inhibition, and necrosis. The shoot response comprises *stomatal closure*, chlorosis, epinasty, leaf senescence and abscission, partial or complete suppression of *photosynthesis* (see *Photosynthesis*), and growth leading to reduction of biomass and yield (Glinski and Stępniewski, 1985).

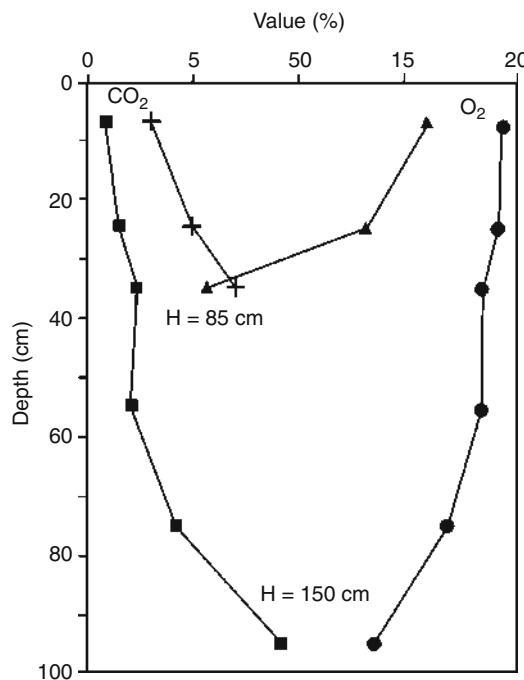

Aeration of Soils and Plants, Figure 6 Annual dynamics of soil respiration as measured by oxygen uptake rate in an uncropped (1) and cropped (2) soil under moderate climate conditions of England. (Modified from Currie [1975].)

Carbon dioxide and other gases

Production of carbon dioxide in soil under oxic conditions is directly related to oxygen uptake and all the factors influencing oxygen uptake affect also the emission of carbon dioxide.

Because of complementary character of oxygen uptake and carbon dioxide production their sum in soil air is usually about 20% by volume (cf. Figure 7). It means that also their fluxes between soil and the atmosphere are approximately equal. Concentration of oxygen in soil air decreases with depth and that of CO₂ increases. The composition of soil air is a decisive factor for microbial and plant metabolism, for many *oxidation-reduction reactions* and oxidation state of numerous soil nutrients, as well as for soil fertility and crop productivity. It should be kept in mind that under anoxia CO₂ can be produced without oxygen consumption (sum of O₂ and CO₂ >20%) and the emission of CO₂ from the soil exceeds the volume of oxygen taken up. However, long-term CO₂ emission under anoxia is reduced, what leads to carbon accumulation in soil.

Soil aeration state effects not only global turnover of oxygen and *fluxes of greenhouse gases* (see *Greenhouse Gas Fluxes: Effects of Physical Conditions*) such as carbon dioxide, methane, and nitrous oxide but also the emission of ammonia, NO_x, and ethylene. Methane emission increases under anoxic conditions. Ethylene is generated within plants under moderate hypoxia. Nitrous oxide is formed and is stable under moderate hypoxia and undergoes decomposition both under oxic conditions and under severe anoxia. Ammonia under oxic conditions undergoes oxidation to nitrates.

Aeration of Soils and Plants, Figure 7 Distribution of oxygen and carbon dioxide concentration in a gley meadow soil (Garbow, near Lublin, Poland) at two levels of ground water on 1971.06.19 (ground water level $H = 85\text{ cm}$) and the same point on 1971.09.04 ($H = 150\text{ cm}$). (From unpublished data of Stepniewski.)

AGRICULTURE AND FOOD MACHINERY, APPLICATION OF PHYSICS FOR IMPROVING

Leszek Mieszkalski

Department of Agricultural Engineering and Natural Raw Materials, University of Varmia and Mazury in Olsztyn, Olsztyn, Poland

Definition

Physics is the science concerned with the study of matter and natural forces, such as light, heat, movement.

Design is an intellectual activity; it is the oldest mental process engaged in by man to solve complex problems, develop and improve technical systems, including farming and food processing machines. Design is a process of drawing logical conclusions from empirical observations. It enables man to create artificial objects that support his existence and to introduce technical systems into the natural environment.

A machine is a set of interconnected elements that perform a given set of operations, carry the load and the moment of force to perform useful work as an energetic effect, and transform any type of energy into mechanical energy or mechanical energy into a different type of energy. Motion is transferred by mechanisms.

Introduction

The primary goal of physics is to examine the material world and search for the truth and the fundamental properties of matter on the assumption that the laws of physics are consistent and universal. Physics studies natural objects with the application of universal methods, concepts, and laws. Physical sciences support the design of farming and food processing machines by solving complex problems relating to the physical properties of soil, organic materials, and food products with the use of methods that involve the determination of physical quantities and process descriptions, based on the principles of mechanics, thermodynamics, optics, electrodynamics, electronics, acoustics, and nuclear, molecular, and solid-state physics, as well as the principles of other modern fields of physics.

Rising competition in food production requires product quality growth and production costs reduction. Physical prosperities of raw materials make designing agricultural machinery and food processing machinery difficult. Precise knowledge of raw material prosperities is a condition to create appropriate food processing technologies and machinery. There are many problems to solve in machine designing, e.g., soil degradation, excessive chemicalization, food safety, etc. Sciences as agrophysics, agricultural engineering, food engineering, and other related sciences as mechanics, mechatronics, computer sciences, genetic engineering are used to help with gathering and receiving information for machine designing.

Changing rapidly global economy uses robots on a big scale in food production. Today human work in food production is replaced by machinery with complicated mechanisms, working units, sensors, and board computers. In current mechanical production dynamic development of mechanization, atomization and robotics takes place.

The importance of the physical properties of raw materials and food products in machines designing

Animate and inanimate matter differs as regards the values of state parameters such as temperature, pressure, radiation field intensity, and humidity. Live cells of animate

matter used in the production of food have a highly complex microstructure, and its specific attributes, the observed chemical and biological processes reflect the universal laws of physics. The laws of physics attributed to complex systems imply various characteristic properties that have to be taken into account when designing food processing machines. Raw materials and food products have unique physical characteristics such as stretch, location, velocity, mass, momentum, temperature, color, and chemical and biological attributes. The raw materials used in the production of foodstuffs are examined with the use of physical methods to select the appropriate working parameters of the designed farming and food processing machines. The study of physical phenomena occurring in plant and animal material, i.e., anisotropic objects, in an unstable and an unpredictable environment poses a challenge for contemporary physics which, in addition to investigating the occurring processes, accumulating data and expanding our knowledge base, also aims to expand the intellectual capacity of technical sciences and offers solutions to specific problems. Scientific knowledge should have a practical dimension, and it should satisfy man's nutritional needs. Physical phenomena are described with the involvement of measurable properties, referred to as physical quantities. The process of examining the physical phenomena attributed to raw materials for the food industry can be divided into several stages. The first stage involves the selection of parameters that support the investigation of the studied object's suitability for processing and its description. The method of measuring the selected parameters is determined at the second stage. At the third stage, researchers develop the general concept and the structure of measuring equipment; they select the units of measurement and calibrate tools. At the following stage, measurements are performed at the required level of precision, the results are analyzed, and conclusions are formulated. At successive stages, the obtained results are applied to design and upgrade farming and food processing machines.

The relationship between motion and the force of raw material and food product molecules at the microstructure level is very important during the construction of farming and food processing machines. Motion is described with the use of parameters such as the components of a position vector that changes over time, which are attributed to the discrete morphological elements of a biological object. The measured quantities include distance, angle, and time. The correlation between the above quantities is investigated with the use of mathematical formulas. The human senses do not respond to many physical phenomena, including field and radiation. Such phenomena are often encountered in food processing technology. They are measured with the application of detectors that convert various pulses into observable signals. Detectors are clocks, weighing scales, thermoscopes, baroscopes, electroscopes, spectrometers, microscopes, etc. A measuring device is closely interrelated with the physical quantity that is being measured at a given level of precision.

Measurement precision determines the quality of physical observation. The results of measurements in a discrete system are expressed in the form of a finite set of numbers to which quantitative data are attributed. The studied processes involve recurring phenomena and phenomena that constitute the laws of physics. Those phenomena can be used to formulate theoretical structures and design many practical applications. The laws of physics are expressed in the form of mathematical relations between symbols representing different quantities. The discovery of new, validated laws of physics expressed by equations and inequations supports the examination of the resulting consequences. The application of physics theories in engineering and machine construction, including farming and food processing equipment, is important for the process of designing processing technologies. The physical properties of raw materials are transformed during processing into food products. The principal physical quantities describing a particle of the studied raw material or product are particle mass, vectors of position, and forces applied to those particles. If those quantities are known at a given time, then the velocity and acceleration of particle mass moved by that force is also known. Other quantities include momentum, angular momentum, and torque. Newton's laws of dynamics, described as a system of three quadratic differential equations for unknown time functions, support an infinite number of solutions. A fixed solution can be obtained only by determining the initial conditions.

In the process of building farming and food processing machines with the use of laws of physics that describe the general relationships associated with an infinite number of physically admissible solutions, a specific physical situation at a given point in time should be determined and implemented. Food engineering deals with various objects, including elementary particles, atoms, cells, tissues, ions, molecules, systems of microscopic and macroscopic particles as well as fields. One of the many goals of food engineering is the use of physics theories, namely the laws of physics written down in mathematical form, in a strictly defined environment. The above also applies to farming and food processing equipment, raw materials of plant and animal origin, and end products. For a physics theory to be useful in the process of solving technical problems, the number of predictions has to be consistent with experimental results. Established physics theories are not always fit for use in farming and food engineering. Despite their universal character, the applicability and precision of those theories may be limited in this particular context. If this is the case, a theory has to be adapted to a given situation to ensure a higher level of accuracy and consistency with the experiment. Experiments support the discovery of new physical phenomena and new attributes of technical and biological objects (Shao et al., 2009), and they are of paramount importance in the process of solving technical problems in agriculture, food engineering, and production. The measurements used to determine the physical quantities of the studied

raw materials and food products contribute to the discovery of rules, correlations, structures, and dependencies. These experimental and intellectual methodological operations support the development of new concepts, conceptual structures and theories, the discovery of important phenomena for biological objects and dynamic causal relationships. The acquired knowledge on raw materials and food products, expressed in mathematical form, enables researchers to examine and determine the effect of changes in the physical qualities of the studied objects owing to different factors (conditions), to subject their findings to a critical evaluation and formulate logical conclusions. A physics theory that is free of logical and mathematical contradictions is a venture point for explaining causally connected facts, and it supports the prediction of new, unknown facts.

Many problems in agricultural and food engineering may be solved with the use of data in the existing knowledge database. Scientists developing new farming and food processing machines rely on information describing the physical properties of raw materials and food products as well as established scientific theories and laws of physics. Biological objects have a complex structure. The attributes of complex objects are determined by the laws and properties applicable to their components. Their geometric form follows from the surface structure of the morphological components of a biological object. Physics and its laws are closely related to natural sciences, which is why the laws of science have many applications in agricultural and food engineering, in particular in describing working processes and developing new technologies and machines. A sound theory of elementary particles should support the discovery of new phenomena and laws that may be applied in designing new technologies for processing a given type of raw materials into food products with the anticipated properties. As a rational science supporting the development of formal languages for the precise description of abstract concepts and relations, mathematics plays an important role in the physical description of the actual condition of farming and food processing machines. From among a variety of mathematical equations describing a given phenomenon, scientists have to choose the propositions, concepts, and statements that are fit for use in the process of building models of farming and food processing machines and modeling working processes in food production (Mieszkalski, 1996; Hardin and Searcy, 2009). Many biological objects with technical applications can be described with the use of geometric and mechanical models as discrete structures. A system of spatially distributed mass particles may serve as a model of raw materials and food products. The distance between mass particles is modified under the influence of the applied force. The physical quantities indicating displacement over time are described with the use of mechanics, thermodynamics, and other existing theories.

The design of new farming and food processing machines as well as food processing technologies relies

heavily on mathematical modeling, which will develop as new advances are made in IT and computer systems. A preferred mathematical model for describing physical processes in farming and food engineering should have the widest possible range of applications, it should deliver a high degree of precision and, above all, it should support the prediction of experimentally validated events.

Many discoveries have been made as regards measuring devices for observing the structure of biological objects of plant and animal origin. Small objects in the structure of the studied raw materials are investigated with the use of microscopes. Vast advancements have been made in the field of microscopy, leading to the development of electron and confocal microscopes (Entwistle, 2000; Danilatos and Postle, 1982; Inoue, 1986). New solutions simplifying the observation of the spatial structures of those objects are likely to be introduced in the future. Empirical knowledge on the spatial distribution of particles with a complex shape will contribute to the development of more accurate particle models as well as theories that offer practical implications for farming and food engineering.

Testing raw materials and food products

There is a need to isolate a field of physics dealing exclusively with physical relations in the natural environment, soil, water, air, plants, animals, raw materials of plant and animal origin, and food products. This field – agrophysics – should have its own conceptual system covering a specific field of study.

Agrophysics studies the ecosystem and biological objects that participate in the food production process, which are processed by human activity and whose mathematical, physical, and chemical attributes are described with the use of scientific methods. Agrophysics could further the development of food research by:

- Introducing universal standards applicable to biological objects for food production
- Promoting the development of high-precision research methods investigating the phenomena and properties encountered in the food production process
- Describing physical processes in food production
- Examining the physical properties of farming produce used for food processing
- Investigating mutual relations in the natural environment relating to food production
- Designing new methods that restrict the degradation of the environment where raw materials and food are produced
- Monitoring and storing data on changes in physical quantities characteristic of raw materials and food products during processing
- Developing mathematical models of the processes observed in biological objects that are marked by high variability and anisotropy during food production

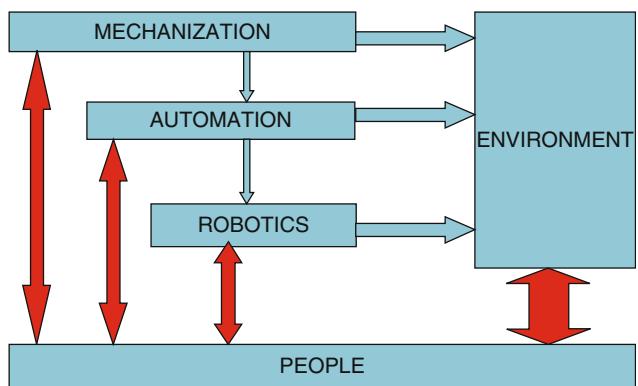

- Developing advanced measuring systems supporting fast and precise measurement of physical properties in automated food production
- Improving physical methods in the area of food production
- Developing new methods for evaluating food quality and safety

Physics supports agricultural engineering that deals mainly with soil – machine – plant systems and breeding animals, as well as food engineering, which investigates the relationships between farming produce and machines, and machines and food products. The relationship between physics, agricultural engineering and food engineering is based on the supply of data from physical experiments for developing new production technologies, preserving and storing food, designing machines, devices, research methods, measuring equipment and apparatuses. Physics will have a growing role in agricultural and food engineering because the progressing drop in employment levels in the farming sector will force farming corporations and local food producers to modernize and expand their resources.

Trends in the development of agricultural machinery and food machinery

There will be a growing demand for new technologies yielding high quality raw materials and food products (Semos, 2004). The interest in new-generation machines will rise. New computer-aided design solutions will shorten design time and cut the relevant costs, while significantly enhancing the quality of the end product. 4D computer-aided design which, in addition to 3D modeling principles, accounts for the time factor, will enable scientists not only to model but also to simulate the kinematics of mechanical motion and the dynamics of changes taking place in machines, raw materials, and food products over time.

According to the National Academy of Engineering, the quality of life in the twentieth century improved dramatically owing to technological progress in areas such as electrification, the invention of mechanical vehicles and airplanes, potable water networks, electronics, radio, television, computers, telephones, paved roads, spaceships, the Internet, medical technology, crude oil processing, lasers and optical fibers, nuclear technology, and state-of-the-art materials. Living standards also improved owing to farming mechanization (ranked 7th), air-conditioning and cooling (ranked 10th) and household equipment (ranked 15th). The twentieth century brought the mechanization era to a close. The current level of technological process supports the construction of machines that may successfully replace human labor. The twenty-first century will witness the development of scientific fields such as information technology, biotechnology, and mechatronics, which will automate and robotize production processes, including farming and the food industry (Figure 1). Physics will play an important role in this

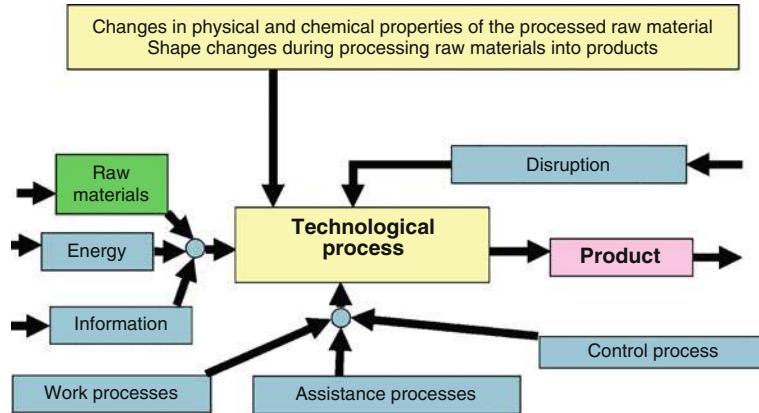

Agriculture and Food Machinery, Application of Physics for Improving, Figure 1 Stages of technical modernization in agriculture and the food processing industry.

process. Highly industrialized countries are entering a new phase of technological advancement marked by automation and robotization of production and services (Liu et al., 2009). Efforts must be made to ensure this progress does not have adverse consequences for the natural environment, which is of fundamental importance for the quality of life on Earth.

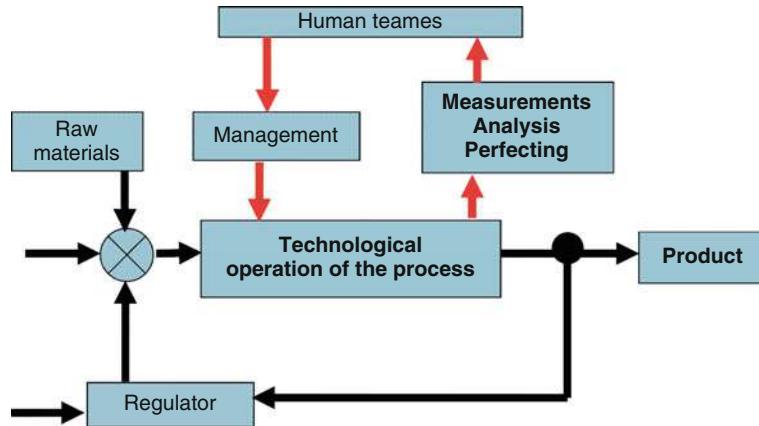

The challenges presently faced by physics, agricultural and food engineering involve rational and pragmatic needs analyses, systematic research, the development of theoretical systems based on the results of scientific experiments and observations, and expanding and building a reliable knowledge base with practical implications leading to the implementation of new concepts. A reliable knowledge base delivers practical results and contributes to an improvement in the quality of life. Scientific progress in new farming and food processing technologies can be used to ensure social demands and can be implemented on a mass scale.

In the process of dynamic civilizational development, science should be independent and free of any political influences in order to deliver unbiased solutions at every stage of development of new technologies and machines. Above all, scientific advancement should support the establishment of a sustained relationship between artificial systems, the natural environment, and man (Arvanitoyiannis et al., 2000; Ravertz, 2002). In designing optimal design, decisions must be taken, having a serial structure which affects the quality of the proposed agricultural machinery and food machinery. This process has very serious consequences as it determines the final quality of farming and food processing machines. Scientific teams designing farming and food processing machines rely on data that deliver information on the physical and chemical properties of soil, plants, animals, and end products (Mieszkalski, 1997). Physics must fill the existing knowledge gaps in a structured way to support technology process design and then the machine design (Figure 2).

A technological process is a dynamic system where the set of input data accounts for raw materials, energy, and

Agriculture and Food Machinery, Application of Physics for Improving, Figure 2 Block diagram of a technological process.

Agriculture and Food Machinery, Application of Physics for Improving, Figure 3 Block diagram of a technological process operation.

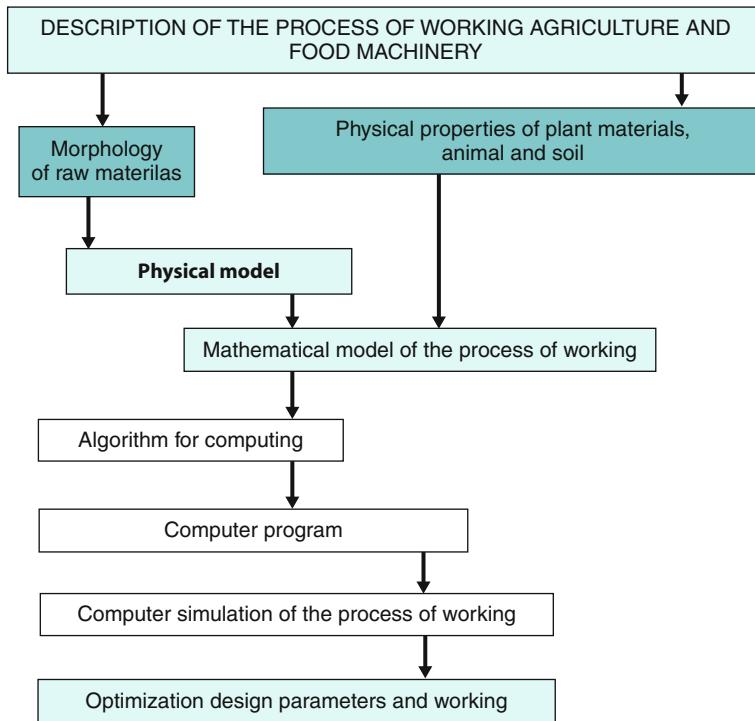

information, and the set of output data comprises end products and waste. In the initial design phase, the technological process and the process line supplying farming and food processing machines have to be thoroughly evaluated to guarantee the highest quality of the end product. Scientists should develop structural solutions to search for appropriate solutions in the design process of machines farming and food processing machines.

A well-designed process that accounts for economic, ergonomic, environmental, and social criteria consists of a series of activities that modify the physical and chemical parameters and the shape of the processed materials, and facilitate the search for new structural solutions. A thorough examination and a detailed description of the technological process should underlie all research efforts in physics, agricultural engineering, and food processing engineering (Figure 3).

Every working process in the food processing industry comprises many complex and interconnected factors. Their impact on the technological process is determined

by the physical condition of the processed plant and animal material as well as the kinematic and dynamic parameters of the processing system. An algorithm describing the technological process of a machine is presented in Figure 4 (Mieszkalski, 1998a). The food production process involves physical events and phenomena. A physical phenomenon is an event during which the form of a biological object is transformed by modifying its physical properties. The occurrence of a physical phenomenon requires electrical, magnetic, gravitational and particle interactions as well as friction. A phenomenon is a unitary event, an existing fact. The physical state of a material object embodies its quality, form, level, quantity, number, and location at a given time. The technological process of a farming and food processing machine encompasses a number of constituent processes, which form a sequence of actions and measures required to achieve the planned goal.

In the technological process of a machine, the processing of raw materials into food products involves

Agriculture and Food Machinery, Application of Physics for Improving, Figure 4 Block diagram of a farming machine's technological process.

the modification of their physical and chemical properties. Those changes and their course have to be taken into account at the stage of designing the working process as the quality of the end product can be modified during that phase. An analysis of the food production process relies on the results of research involving a verified mathematical model that constitutes a formal basis for the computer-aided simulation of that process. A computer simulation is a method of investigating an empirical system which, in view of the objective of modeling, may replace natural experiments in the process of acquiring information on the efficacy of the analyzed technical system. This research method will have a growing role in the design of farming and food processing machines. The precision of computer simulations is determined mainly by the degree of accuracy delivered by the mathematical model, the description of input data, errors, and the applied simplifications. Physical sciences are of utmost importance in this type of research. By selecting the appropriate research methods, physics theories and other cognitive instruments, scientists are able to explain how physical quantities affect vital changes in the physical properties of raw materials and food products. Computer simulations involve the use of software based on algorithms that allow the user to generate a history of raw material stocks and monitor the progress in machine construction. It should be noted that a simulated working process is merely an approximated representation of the real process rather than its faithful replication. By relying on

computer simulations as a research method in designing technological processes and machines, scientists select a sequential system of events and simulate elementary processes in a given order. The majority of simulations rely on the fixed time-step method and the discrete event method. In the fixed time-step method, events take place in steps that increase by a fixed time increment. In the discrete event method, a growing time increment is attributed to the next event. The results of a computer simulation are verified experimentally.

Technical progress will also modify the structural solutions applied to farming equipment. There will be growing demand for new-generation farming machines equipped with satellite navigation, board computers, and feedback control systems. GPS navigation and the development of computer technology will create new prospects for intelligent farming machines. The operating conditions and the requirements imposed on such equipment will be determined by physics and agricultural engineering. We must create a design-effective system for controlling and managing agricultural production while ensuring that the technical advancements in farming directly contribute to the quality of the end product. In the near future, precision farming will become the leading branch of agriculture. Many tractors, fertilizer distributors, seeding machines, and combines for harvesting cereal and root crops are equipped with electronic and data transmission systems. Farming and food processing machines are turning into complex mechatronic systems. We are witnessing the

rapid development of remote control solutions for farming machines supplying raw materials for the food production industry. A machine that is a programmable mechatronic system (Mieszkalski, 1998a) equipped with sensors receives signals from the environment during the working process. Those signals are processed and interpreted in view of the existing situation and possible control errors, after which they are transmitted to the machine's steering unit to maintain adequate working parameters and optimize the movement of working elements. In systems equipped with feedback control, the operator is no longer required to directly control the machine's operating parameters. The operator enters into a relationship with a mechatronic system by inputting system data and controlling processed output data. In a mechatronic system, sensors generate signals on the physical quantities of a working process that involves the machine and raw materials. After processing, the signal is transmitted to the steering unit, which modifies working parameters accordingly. Physics also aims to devise new solutions for sensors analyzing the physical condition of the processed plant and animal raw materials. One of such examples is the electronic nose, which monitors changes in the aroma of farming produce during storage. This solution involves artificial neural networks that have been trained to detect the age of grain (Zhang and Wang, 2008).

The contemporary GIS technology with 3D spatial data and the option of developing numerical terrain and field maps, crop maps, and soil nutrient maps are the stepping stone on the road to developing remotely controlled machines (Karimi et al., 2008). Technological progress in farming production will further the development of sensors for measuring and, when coupled with the possibilities offered by IT systems, monitoring the characteristic properties of the soil, plants, and the atmosphere. Physics and agricultural engineering will propose a variety of new solutions in the area of machine and sensor construction.

Tractors have played and continue to play a vital role in farming. Their horsepower ranges from 30 to around 650. Tractors with the highest output weigh around 20 t. The dynamic growth of physics, farming, biological, technical, and IT sciences has visibly furthered the development of the tractor industry. The leading manufacturers of farming equipment have been conducting intensive research into

the design of driverless tractors. The most important considerations that have to be taken into account in the design of modern tractors are steering systems, control systems as well as ergonomic solutions (Drakopoulos and Mann, 2008). Similar problems have to be tackled as regards other types of farming and food processing equipment.

The requirements imposed on agricultural machines will change owing to the vast variation in the size of farming areas. The main problem is the selection of production technologies and machines that would not lead to the degradation of soil and the natural environment. Heavy-duty, self-propelled farming machinery delivering a high productive yield is developed to cater to the needs of large commercial farms. The problem of excessive pressure exerted on soil by farming equipment, in particular heavy-duty machines, has not been solved to date. Designers are short of ideas for building an innovative drive system. The existing choice is limited to wheel and caterpillar drive systems (Figure 5). Farming machinery is becoming heavier, and it exerts a growing load on the soil. The intensive use of contemporary machines leads to soil rolling, structural damage, and degradation. Machines weighing 20 t, mostly potato harvesters, exert a highly negative effect on loosened soil by compacting it excessively (Figure 6). Vehicles transporting the harvested crops to the place of storage also contribute to soil damage.

Soil fragmentation and structural damage caused by rotary and swirl harrows are also a serious problem (Figure 7). Disk blades of rotary and swirl harrows used in simplified farming systems produce a cycloidal motion and exert an uneven effect on the soil (Figures 8 and 9) (Mieszkalski, 1998b). There are no effective solutions protecting harrows against damage when the disk blade hits a hard obstacle, such as a rock.

Global climate change will have a growing impact on agriculture. In many regions, milder winters marked by fewer days with below-zero temperatures and less snow undermine the purpose of deep fall plowing. A detailed analysis of the effect of plowing on the dynamics of soil changes in view of climate change will contribute to the search for new cultivation technologies, including methods that do not rely on plows.

The challenge for designers is to develop new technologies to minimize the adverse effects of chemicalization of

Agriculture and Food Machinery, Application of Physics for Improving, Figure 5 Wheels and caterpillars in farming machines.

Agriculture and Food Machinery, Application of Physics for Improving, Figure 6 Excessive soil compaction caused by farming machines.

Agriculture and Food Machinery, Application of Physics for Improving, Figure 7 Harrow rotor's effect on the soil.

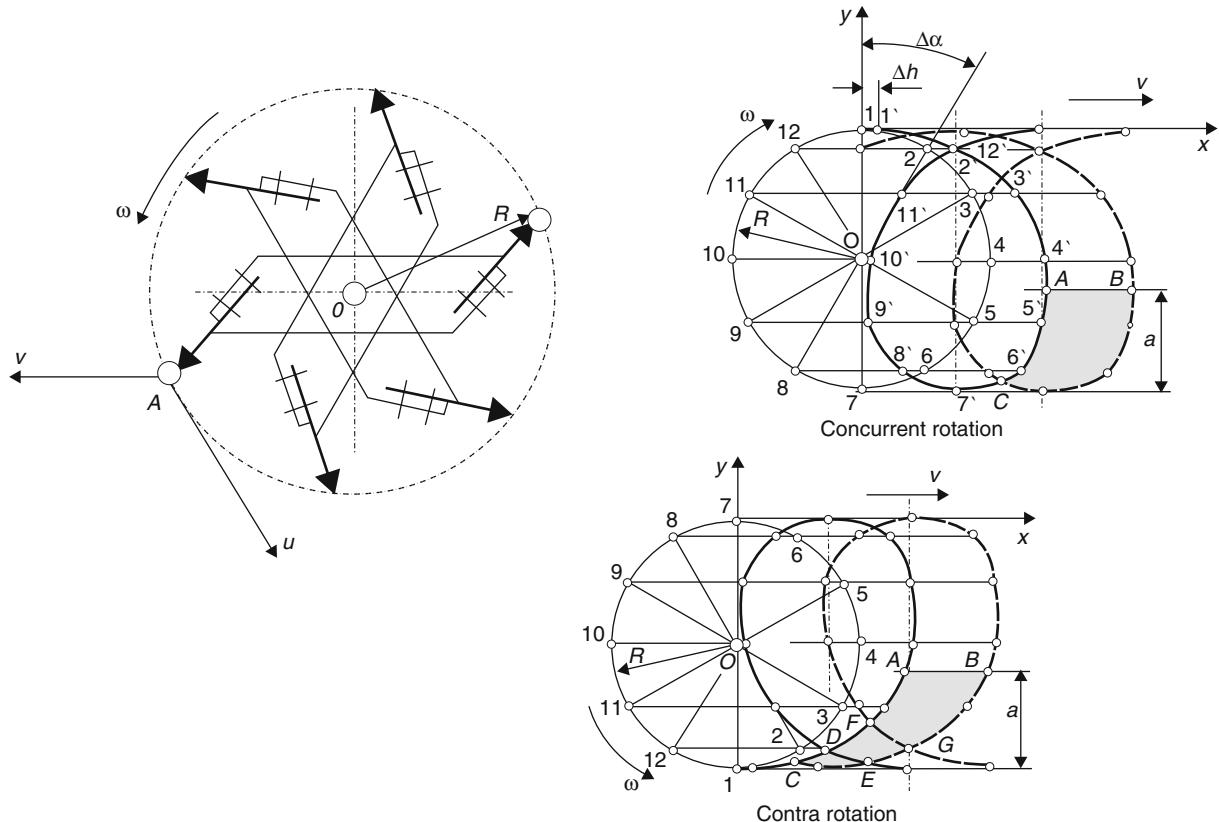

food products and production in general. We must prevent environmental degradation of not reducing the standards of living. Environmental contamination caused by physical, chemical, and biological factors applied in the growing of farm produce and the food processing industry poses a mounting problem. The production of wheat grain, for example, involves around six chemical treatments. Designers are faced with the challenge of inventing machines and equipment that support such technological processes.

The problem of excessive chemicalization is also encountered in the food processing industry. The applied pesticides and mineral fertilizers systematically introduce toxic substances to the soil across large areas. An

interesting alternative is the use of optical sensors in electronic weed control systems, which selectively spray herbicides on crop plantations (Celen et al., 2008). The failure to observe waiting periods makes the soil, plants, seeds, and crops susceptible to the deposition of toxins. As a result, harmful substances enter the food chain of humans and breeding animals. Despite the application of precision farming methods (soil fertility maps, board computers), the disks of fertilizer distributors do not spread the fertilizer evenly across the field. There is a dire need for new methods of protecting plants against weeds and pests that do not rely on chemicals and minimize environmental contamination. Precision agriculture offers such a solution. New methods are also needed for the early detection of disease sources and pest development stages to support the quick implementation of treatment methods that do not involve chemicals. Image analysis coupled with precision pesticide application is an innovative option. For the needs of farming production, chemicals should be regarded as medical treatment, not a method of increasing crop yield that disregards quality considerations. Product chemicalization in the food processing industry adds to the problem. Appropriate solutions should be offered by science, in particular agrophysics, agricultural engineering, and food engineering.

Combines for harvesting grain, potatoes, carrots, and beets are part of a rapidly developing market of farming machines. Advanced solutions are implemented in the group of combine harvesters whose main working elements have not been upgraded in the past 150 years. The introduced modifications include double-rail axial threshing mechanisms, double-cylinder threshing units, straw shaker supports, belt conveyors instead of worm conveyors in combine headers, laser remote control systems for guiding combines, and many other solutions. In designing, it is important to ask and seek answers for questions, for example: Is a combine harvester the ultimate solution? Should threshing take place in the field? How can the seed ripening period be prolonged? Can grain harvesting be mechanized or automated with the use of modern technology that replaces combines and economizes the harvesting process? Modern combine harvesters are equipped with board computers for controlling and monitoring the machine's working parameters and the quality of harvesting operations. Satellite navigation systems support the generation of digital yield maps (Fulton et al., 2009). Combine harvesters are also equipped with vision systems comprising several video cameras outside the machine for surveying the harvested area.

By-products of the farming process, such as straw, are also an important consideration in view of the changes taking place in agricultural practice. Straw is pressed in the field, and its density reaches around 180 kg m^{-3} . Various structural solutions for straw presses are available. Presses are equipped with control units for monitoring the compacting process and its working parameters. Straw used as an energy resource is compacted into pellets with density of up to $1,400 \text{ kg m}^{-3}$ as well as into briquettes

Agriculture and Food Machinery, Application of Physics for Improving, Figure 8 Motion trajectory of rotary harrow disk blades.

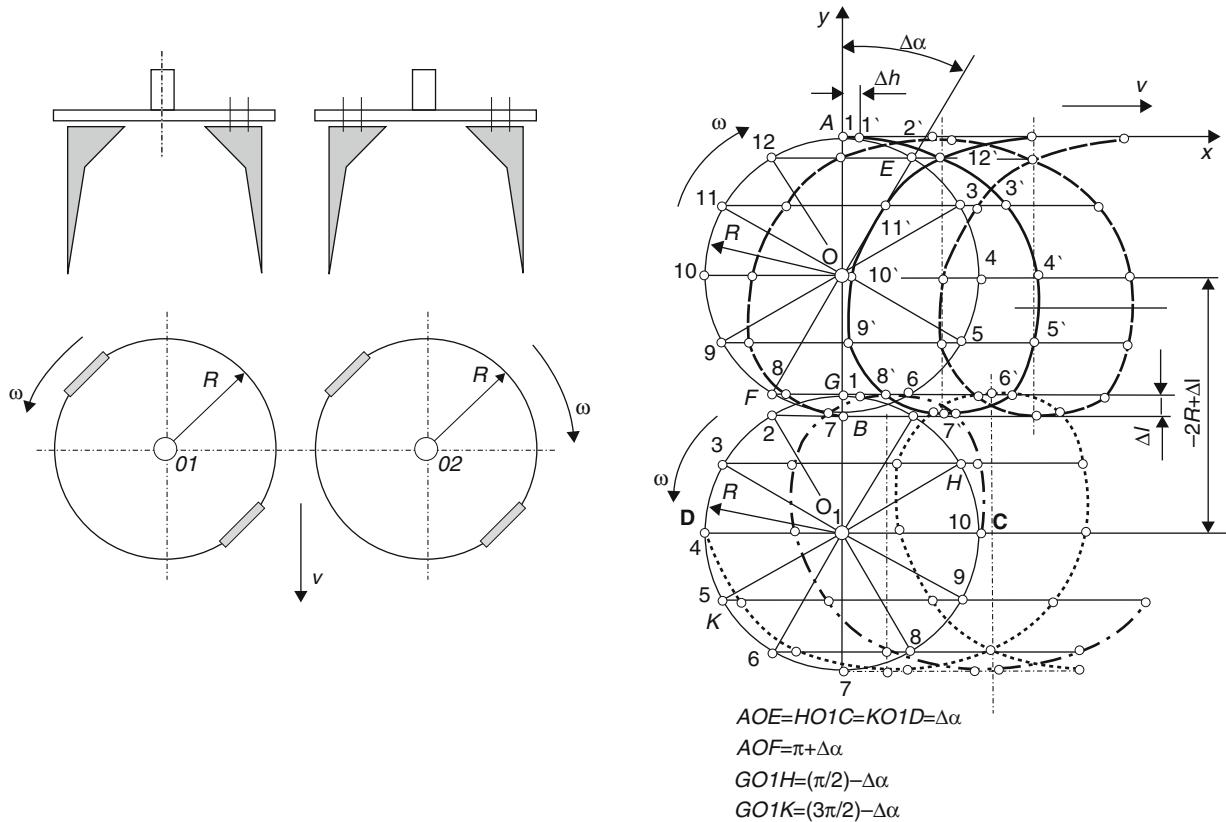

with density of around 700 kg m^{-3} . New briquetting techniques will soon be developed with the involvement of, for example, straw rolling, to produce briquette density of 500 kg m^{-3} or higher.

Significant progress is also noted in numerical methods for data processing and process virtualization in farming and food production. Production lines with a feedback control signal are implemented in food processing plants.

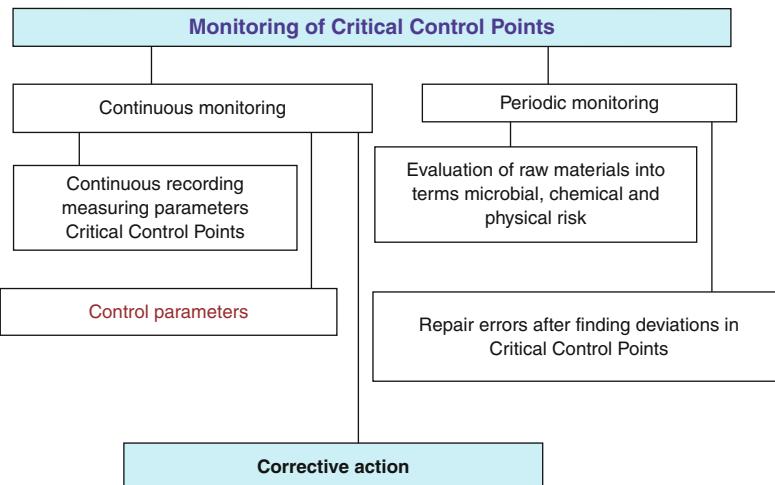

Production of raw materials and food processing technologically must be adapted to quality management requirements. Food processing plants implement HACCP systems for analyzing biological, chemical, and physical threats and for measuring and monitoring critical parameters that significantly affect food safety and quality. Risk evaluation in food production poses another challenge. The task of food engineering, agricultural engineering, physics, and other sciences is to devise methods ensuring the safe application of chemicals, food additives, and bio-engineered foods. The selection of adequate risk evaluation methods in the food industry is a difficult process because food products contain a high number of ingredients, which form a variety of combinations (Brock et al., 2003; Blaha, 2001). Biotechnology plays an increasingly important role in food production, and it involves the modification of the natural ingredients of foodstuffs (Taylor, 2003). Various branches of science, including

food engineering, agricultural engineering, and physics, search for effective and transparent production methods that guarantee the safety of bio-engineered products that have not been mass produced to date. Food safety systems monitor the value of critical parameters at control points of the production line to ensure that qualitative requirements are met. Critical parameters are monitored continuously and periodically with the use of principles of mathematical statistics (Figure 10). Continuous monitoring supports production with a feedback control signal. The production process is observed by experts on computer screens. Many operations are performed on fully automated lines. Automated systems are tested on grafted tomato seedlings for monitoring the external features of plants during growth (Chiu et al., 2008). Camera vision systems are used to classify farming produce by determining its physical properties such as length, diameter, curvature, flower color, flower size, and surface damage (Chong et al., 2008).

Robots are increasingly often used in food production. New robots equipped with complex kinematic systems, sensory devices, vision cameras, and complex control algorithms have a growing number of applications in the food industry. They are used for object grabbing with pressure control, transporting, packaging, palletizing, production line work (e.g., carcass dressing), cooling plant

Agriculture and Food Machinery, Application of Physics for Improving, Figure 9 Motion trajectory of swirl harrow disk blades.

Agriculture and Food Machinery, Application of Physics for Improving, Figure 10 Block diagram of monitoring physical quantities and working parameters during a technological process.

operations, etc. Greenhouses were the first farming sites to introduce mobile robots (González et al., 2009).

In an era marked by dynamic changes in the global culture, which is becoming dominated by politics, free

market principles, consumerism, temporary solutions, and the flood of information that dulls our senses, scientists have to ask precise questions and search for the answers. Modern technology and economy cannot replace

quality. The most urgent task for physics, agricultural and food engineering is the search for effective production methods that guarantee the highest quality of both raw materials and the end product. The above will be determined by their willingness to tackle complex problems. In an era marked by growing production, higher work efficiency, and soaring competition, we need to reflect and develop a rational approach to technological progress in line with the following motto: "to produce, but without doing harm to nature and mankind".

The process of building contemporary machines relies on data from various fields of science. Physics plays an important role in this process by searching for new structural materials, methods for determining their physical properties, and the displacement of elementary particles under the influence of internal and external forces. As regards the design of farming and food processing machines, the role of physics is to find new mechanisms and new methods of kinematic and dynamic analyses. The determination of trajectory, speed and acceleration, and the search for motion that meets a given set of kinematic conditions are very important considerations in the kinematics of mechanisms. Dynamics is also of paramount significance in the construction of farming and food processing machines as it determines changes in force over time during operation and the correlation between motion and the forces acting on different parts of a machine. The variability of load applied to the working elements of a machine results from the non-homogeneity of the processed biological material. Substrate variability and changes in its spatial configuration affect the load applied to the working elements of a farming machine. The elements of farming and food processing machines are subjected to complex, often nonlinear load. The search for methods of anticipating the behavior of machines and their subassemblies under the influence of variable and stochastic load poses a serious challenge for contemporary physics. New scientific theories in the field of nonlinear system dynamics need to be formulated. The working process of farming and food processing machines is the result of many complex relations between the machine, its operator, and the operating environment. Physics should play a fundamental role in the search for relations that are optimal for machines, man, and the environment.

Owing to the vast diversity of farming and food processing machines, the role of physics in the process of designing and modifying all models cannot be described in detail. In this group of machines, a number of work processes have a universal character. The key processes in obtaining plant materials for food production are: soil engaging operations, seedbed preparation, inter-row tillage, spreading of organic and mineral fertilizers, distribution and planting of seeds, seed-potatoes and seedlings, formation of liquid droplet streams for plant protection and stream distribution on plant surface, cutting plant material, reeling, gathering, shaking, raking and transporting stem material, crushing stem material, threshing, separating, and transporting crops. The following general

processes take place in food production: shredding, separation, liquid flow, filtration, pressing, forming, liquid squeezing, movement of solids in liquid, movement of liquids in liquid, agglomeration, hulling, peeling, drilling, cleaning, germination, polishing, removing inedible parts, gravitational and centrifugal separation, straining, settling, classification, transport, mixing and dosing, cleaning, packaging, drying, distilling, extracting, leaching, cooling, freezing, heat processing, and pressure processing. The design of farming and food processing machines relies heavily on data on the physical and chemical properties of soil, raw materials, food products, technological process, and the design methodology. Physics contributes vast amounts of information on the physical properties of soil, raw materials, and food products, and it describes physical phenomena that occur when raw materials are processed into foodstuffs.

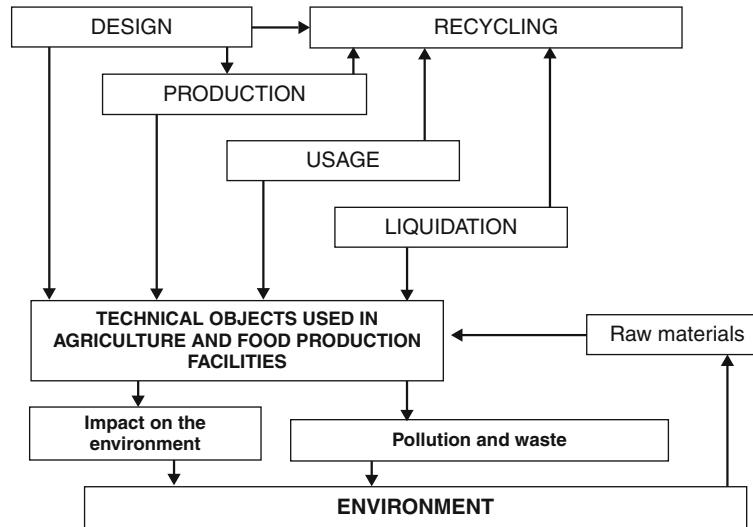

Designers building farming and food processing machines have to account for all stages in the machine's life cycle (Figure 11). The quality of serially structured design decisions determines the usable properties of machines, the safety of operators, and the impact of machines on the natural environment. Farming machines are closely interrelated with the environment throughout their entire working life. The natural environment supplies nonrenewable resources for the production of structural materials. The manufacture, use, and scrapping of farming and food processing machines is a source of waste and pollution that has a highly adverse effect on man and the environment (Park and Kim 2009a, b, c). New solutions are needed for recycling used materials to limit or eliminate the disposal of worn-out machines and lower the demand for new resources. Physical sciences will support the development of new methods for applying recycled materials in the production of brand-new items and protecting the natural environment against the hazards posed by other scientific inventions, such as gamma ray and X-ray radiation.

Above all, the main goal of practical inventions delivered by research in physics should be the well-being of humans and the protection of the natural environment.

Summary

Many problems still await a solution. The greatest challenges involve the standardization of farming sites, determination of the spatial and structural attributes of soil, raw materials and products, protection of food products against negative factors, modeling and computer-aided simulation of food production processes, developing effective methods for evaluating food quality, designing new measuring systems for monitoring, storing and processing data, and effective decision-making at different stages of the food production process.

Use of latest achievements of science is required in studies of physical properties of raw materials and food products. Use of advanced measuring technologies is essential in gaining new information on the raw material and food production. In the production of raw materials

Agriculture and Food Machinery, Application of Physics for Improving, Figure 11 The main stages in the life cycle of a farming and a food processing machine and its impact on the natural environment.

increasing role plays precision farming. Automatization with robots use is developing rapidly. Further interdisciplinary research is needed to achieve safe food product, both produced on an industrial scale and in small manufacturing plants. It is important to search for new food products, and new food technologies in mass and local production. Modern machines should concerned new technologies of food preservation, conservation and food packaging considering positive influence on peoples' health.

AGROFORESTRY SYSTEMS, EFFECTS ON WATER BALANCE IN CROPPING ZONE

Andrzej Kędziora
 Institute for Agricultural and Forest Environment, Polish Academy of Sciences, Poznań, Poland

Definition

Many definitions were formulated within last few decades. One of the last definitions was made up by World Agroforestry Centre (ICRAF) in 1993:

Agroforestry is a collective name for land use systems and practices in which woody perennials are deliberately integrated with crops and/or animals on the same land management unit. The integration can be either in a spatial mixture or in a temporal sequence. There are normally both ecological and economic interactions between woody and nonwoody components in agroforestry.

Agroforestry is a land use system that allows for the concurrent production of trees and agricultural crops from the same piece of land (Gordon and Newman, 1997).

Agroforestry should be considered as a dynamic, ecologically based, natural resource management system that, through the integration of trees in farm and rangeland, diversifies and sustains production for increased social, economic, and environmental benefits (Leakey, 1996).

History

It has a rich history of development and has been practiced in some parts of the world for more than 6,000 years. Much recent research into agroforestry has been carried out in the tropics and within the context of developing nations, where land shortages brought about by the rapid growth in population demand that efficient production systems for both wood and food be developed and enhanced.

Agroforestry is an age-old practice throughout the world, but its recognition as a science is nearly 5 decades old. For example, during the Han Dynasty (206 BC to AD 220), administrators recommended that forests be developed to accommodate livestock husbandry and crops, according to varying site conditions. Qi Min Yao Shu reported that during the sixth century, the Chinese scholar tree (*Sophora japonica*) was planted with hemp for the purpose of increasing hemp growth and to improve the form of trees for future roadside plantations (Gordon and Newman, 1997).

In mid-1970s, the International Center for Research in Agroforestry (ICRAF) was created in response to a visionary study in the mid-1970s led by forester John Bene of Canada's International Development Research Centre (IDRC). The study coined the term "agroforestry" and called for global recognition of the key role trees play on farms. This initiation led to the establishment of ICRAF in 1978 to promote agroforestry research in developing countries.

During the 1980s, ICRAF operated as an information council focused on Africa. It joined the Consultative Group on International Agricultural Research (CGIAR) in 1991 to conduct strategic research on agroforestry at a global scale, changing its name from Council to Centre. After joining the CGIAR, the Centre explicitly linked its work to the goals of the CGIAR – reducing poverty, increasing food security, and improving the environment – through two means: overcoming land depletion in smallholder farms of subhumid and semiarid Africa, and searching for alternatives to slash-and-burn agriculture at the margins of the humid tropical forests. In implementing this strategy, the Centre expanded into South America and Southeast Asia while strengthening its activities in Africa.

Within 1990s, ICRAF continued the process of institutional transformation by developing a science culture, building excellent research facilities, and doubling its financial and human resources by 1996. The Centre formally adopted an integrated natural resource management framework for all of its work, and institutionalized its commitment to impact by creating a Development Group dedicated to moving research results onto farmers' fields.

In 2002, the Centre acquired the brand name the “World Agroforestry Centre”; however, the “International Centre for Research in Agroforestry” remains our legal name. The new name reflects the fact that the Centre is now recognized as the international leader in agroforestry research and development. Realistically, however, the Centre cannot possibly provide expertise on all conceivable dimensions of agroforestry – nor do we wish to do so. There are advantages to specialization, which is why the Centre engages in strategic alliances with a range of other institutions. Some of these partners are centers of scientific excellence in specific topics of relevance to agroforestry; others specialize in the effective delivery of research results to farmer’s fields (Technical Advisory, 1993).

Agroforestry

The “art” of agroforestry has evolved over centuries; agroforestry as a formalized approach to land use is more recent. Agroforestry is promoted on the basis that it can provide biological, economic, and social advantages. ICRAF’s Strategic Plan (Technical Advisory, 1993) states “resource-poor rural households benefit from improved soil fertility coming from the introduction of nitrogen-fixing trees in enriched fallows or through interplanting; they gain additional income through sale of tree products such as fruit or timber; and gain improved food security associated with the way the perennial component of agroforestry systems extends the season when green fodder and food supplies are available. The latter benefit has significant implications for the nutritional vulnerability of the poorest groups, especially women and children. At the same time, the quality of the environment is maintained through the maintenance of biological diversity, preservation of water catchments and soil quality, and a halt to the net loss of forested land.”

Agroforestry combines agriculture and forestry technologies to create more integrated, diverse, productive, profitable, healthy, and sustainable land-use systems. It means that trees are intentionally used within agricultural systems. Knowledge, careful selection of species, and good management of trees and crops are needed to maximize the production and positive effects of trees and to minimize negative competitive effects on crops.

Agroforestry must satisfies four requirements: (1) it is a form of multiple cropping, (2) at least one component is a woody perennial, (3) the component interacts biologically, (4) at least one of plant species is managed for forage, annual or perennial crop production (Somarriba, 1992). Agroforestry must be compatible with local socio-cultural practices and serve to improve living conditions in the region.

Agroforestry systems can be advantageous over conventional agricultural and forest production methods through increased productivity, economic benefits, social outcomes, and the ecological goods and services provided.

There are five basic types of agroforestry practices today: alley cropping, silvopasture, windbreaks, riparian

buffers, and forest farming. Within each agroforestry practice, there is a continuum of options available to land-owners depending on their own goals (e.g., whether to maximize the production of interplanted crops, animal forage, or trees).

Alley cropping

Alley cropping, sometimes referred to as “sun systems,” is a form of intercropping, and can be applied by farmers as a strategy to combat soil erosion, to increase the diversity of farmland, as a means for crop diversification and to derive other integrated benefits. In this practice, crops are planted in strips in the alleys formed between rows of trees and/or shrubs. The potential benefits of this design include the provision of shade in hot, dry environments (reducing water loss from evaporation), retention of soil moisture, increase in the structural diversity of the site, and wildlife habitat. The woody perennials in these systems can produce fruit, fuelwood, fodder, or trimmings to be made into mulch.

Alley cropping involves growing crops (grains, forages, vegetables, etc.) between trees planted in rows. The spacing between the rows is designed to accommodate the mature size of the trees while leaving room for the planned alley crops. When sun-loving plants like corn or some herbs will be alley cropped, the alleyways need to be wide enough to let in plenty of light even when the trees have matured.

Like all integrated systems, alley cropping requires skillful management and careful planning. Both the crop and the trees have requirements that sometimes necessitate tradeoffs between them. The design must allow sufficient room for the equipment needed to service each enterprise.

Silvopasture

Silvopastures combine livestock grazing on forage crops or pastures within actively managed tree or shrub crops. Cattle, sheep, and goats are the most common livestock incorporated into silvopasture systems and they may be deployed entirely within a private farm/woodlot silvopasture or through collaborative arrangements between forest licensees and livestock producers on public lands. Tree and pasture combinations are called *silvopastoral agroforestry*. Hardwoods (sometimes nut trees) and/or pines are planted in single or multiple rows, and livestock graze between them. Although both the trees and the livestock must be managed for production, some systems emphasize one over the other. Usually, in the early years of establishment, crops or hay are harvested from the planting. Grazing generally begins after 2 or 3 years, when the trees are large enough that the livestock cannot damage them. In other instances, tree tubes and electric fencing protect the young trees, and grazing begins immediately.

Grazing livestock on silvopasture eliminates some of the costs of tree maintenance. With good grazing management, for example, herbicides and mowing may become unnecessary. Grazing also enhances nutrient cycling and

reduces commercial fertilizer costs; the animals remove few nutrients, and their waste is a valuable input for the trees. Well-managed grazing will increase organic matter and improve soil conditions. However, controlling the number of animals per area, limiting the number of days those animals remain on each site, and avoiding compaction are critical for a successful silvopasture system.

Windbreaks or shelterbelts

Extensive research on windbreaks, also called *shelterbelts*, has been carried out in many countries. Trees are planted in single or multiple rows along the edge of a field to reduce wind effects on crops or livestock. Windbreaks have been shown to reduce wind impact over a horizontal distance equaling at least ten times the height of the trees. Wind and water erosion are reduced, creating a moist, more favorable microclimate for the crop. In the winter the windbreak traps snow, and any winter crops or livestock are protected from chilling winds. Beneficial insects find permanent habitat in windbreaks, enhancing crop protection.

Although the trees compete for available water along the edges between the windbreak and the crop rows, potentially reducing crop yield near the windbreak, the net effect on productivity is positive. In fact, even on land that is well suited for high-value crops, a windbreak can increase the crop yield of the entire downwind field by as much as 20%, even when the windbreak area is included in the acreage total.

Windbreaks can be designed specifically for sheltering livestock. Studies have shown the economic advantages of providing protection from wind chill, a major stress on animals that live outside in the winter. Reduced feed bills, increases in milk production, and improved calving success have resulted from the use of windbreaks. Besides providing protection to crops and livestock, windbreaks offer other advantages. They benefit wildlife, especially by serving as continuous corridors along which animals can safely move.

Any tree species can be used in a windbreak. However, deciduous species, even in multiple rows, will lose effectiveness when they lose their leaves. For year-round use, some of the species selected should be evergreen. Fast-growing trees should be included; it is best to plant deep-rooted, noncompetitive species along the edges. Regular deep chisel plowing along the edges will keep roots from spreading into the crop rows. If some of the trees are harvested periodically, replacements can be planted, establishing a long-term rotation.

Riparian buffers and integrated riparian management

Riparian buffers are managed forest and shrubs belts in areas bordering lakes, streams, rivers, and wetlands. Integrated riparian management systems are used to enhance and protect aquatic and riparian resources as well as generating income from timber and non-timber forest

products. Similar to shelter and timberbelts, integrated riparian management systems can employ a wide variety of tree and shrub species, with specific plantings tailored to suit the specific growing conditions and production opportunities.

Trees, grasses, and/or shrubs planted in areas along streams or rivers are called *riparian buffers* or *filter strips*. These plantings are designed to catch soil, excess nutrients, and chemical pesticides moving over the land's surface before they enter waterways. Such plantings also physically stabilize stream banks. On cropland that is tiled to improve drainage, polluted water can flow directly into streams; constructed wetlands installed in the buffers can capture and clean this drainage water before it enters the stream. Shading the water keeps it cooler, an essential condition for many desirable aquatic species. Buffer strips also provide wildlife habitat and can be managed for special forest products.

Forest farming and special forest products

Forest farming, also known as "shade systems," is the sustainable, integrated cultivation of both timber and non-timber forest products in a forest setting. Forest farming is separate and distinct from the opportunistic exploitation – wild harvest of non-timber forest products. Successful forest farming operations produce mushrooms, maple and birch syrup, native plants used for landscaping and floral greenery (e.g., salal, sword fern, bear grass, cedar boughs, and others), medicinal and pharmaceutical products (e.g., ginseng, goldenseal, cascara, or yew bark), wild berries, and fruit. When a natural forested area is managed for both wood products and an additional enterprise, it becomes an agroforestry system. Besides producing saw timber and pulpwood, woodlands can generate income from many other products. Established forests offer many non-timber "special forest products" that contribute to cash flow without requiring the one-time harvest of old trees. For example, landowners can manage established woods to encourage naturally occurring patches of berries or bittersweet. Or they might plant understory crops adapted to the forest type and climate. Growing mushrooms on logs is another, more labor-intensive, possibility; a canopy of either hardwoods or pine will provide the shade needed to maintain moisture for fruiting.

Benefits

Agroforestry practices may also be employed to realize a number of other associated environmental services, including

- Carbon sequestration
- Odor, dust, and noise reduction
- Wastewater or manure management (e.g., utilizing urban wastewater on intensive, short rotation forests for wood fiber production)
- Green space and visual aesthetics
- Enhancement or maintenance of wildlife habitat

Biodiversity in agroforestry systems is typically higher than in conventional agricultural systems. Agroforestry incorporates at least several plant species into a given land area and creates a more complex habitat that can support a wider variety of birds, insects, and other animals. Agroforestry also has the potential to help reduce climate change since trees take up and store carbon at a faster rate than crop plants.

The resulting biological interactions provide multiple benefits, including diversified income sources, increased biological production, better water quality, and improved habitat for both humans and wildlife. Farmers adopt agroforestry practices for two reasons. They want to increase their economic stability and they want to improve the management of natural resources under their care.

Agroforestry practices can increase farmer's annual incomes. Some increases in revenue come from harvesting different tree crops in different seasons. The result is that income and employment are distributed more evenly throughout the year. There are also many other reasons for growing trees on farms, such as the provision of shade for cooler soil temperatures, reduction of soil moisture loss, and protection of the soil from wind and water erosion. Agroforestry systems can reduce the risk of total crop failure. For example, if the viability of one crop is reduced by pest damage or market failure, the farmer can make up for it by harvesting another crop.

Summary

Land-use options that increase resilience and reduce vulnerability of contemporary societies are fundamental to livelihood improvement and adaptation to environmental change. Agroforestry as a traditional land-use adaptation may potentially support livelihood improvement through simultaneous production of food, fodder, and firewood as well as mitigation of the impact of climate change.

To promote well-being of the society, management of multifunctional agroforestry needs to be strengthened by innovations in domestication of useful species and crafting market regimes for the products derived from agroforestry and ethnforestry systems. Future research is required to eliminate many of the uncertainties that remain, and also carefully test the main functions attributed to agroforestry against alternative land-use options in order to know equivocally as to what extent agroforestry served these purposes.

The ecological integrity of an agroforest is a state of system development in which the habitat structure, natural functions, and species composition of the system are interacting in ways that ensure its sustainability in the face of changing environmental conditions as well as both internal and external stresses (Wyant, 1996).

AGROGEOLOGY

Ward Chesworth
Department of Land Resource Science, University of Guelph, Guelph, ON, Canada

Synonyms

Agricultural geology; Soil science (obsolete)

Definition

Agrogeology: any and all aspects of earth science that relate to agriculture and are impacted by agriculture.
Anthrobleme: the physical manifestation of human activities on the surface of the earth. From Greek roots meaning "human scar."
Anthropocene: the present geological age, taken to date from the Neolithic Revolution, approximately 10,000 years ago.

Biosphere: the surface and near-surface region of the earth where living organisms exist.

Deposition: the laying down or precipitation of materials at the surface of the earth.

Erosion: the loosening and removal of a rock or soil formation by natural or anthropic agencies.

Malthusian collapse: the state reached when population increases to outrun food resources. Named for the Reverend Thomas Malthus who published An Essay on the Principle of Population in 1798.

Neolithic Revolution: the transformation in human lifestyle that began slightly more than 10,000 years ago, when hunting and gathering began to give way to agriculture as the principal means of food production.

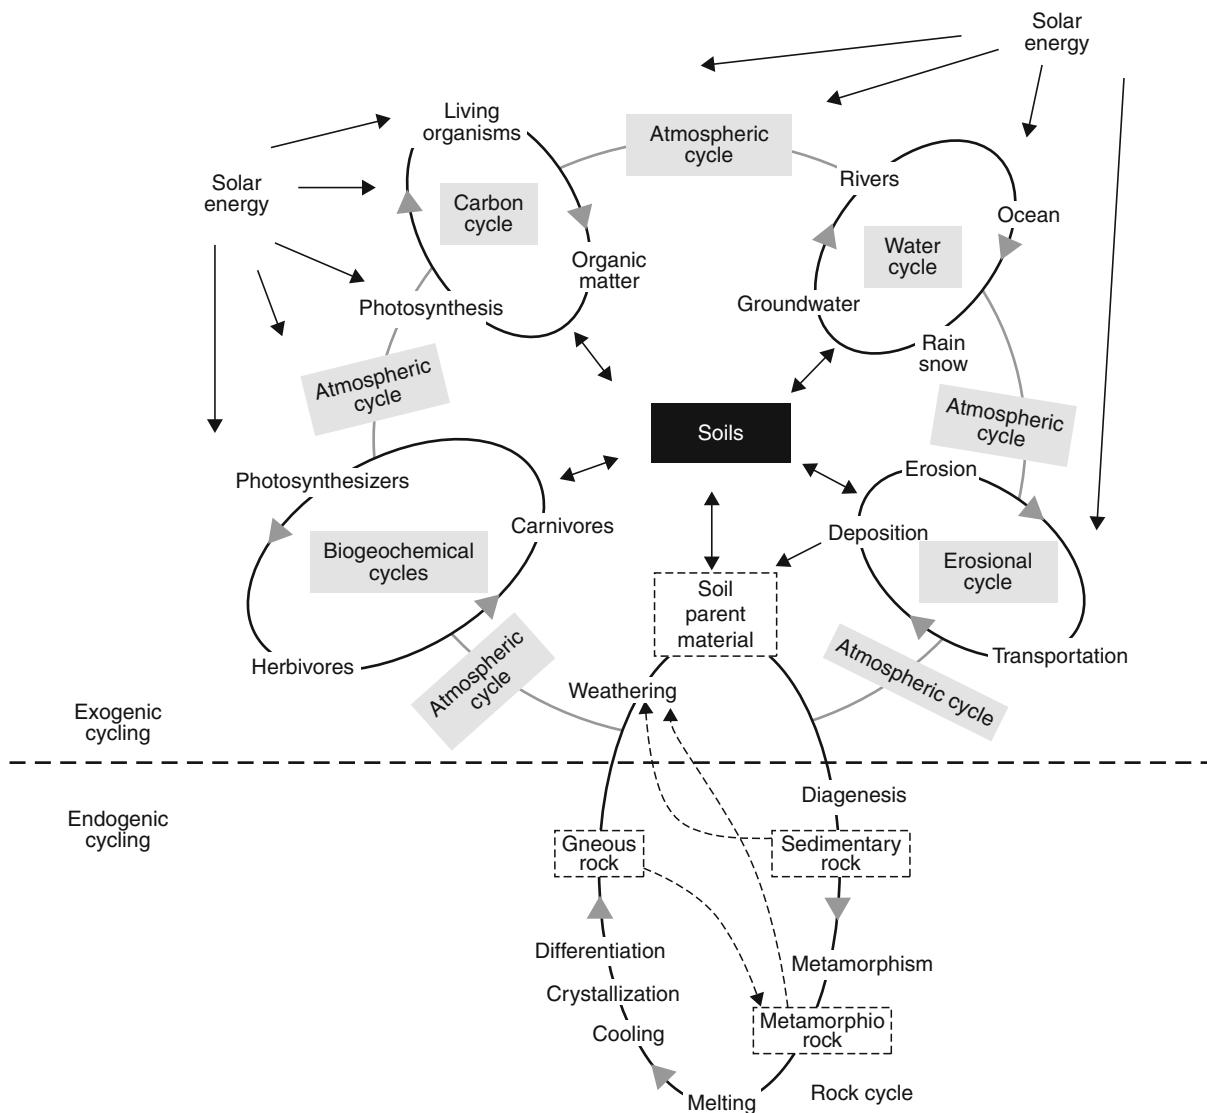

Transport: the movement of the products of weathering and erosion by water, wind, ice or biological (including human) activity.

Weathering: the chemical and physical breakdown of rocks and minerals at the surface of the earth.

Würm: the last ice sheet in Europe, between 24,000 and 10,000 years before the present. Roughly equivalent to the Wisconsinan glaciation in North America. Other local equivalents exist.

Introduction

Agrogeology is concerned with the science of geology in the context of agricultural science. The most obvious

Agrogeology, Figure 1 The centrality of soil in the exogenic, or external geological cycle on the earth, and its relationship with the endogenic, or internal cycle.

connection between the disciplines is soil, the geological substrate for the farmers' crop. But agriculture is massively contingent on geology for other reasons as well. Not only do the common geological processes of the planetary surface – weathering, transport and deposition – form soil in the first place, they are also implicated in the demise of soil, especially by the process of erosion (Chesworth, 2008).

Soil: the primary geological resource of the farmer

The centrality of soil on the earth's land surface is shown in Figure 1. It is an integral component of all major chemical and physical cycles of a geological nature, that take place there. Figure 2 depicts similar relationships, but with an important change of perspective. Seeing soil metaphorically in the neck of an hourglass, emphasizes its strategic position in the biosphere, but, importantly in the present context, emphasizes the vulnerability of the biosphere to any damage to the soil from natural or anthropic activities.

The evolution of soil can be thought of in terms of two geochemical pumps – a proton pump, and an electron pump. Protons are provided by two sources, rainwater (charged with CO₂) and the dissociation of –COOH

groups on the breakdown products of organic matter. The dominant form of electrons in soil is decaying organic matter.

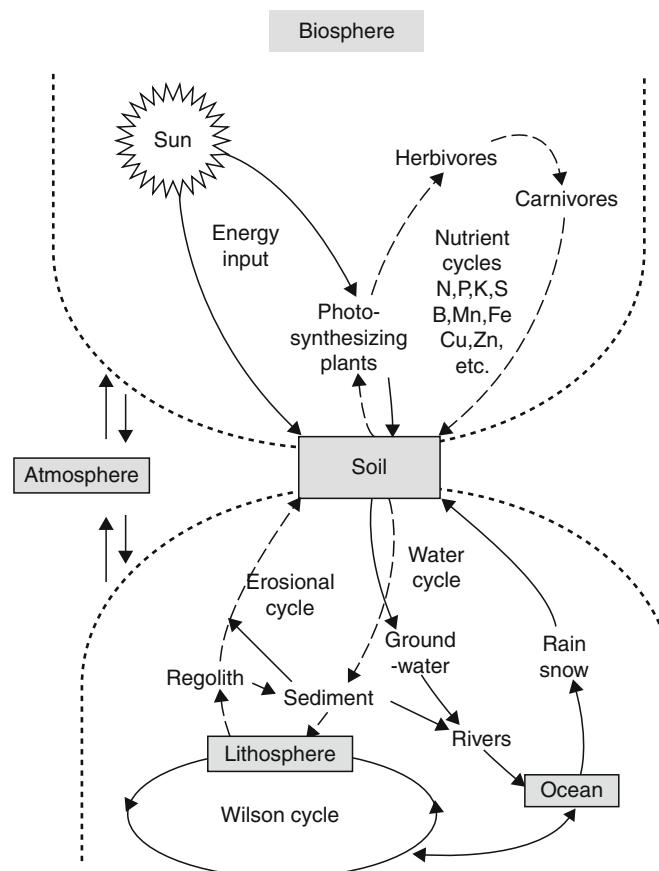

Protons flow from their source to a sink represented by the earth's surface, which acts as a base. A massive titration takes place during weathering, and in humid climates it amounts to an over-titration resulting in a progressive acidification of the soils of the land surface. In arid climates it is an under-titration, and soils progress along a path of alkalinization.

The dominant sink for electrons at the earth's surface, including within the pore space of unsaturated soils, is atmospheric oxygen. When this is unavailable, several ions in high oxidation states, may serve this function, e.g., nitrate, ferric Fe, manganic Mn, and others.

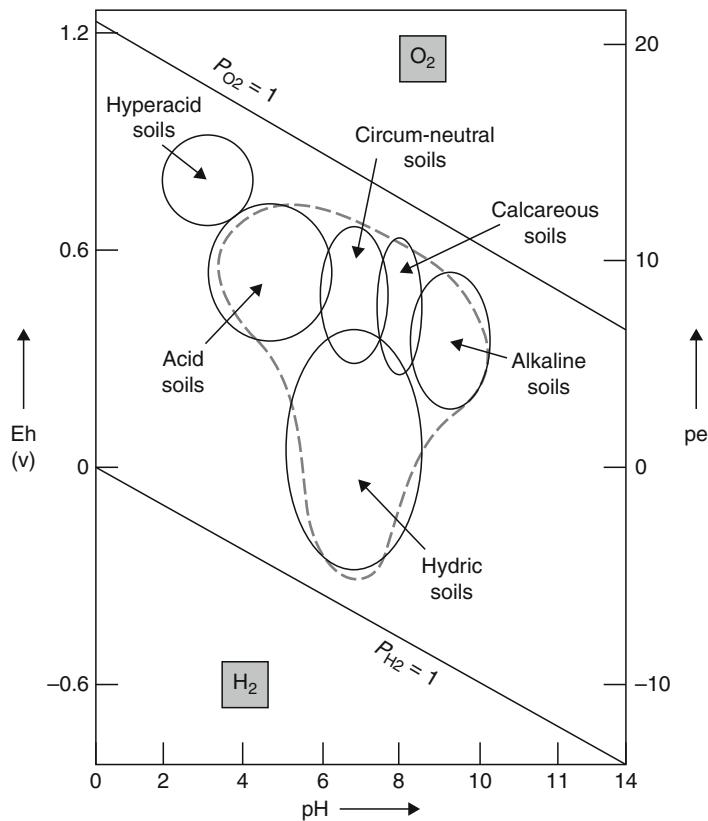

As a result of protons and electrons flowing from source to sink, the geochemical field of soil evolution covers an area of pe–pH space shown in Figure 3.

The geological scar of agriculture

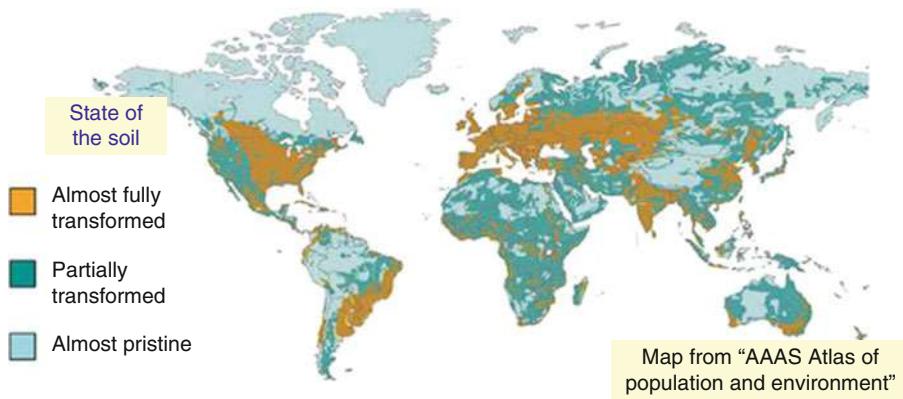

Anthropic effects on soil were relatively minor and local while the genus *Homo* was exclusively hunting and gathering, though when *Homo erectus* learned to control fire

Agrogeology, Figure 2 The hourglass paradigm, showing the critical vulnerability of the biosphere to changes in the soil covering the terrestrial landscape.

Agrogeology, Figure 3 A graphical representation of soils in terms of electron (pe) and proton (pH) variables. Hyperacid soils require a higher concentration of protons than those mentioned in the text, namely by the weathering of sulfides.

Agrogeology, Figure 4 Geological determinism in the pattern of human settlement (the anthroleme, or human scar).

(perhaps as early as 1.8 million years ago), a powerful tool for clearing land became available. It may have been used as such by the hunters and gatherers in order to control the ease with which prey animals were hunted, but with the Neolithic invention of agriculture by *Homo sapiens*, some 10,000–12,000 years ago, it became the principal means by which land was deforested and made ready for cultivation. According to Ruddiman (2010), the agricultural

deforestations that began then, marked the start of a buildup of greenhouse gases in the atmosphere, that received a further boost (as methane) when paddy-rice cultivation became dominant in east Asia about 5,000 years ago. The current threat of global warming may have a long agricultural pedigree.

The earliest agriculturalists for which we have reliable archeological records, practiced their art in the crescent

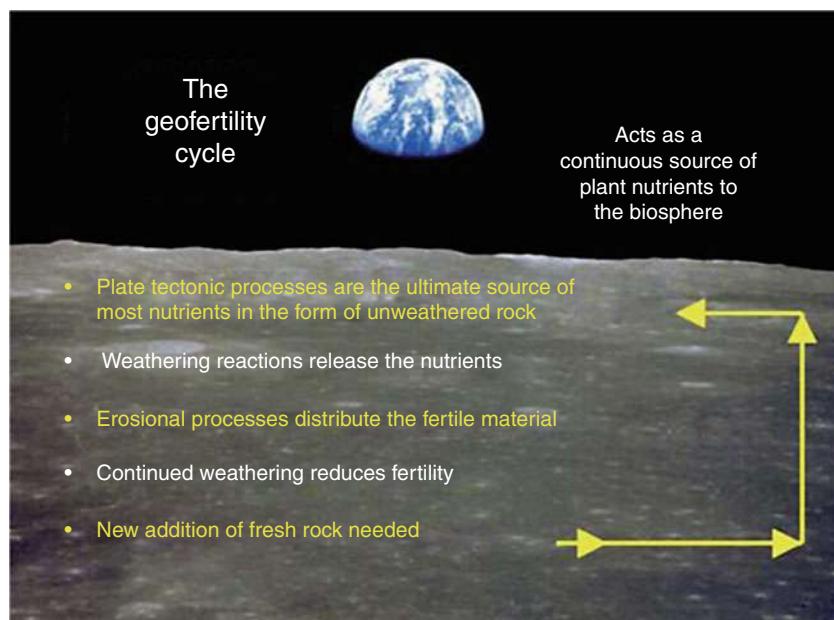

of highland that stretches from the Taurus mountains of southern Turkey to the Zagros mountains of Iran. Çatalhöyük in Turkey is particularly well investigated. Here, farmers depended on the soils developed on geological deposits laid down principally as alluvial fans. They chose light, silty soils that were easy to work, and that were moist for much, if not all of the year. They required no great advancements of technology – no ploughs, no irrigation canals – and they were in a region where the wild progenitors of their crops and farm animals were to be found. Large-scale developments became possible when the farmers, or their technologies migrated into the great river valleys enclosed by the highland rim. The Tigris and Euphrates provided a good source of water and of fertilizing sediments, and the effect was eventually extended onto arid soils when irrigation began to be practiced. It has been surmised that the need to manage water communally was an important impulse in the development of the first civilizations – Sumer, at the head of the Persian Gulf being the earliest on record.

Agriculture spread from its Middle Eastern birthplace to the Nile and the Indus, and because of their dependence on great rivers, the civilizations that developed are commonly referred to as hydraulic civilizations. The advent of agriculture in eastern Asia was probably independent, though it too was based on a large river system, the Huang Ho. In the Americas, farming developed independently of the Old World, and had a geological basis more similar to the agriculture of the Turkish highlands in being based on damp soils on the edges of lakes and wetlands, rather than the soils of large river valleys.

When agriculture expanded into Europe, it took two principal routes and each was facilitated by specific geological circumstances (Chesworth, 2010). The quicker route to the Atlantic was along the Mediterranean, with isolated communities probably developing at the mouths of coastal rivers where wet, light soils could be found. The original sites are probably lost now as a consequence of sea rise as the Würm ice sheet continued to retreat. But isotopic dating confirms that the Mediterranean Coast of Iberia was reached some 7,500 years ago, and the Atlantic coast about a thousand years later. The slower route moved up to the Danube valley and used the light, fertile deposits of loess to cross central Europe to the west. In fact, the footprint stamped on the planet by *H. sapiens*, contains a large component produced by agriculture following the pattern of this important geological sediment, formed by the wind erosion of deposits left by receding ice (Figure 4). Agriculture reached the Atlantic coast of Ireland about 5,000 years ago.

Anthropocene

The early farmers depended in large part on the inherent fertility of the soils they were cultivating. This in turn depends upon the geo-fertility cycle (Figure 5). Following was the simplest technology that allowed a cropped soil to recover fertility (by the weathering of minerals initially provided by the geo-fertility cycle). In essence, this early agriculture depended entirely on renewable resources – sunlight, water, a soil with a good inherent fertility, human muscle. In Egypt, with the Nile as a reliable delivery

Agrogeology, Figure 5 The geo-fertility cycle, the natural means whereby the inherent fertility of the soils of the biosphere is maintained. One major nutrient is not provided by this cycle, nitrogen. That requires the activity of nitrogen-fixing plants in the standing biomass.

system of both water and fertility, agriculture reached as close to a sustainable state as it is likely to get.

Since its Neolithic beginnings, has followed a path from the digging stick, to the ard, the wooden plough, and metal ploughs of increasing power, evolving in tandem with an increasing energy intensiveness, from human to animal muscle, and now to fossil fuel. Over the last 10,000 years or so, we have become the only organism to qualify as a geological force in our own right, a new phenomenon in the geological history of the planet, and one that justifies the recognition of the post Neolithic as a new geological period: the Anthropocene (Crutzen, 2000).

Conclusion

Currently, modern agriculture is utterly dependent on fossil fuels as well as on other nonrenewable geological resources. The rapidly depleting global reserve of natural gas, allows the artificial fixation of nitrogen, a service originally provided in the biosphere by N-fixing organisms. Other nutrient elements are made available by extraction from geological raw materials (phosphorites and potassium-bearing evaporates for example) on an industrial scale. The farming enterprise is now as far from sustainability as it has ever been, and with a world population of almost 7 billion people, a Malthusian collapse of human civilization in its present form, becomes ever more probable.

AGROPHYSICAL OBJECTS (SOILS, PLANTS, AGRICULTURAL PRODUCTS, AND FOODS)

Jan Gliński

Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland

Definition

Agophysical objects are those materials that play an important role in agricultural production. They are characterized by specific physical properties and undergo various natural and human-induced processes.

Four groups of main agrophysical objects are distinguished: soils, agricultural plants, agricultural products, and foods of plant origin.

Soils represent the greatest group among agrophysical objects. For agricultural crops, they are a medium, which is capable of physically supporting plants and constitutes a magazine for the water and nutrients essential for plant growth (Hillel, 2007; Chesworth, 2008). Soils are formed from the uppermost layer of earth crust (mother rocks) under the influence of five main factors: mother rocks, climate, vegetation, relief, and time. The properties of the soils are, in general, dependent on the above factors and therefore create a mosaic of taxonomic soil units as well over small as large areas, which are combined in very different qualities, quantities, and patterns. Soils are extraordinarily complex media, made up of a heterogeneous mixture of solid, liquid, and gaseous phases, as well as a diverse community of living organisms forming irregularities in their physical structure. They are comprised of different soil horizons (layers), aggregates, cracks, and texture classes. The mass of soil is nonrenewable. Even within the same volume of soil a great heterogeneity and anisotropy can be observed. Most soils are predominantly built of mineral material, but they have upper horizons of organic materials and there is a group of typically organic soils. In the near ground area, *microclimate* of cultivated field is distinguished ([Physics of Near Ground Atmosphere](#)).

From about 300 *agricultural plant* species 14 represent the major crops as a source of foods: wheat (the highest area in the world production), rice, maize, potatoes, barley, cassava, sweet potatoes, soya, beans, tomatoes, sorghum, leguminous grains, oats, millet, and rye (the lowest area in the world production) (Langer and Fill, 1991). Plant structure differs with growing conditions of plants and their individual organs (roots, stems, foliage, and harvestable products). As regards masses of plants, they may be bulk- or stored crops, or chopped or even pressed materials. Some plants, for example, willow, fiber crops,

medicinal plants in the form of dead state, are used as agro-resources for the renewable energy, textile industry, building, and medicine.

Agricultural products are living or dead objects. Within their structure, particles, pores, and cells are distinguished. They have typical macroscopic dimensions and shapes. According to their mechanical properties they are divided into four classes: fluids, semiliquids, semisolids, and solids (Blahovec, 2008). Physical conditions during storage and processing of agricultural products such as temperature, moisture, aeration, and pressure affect their structure and quality.

Plant foods include plant and plant parts eaten as food without or after their processing. There are grain-based foods (cereals, legumes, and nuts), oils from oilseeds, fruits, vegetables, bread, and food extrudate products (Guy, 2001).

AGROPHYSICAL PROPERTIES AND PROCESSES

Jan Gliński, Józef Horabik, Jerzy Lipiec
Institute of Agrophysics, Polish Academy of Sciences,
Lublin, Poland

Definitions

Physical process is defined as: "A continuous action or series of changes which alters the material form of matter" and *physical property* as: "Any aspect of an object or substance that can be measured or perceived without changing its identity."

The term *Agrophysical processes and properties* concerns these processes and properties which are used in agrophysics and are relevant to agrophysical objects, i.e., soils, plants, agricultural products, and foods with particular reference to agricultural and environmental applications. Main agrophysical processes and related properties and their technological functions are: aeration, surface phenomena, electricity, mechanics, heat, and hydrology. Some of them are related to all objects or part of them and they have physical quantities expressed in SI units (Scott, 2000; Blahovec, 2008) (see also *Physical Dimensions and Units Use in Agriculture*). Soils which are the most important element of the natural environment undergo changes in their physical properties during natural soil development and also anthropogenic processes such as plowing, compaction, sealing and crusting, erosion, amelioration, loss of humus, salinization, reclamation, and

contamination by inorganic and organic compounds (Blum, 2002; Horn and Baumgartl, 2002). Soil physical processes and properties and resulting soil functions have been specified by Lal and Shukla (2004). Physical processes and related properties of living plants in the field are subjected to environmental pressure, mainly weather conditions (Monteith and Unsworth, 2007) and agricultural products are subjected to technology of food processing (Mohsenin, 1986).

AGROPHYSICS: PHYSICS APPLIED TO AGRICULTURE

Jan Gliński, Józef Horabik, Jerzy Lipiec
Institute of Agrophysics, Polish Academy of Sciences,
Lublin, Poland

Definition

Agrophysics is a science that studies physical processes and properties affecting plant production. The fundaments

of agrophysical investigations are mass (water, air, nutrients) and energy (light, heat) transport in the soil–plant–atmosphere and soil–plant–machine–agricultural products–foods continuums and way of their regulation to reach biomass of high quantity and quality with the sustainability to the environment. The knowledge of physical phenomena in agricultural environment allows increasing efficiency of use of water and chemicals in agriculture and decreasing biomass losses during harvest, transport, storage, and processing.

Short history

The term *agrophysics* was proposed by the Russian physicist A.F. Ioffe (1880–1960) to cover the relations within the soil environment, and especially those of the mass and energy transfer in the soil–plant–atmosphere system (The Agrophysical Institute of the Russian Academy of Agricultural Sciences in Saint-Petersburg: The Roots of Agrophysics). Agrophysics was defined as “a science that studies physical, physicochemical, and biophysical processes in the system ‘the soil – the plants – the active layer of the atmosphere’ as well as main principles of the production process, physical properties of the system components and of various agricultural products.” Over time, it expanded onto other materials, such as agricultural crops, agricultural raw materials and foods, and soil–machine and machine–plant relations. Penman (1948) called attention to the role of physics in agriculture, and later on Przestalski (2001) explicitly argued that “Many phenomena important for agriculture (e.g., soil structure and interactions that determine it, water transport in the soil, transport of water and mineral nutrients in the soil–plant system, effects of the temperature, radiation and other factors on the crop yields, substance permeation through the membranes, and others) which are subjected to physics laws can be investigated with the physical methods only.”

Agrophysics was further developed by Polish scientists B. Dobrzański, J. Gliński, J. Haman, B. Szot, R. Walczak and East European institutions, such as: Institute of Agrophysics of the Polish Academy of Sciences and European Union Centre of Excellence in Lublin “Agrophysics,” Poland ([Institute of Agrophysics in Lublin: Progress in Agrophysics](#)); Agrophysical Institute of the Russian Academy of Agricultural Sciences in Saint-Petersburg (Russia); Czech University of Agriculture in Prague (Czech Republic); Hydrological Institute of the Slovak Academy of Sciences in Bratislava (Slovakia); Agricultural University in Gödöllő (Hungary); Research Institute of Soil Science and Agricultural Chemistry of the Hungarian Academy of Sciences in Budapest (Hungary); N. Pushkarov Institute of Soil Science, Sofia (Bulgaria); Centre of Agricultural Landscape and Land Use Research, Müncheberg (Germany); Institute for Problems of Natural Resources Use and Ecology BAS, Minsk (Belarus); Research Institute for Soil Science and Agrochemistry, Bucharest (Romania); Institute for Soil

Science and Agrochemistry Research, UAN, Kharkiv (Ukraine); and Institute of Physicochemical and Biological Problems of Soil Science and Institute of Basic Biological Problems RAS, Puschino (Russia). This cannot be forgotten about other institutions contributing in the progress of agrophysics, collaborating for many years with the Institute of Agrophysics in Lublin. They are: University of Agricultural Sciences, Institute of Soil Science, Vienna (Austria); Ghent University, Department of Soil Management and Soil Care, Gent (Belgium); University of Guelph, Ontario Agricultural College, Department of Land Resources Sciences (Canada); Institute of Soil Science, Academia Sinica, Nanjing (China); Cranfield University, Silsoe College, Land Resources Division, Silsoe (England); University of Helsinki, Agricultural Chemistry and Physics, and Agrifood Research Centre of Finland, Jokioinen (Finland); Institute of Soil Science, Montfavet (France), Christian Albert University, Institute of Soil Science and Plant Nutrition, Kiel; University Hohenheim, Institute of Soil Science, Stuttgart; Technical University Berlin, Institute Ecology, Department of Soil Science and Soil Protection, Berlin (Germany); Winand Staring Center for Integrated Land, Soil and Water Research SC-DLO, Wageningen (Holland); Institute of Mechanisation of Agriculture CNR, Torino (Italy); Hokkaido University, Laboratory of Soil Science, Sapporo, and Graduate School of Bioagricultural Science, Nagoya (Japan); Institute of Natural Resources and Agrobiology IRNAS-CSIC, Sevilla (Spain); Sweden University of Agricultural Sciences, Department of Soil Science, Uppsala (Sweden); University of Kentucky, Department of Agricultural Engineering, Lexington; and Coastal Plains and Soil Water Conservation Research Center, Florence, South Carolina (USA).

Scientific symposia, conferences, and meetings presented various aspects of agrophysics. The most progressive were the international conferences organized in: Lublin, Poland (1976, 1997) ([Figure 1](#)); Gödöllő, Hungary (1980); Prague, Czechoslovakia (1985); Rostock, East Germany (1989); Bonn, West Germany (1993); Brussels, Belgium (2004); Lublin, Poland (2005). Also many bilateral conferences: Polish–Czechoslovak on “Physics of soil water,” Polish–Hungarian on “Mechanical properties of agricultural materials” and on “Soil degradation,” Polish–French on “Agricultural and hydrological aspects of soil amelioration” were organized since 1973. Most presentations from these conferences were published in various journals, including the International Agrophysics, e.g., Special issue, 1994. Vol. 8, Nos. 1–4.

In Poland, very active is the Polish Society of Agrophysics ([Polish Society of Agrophysics](#)) and an important role in the promotion of agrophysics is played by the journals *International Agrophysics* and *Acta Agophysica*.

Since 2001, every spring international workshops for young scientists, *BioPhys Spring*, are systematically organized, alternately by the Czech University of Agriculture

Agrophysics: Physics Applied to Agriculture, Figure 1 Participants of the 6th International Conference on Agrophysics, (6 ICA), September 15–18, 1997, Lublin, Poland.

in Prague and the Institute of Agrophysics in Lublin. The meetings are oriented on training of young researches and on exchange of professional experience in physics applied to biological, agricultural, and food systems. In 2008, the Slovak University of Agriculture in Nitra and the Szent Istvan University in Gödöllő (Hungary) joined the Organizing Committee of the Workshops, increasing the international level of the event.

Books (Gliński and Stepniewski, 1985; Gliński and Lipiec, 1990; Przestalski, 2009) and a set of monographs on various problems of agrophysics were published within the scope of activity of the Institute of Agrophysics in Lublin and the EU Centre of Excellence “Agrophysics”: Baranowski and Walczak (2004); Bieganowski and Walczak (2004); Bieganowski et al. (2004); Józefaciuk (2004); Józefaciuk et al. (2004); Gliński et al. (2004); Lipiec et al. (2004); Matyka-Sarzyńska and Walczak (2004); Skierucha and Walczak (2004); Skierucha and Malicki (2004); Skierucha et al. (2004); Ślawiński et al. (2004); Stepniewski et al. (2005); Usowicz and Usowicz (2004); Witkowska-Walczak et al. (2004); Baranowski et al. (2005); Horabik and Laskowski (2005a, b); Konstankiewicz and Zdunek (2005); Raytchev et al. (2005a, b); Szot et al. (2005); Włodarczyk and Kotowska (2005); Dobrzanski et al. (2006); and Szymanek et al. (2006). To facilitate access to the worldwide literature on agrophysics, a six-language (English, German, Spanish, French, Polish, and Russian) dictionary on agrophysics, containing 2,800 terms, was elaborated (Dębicki et al., 1991).

Agrophysics is related to the *agrosphere* which is one of the Earth spheres. The Agrosphere Institute ICG-4 of the Forschungszentrum Jülich, Germany, indicates a role of a network of scales and disciplines in the agrosphere. They start with molecule scale to soil column, pedon, field, regional, and superregional scales using NMR, NMR imaging, resistance tomography, and remote sensing methods depending on the scale (<http://www.fz-juelich.de/icg/icg-4/>).

Importance of agophysical research

Agrophysics is developing dynamically, linking knowledge in environmental physics, plant physics, and food physics, filling the gap between such disciplines as agrochemistry, agrobiology, agroecology, and agroclimatology. Agophysical knowledge is useful in agricultural research and practice, especially in agronomy, agricultural engineering, horticulture, food and nutrition technology, and environmental management (Frączek and Ślipek, 2009). Application of agophysical research allows reduction of losses of agricultural products at harvest and post harvest processes and storage.

Progress in agrophysics was possible due to the joined activity of agronomists, physicists, chemists, and biologists, resulting in interdisciplinary approach and solution of theoretical and instrumental problems focused on their practical application in agriculture and natural environment. Agriculture contribution to greenhouse gases production and sink in soils and emission to the

atmosphere is closely connected with soil physical properties (Włodarczyk and Kotowska, 2005).

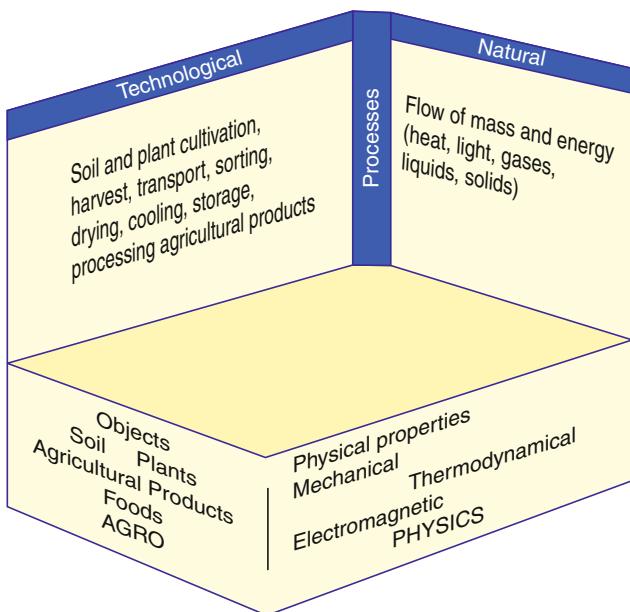

Application of physical methods, laws, and theories for the agricultural problems allowed for more precise description and modeling of the above processes (Haman, 2003).

The area of agrophysical activity may be presented on a three-axial configuration (Figure 2), and the basic scheme of agrophysical research is shown in Figure 3.

Agrophysical knowledge plays an important role in appropriate *processing and storing* of agricultural products and foods which use modern technologies and physical laws that control behavior of biological materials. Agriculture and the food industry belong to largest producers and users of granular materials. Increasing number of processes and operations involving granular materials have resulted in a growing need for new theory and technology. Elaboration of effective design methods of technological processes requires detailed knowledge of physical properties of the processed material as well as proper understanding of interactions with construction materials, e.g., silos (Ravenet, 1981).

Agrophysical objects

The main objects of agrophysical investigations are soils, plants, and agricultural products and foods (see *Agrophysical Objects (Soils, Plants, Agricultural Products, and Foods)*). From the physical point of view, the three states of matter (solid, liquid, gas) can occur in every agrophysical object.

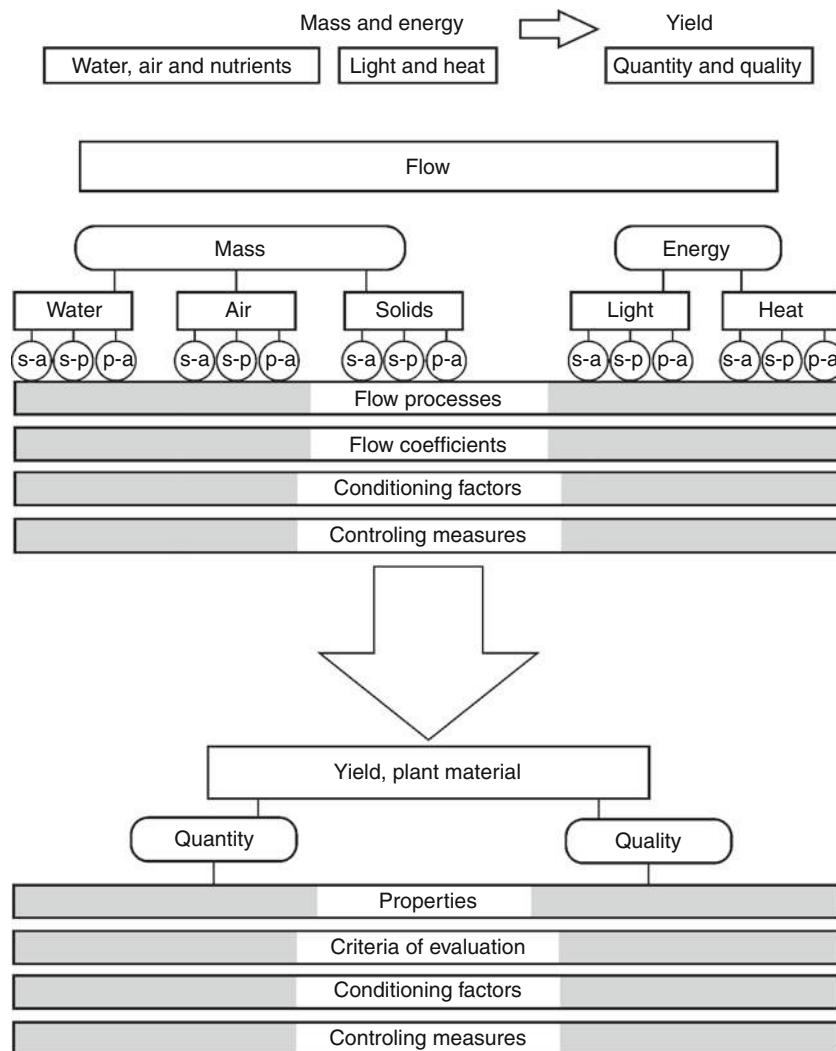

Agrophysics: Physics Applied to Agriculture, Figure 2 Three-dimensional scheme of agrophysical research (Adapted from Gliński, 1992).

Soils

Soils are the central link in the terrestrial environment (Hillel, 2007; Chesworth, 2008) due to their ecological functions (*Soil Functions*). The functions are largely influenced by soil physical characteristic parameters (see *Agrophysical Properties and Processes*) which are well described in many books by e.g., Hillel (1972, 1982, 1998, 2004, 2007); Hanks and Askroft (1980); Gliński and Stepniewski (1985); Gliński and Lipiec (1990); Hartge and Horn (1991); Marshal et al. (1996); Koorevaar et al. (1999); Scott (2000); Shein and Goncharov (2000); Smithson et al. (2002); Warrick (2002); William and Horton (2004); Lal and Shukla (2004). It is enough to mention water, air, and thermal, mechanical, and rheological properties which determine the conditions for crop production, assuming at the same time efficient use of chemicals and agricultural machines. In the evaluation of soil properties and processes, scale (length and time) problems (*Scaling of Soil Physical Properties*) are considered. For water transport in the porous system of soil Kutilek and Nielsen (1994) proposed four length scales, from submicroscopic (10^{-10} to 10^{-8} m) through microscopic (10^{-6} to 10^{-3} m), macroscopic (10^{-1} to 10 m) to watershed (10^2 to 10^4 m and even more). The response time for changes in these parameters is in a broad scale. The changeability of other soil physical characteristics are, e.g., $<10^{-1}$ year for bulk density, total porosity, and composition of soil air, 10^0 – 10^{-1} year for cation exchange capacity, 10^{-1} – 10^2 year for clay mineral associations, $>10^3$ year for texture (Arnold et al., 1990).

Nowadays, worldwide problems closely connected with soil physical properties are soil erosion and compaction. Water and wind erosion are disastrous phenomena in many places. Soil erosion causes tremendous damage, e.g., in America, which loses at the level of 4.8 billion tons of topsoil of agricultural land annually due to erosion (Arnold et al., 1990, p. 78). In Africa, these losses are equal to 700 Mg km^{-2} and in Europe 84 Mg km^{-2} . Closely related with soil erosion are such phenomena as surface soil sealing and crusting, and destruction of soil structure (see *Water Erosion: Environmental and Economical Hazard; Soil Surface Sealing and Crusting*). Soil compaction is a severe problem now due to increasingly using heavier tractors, larger implements, bigger combines, reduced tillage, and no-tillage systems (Horn et al., 2000). Conducting field operations when the soil is too wet, especially in spring and harvesting in the fall increase compaction. Compaction increases soil bulk density and mechanical impedance to root growth and reduces soil macro-porosity, affecting water and air conditions both for plant growth and yield. Nearly all great agroecological programs directed at increasing soil productivity or soil protection against degradation or land conservation include investigations on the physical processes and properties in soils (see *Soil Aggregates, Structure, and Stability; Soil Compactibility and Compressibility; Soil Erosion Modeling; Soil Surface Sealing and Crusting*).

Agrophysics: Physics Applied to Agriculture, Figure 3 Basic scheme of agrophysical research. *a* atmosphere, *p* plants, *s* soil
(Adapted from Gliński, 1992).

Additionally, the variability and large heterogeneity of soil properties gives the view of difficulties to be faced by the physicist dealing with measurements performed in the soil environment (Bieganowski and Walczak, 2004). For this reason, there are still problems concerning standardization of physical methods used in agrophysics (ISO) (see [Standardization in Agrophysics](#)).

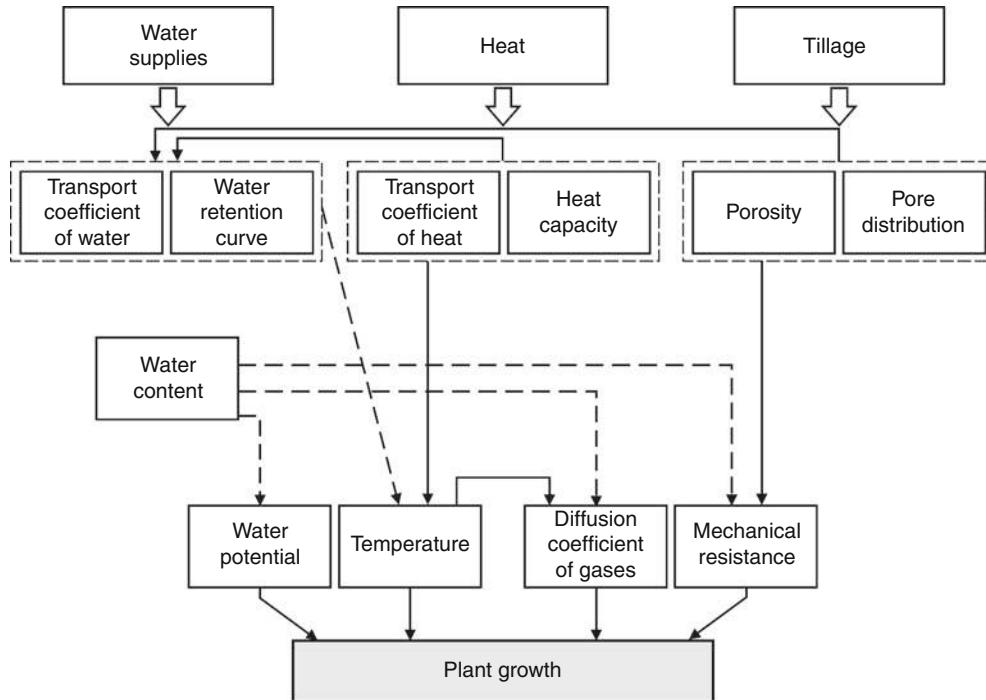

It is worth to mention here the near-ground atmosphere which forms the *microclimate* ([Physics of Near Ground Atmosphere](#)) of a cultivated field with plant canopy, where the processes of evapotranspiration play an important role (Monteith and Unsworth, 2007).

Plants

Productivity of agricultural plants is highly affected by physical factors that are determined by soil tillage, land management, and climate (Szot, 1976; Gliński and

Stepniewski, 1985; Letey, 1989; Gliński and Lipiec, 1990; Lipiec et al., 2004; Gliński et al., 2008) (Figure 4).

Plants differ within themselves and within their organs such as: the root system, stem, foliage, fruit, not to mention the complex structure of each component. Further sharp distinction has to be made as regards the post harvest mass of plants which may be in bulk, stored crops, chopped or even pressed material. The knowledge on the physical properties of plants is useful in plant breeding to improve resistance to lodging and crop productivity and quality (see [Plant Lodging, Effects, and Control](#); [Plant Physical Characteristics in Breeding and Varietal Evaluation](#)). Moreover, plants are important source of biomass for renewable energy production in many countries (see [Alternative Sources of Energy from Agriculture Biomass – a European Perspective](#); [Biomass as an Environmentally Benign Energy Source](#)).

Agrophysics: Physics Applied to Agriculture, Figure 4 Physical factors influencing plant growth (Adapted from Walczak and Zawadzki, 1979).

Agricultural products

Agricultural products are composed of living or harvestable products of plant origin. It is not easy to separate agricultural products from foods. Generally, they are raw materials for foods after their storage and processing, but some of them (vegetables, fruits) can be eaten as fresh foods. Many agricultural products are irregular in shape, with convex and concave parts on different surfaces and a characteristic internal structure consisted of particles, pores, and cells (Blahovec, 2008). The mechanical properties of agricultural products play an important role in the transport, storage, and processing of these materials. Fruit properties, such as porosity, surface area, mass, volume, dimensions, friction, and color are significant in sorting, storing, and packing. Agricultural raw materials, products, and foods must fulfill stringent requirements and standards, including their physical properties, which should be currently and quickly checked during their processing. Agricultural tools and machines used during harvest and transport cause yield losses and mechanical damage (see *Crop Yield Losses Reduction at Harvest, from Research to Adoption*). Physical processes during storage and drying of biological materials may cause their mechanical and biological damage and thus worsening quality. Application of physics provides bases for new technologies on maximal reduction of above-mentioned losses during various operations (Mohsenin, 1986).

Plant foods

Plant foods include plant and plant parts eaten as food without or after their processing (see *Agophysical Objects (Soils, Plants, Agricultural Products, and Foods)*). The knowledge of physical properties affects their quality during post-harvest operations, storing, and processing (Heldman, 2003; Sahin and Sumnu, 2006). Quality of food is the multiparameter attribute related to sensory properties (appearance, texture, taste, and aroma), nutritive values, chemical constituents, mechanical properties, functional properties, and defects. An important physical element of food quality is texture. The texture is a sensory and functional manifestation of the structural, mechanical, and surface properties of foods detected through the senses of vision, hearing, touch, and kinesthesia (Szczesniak, 2002). Texture is affected by the structure of food (Jackman and Stanley, 1995). Texture of plant foods can be attributed mainly to the structural integrity of the cell wall and middle lamella, as well as to the turgor pressure generated within cells by osmosis. It is well known that texture of fruits and vegetables is influenced by cell wall structure (thickness, chemical composition), middle lamella, turgor pressure, parenchyma cells arrangement, quality and volume of intercellular spaces, permeability of cell walls.

Main agrophysical processes, properties, and their technological functions are presented in **Table 1**.

Agrophysics: Physics Applied to Agriculture, Table 1 Main agrophysical processes and properties and their impacts on soil, plants, agricultural products, and food

Physical processes	Physical properties	Impact on soil and plants	Impact on agricultural products and food
Mass transport (water, vapor, air, and chemicals flow; capillary flow, molecular diffusion, osmosis)	Hydraulic conductivity, water diffusivity, vapor diffusivity, air diffusivity, chemicals diffusivity, permeability	Water available to plants, seepage, filtration, drainage, irrigation, flooding, chemical transport, gas emission from soil, aeration, evaporation, respiration, transpiration, weathering, erosion, runoff, soil sealing, and crusting	Chilling, cooling, drying, and fumigation of products in bulk, storage respiration, shelf life
Mass absorption/adsorption (adhesion, cohesion)	Particle size distribution, porosity, surface area, wettability	Waste disposal, gas exchange, coagulation, flocculation, peptization, shrinkage	Drying, hydration, dehydration, storage respiration
Energy transport (heat conduction, convection, radiation)	Thermal conductivity, heat capacity, specific heat, permittivity	Thermal condition	Drying, processing, cooking
Energy absorption/emission (heat conduction, radiation)	Reflectance, absorption, permittivity, dispersion, color indices	Thermal condition, albedo, growing degree-days	Drying, heating, processing
Phase transition (evaporation, condensation, crystallization, melting)	Latent heat, melting heat	Soil freezing/thawing, plant freezing	Freezing, freeze-drying, storage
Mechanical processes (impact, compression, crushing, shearing, tension)	Elasticity, viscosity, plasticity, hardness, density, porosity	Soil tillage, soil aggregation, soil compaction, trafficability, plant lodging, emergence	Harvesting, post-harvest treatment, storage, handling, processing (agglomerating, chopping, mixing, separating)

Agromechanics

Agricultural objects undergo mechanical changes but their cognition is difficult because of the very complicated structure (Koolen and Kuipers, 1983; Husar, 1985; Haman, 1988). Therefore the application of results from engineering mechanics to agromechanics is difficult. The most important areas of agromechanics are related to the strength of agricultural products and to the determination of stresses and strains occurring in the system. Agrophysicists make effort to acquire knowledge on the effects of stresses acting on agricultural objects. In the case of agricultural products, external forces are coming from the effects of a body's own weight, wind force, supporting force, shock, vibration, mechanical interference. Internal forces appear, e.g., between stalk and nodes, stalk and root system in cereals, or tuber and foliage. Examples of stress-strain relations of some agrophysical objects are shown in Figure 5. The tasks connected with the transport and processing of agricultural products, such as baling, milling, grinding, etc., depend fundamentally on the machinery used. In the case of soils, the natural influences and human interventions that cause the stress-strain relations in soils are even more difficult to determine. Advances in applied physics with extended theoretical knowledge are needed to know mutual interactions of machine elements with plants.

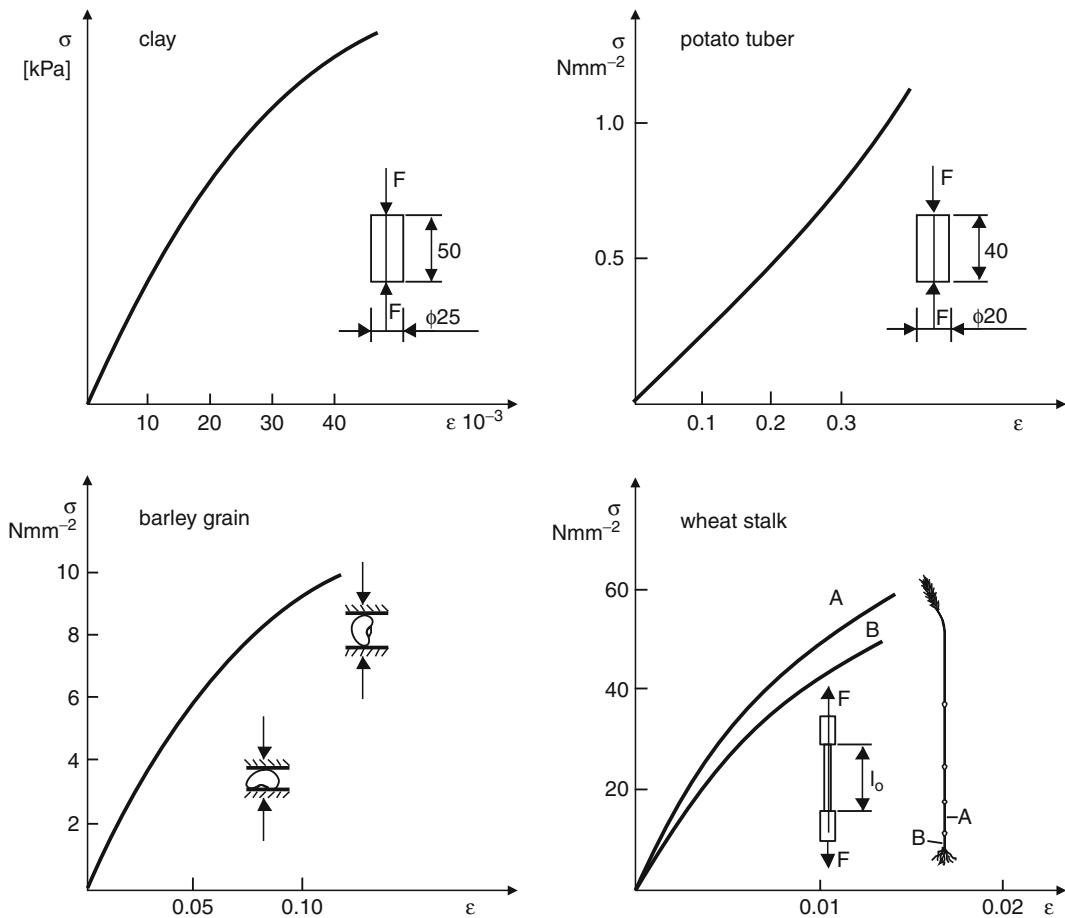

In the conditions of intensive agriculture, problems of the level of *energy use* in various technological processes

are of fundamental significance. Especially soil cultivation and yield harvest consume a lot of energy which can be decreased by applying knowledge of the physical properties of agrophysical objects and machines used.

Main tools in agrophysical research

Measuring methods, instrumentation, and metrology

Study of the multiphase and heterogeneous system of agricultural objects is very complex and therefore needs to adopt many measurement methods and instrumentations used in other scientific disciplines (Gliński and Konstankiewicz, 1991a, b; Walczak, 1993; Blahovec and Kutilek, 2003; Lamorski et al., 2004). The scientists need precise quantitative information concerning the physical behavior and spatial variability of examined objects to create models for practical use after their experimental verification. For this purpose, many advanced methods and measuring tools were recently developed. Some of them are considered in the Encyclopedia of Agrophysics (see *Acoustic Tomography*; *Electrochemical Measurements in Soils*; *Electrical Resistivity to Assess Soil Properties*; *Electromagnetic Fields, Impact on Seed Germination and Plant Growth*; *Fractal Analysis in Agrophysics*; *Ground-Penetrating Radar, Soil Exploration*; *Image Analysis in Agrophysics*; *Nanomaterials in Soil and Food Analysis*; *Neural Networks in Agrophysics*; *Nondestructive Measurements in Fruits*; *Nondestructive*

Modeling

In agrophysics, one of the basic methods of investigation is modeling. Modeling, like scientific observation and experimentation, is a method for increasing our understanding of cause-and-effect relationships. It requires classifying the processes involved according to their importance, which results in the creation of a simplified reality (see *Stomatal Conductance, Photosynthesis, and Transpiration, Modeling*).

Generally, the models used in physics and in other life sciences, including agrophysics, can be divided into

physical and mathematical models. The physical models, with regard to the way of description of processes taking place in the environment, can be divided into: real models, analogue models, and phenomenological models (Mazurek et al., 1996).

The *real models* concern field or laboratory experiments (lysimetric and pot studies, greenhouse experiments). The *analogue models* enable the description of a given object, phenomenon, or physical process with the help of another analogous object, phenomenon, or physical process. The analogue models are created to simulate slow real process, e.g., the flow and accumulation of water in a porous medium can have an analogue in the flow and accumulation in a net of resistances and condensers. The *phenomenological models* are constructed when a real process is too complicated for a detailed physical–mathematical description (e.g., evapotranspiration, erosion, biomass production).

Recent development of computer technology and information management (or programming) enhances the importance of mathematical models. A mathematical

model is an equation or set of equations whose solution describes the physical behavior of a related physical system. A mathematical model is always a simplified description, or caricature, of a physical reality expressed in mathematical terms (Weatherley, 2006).

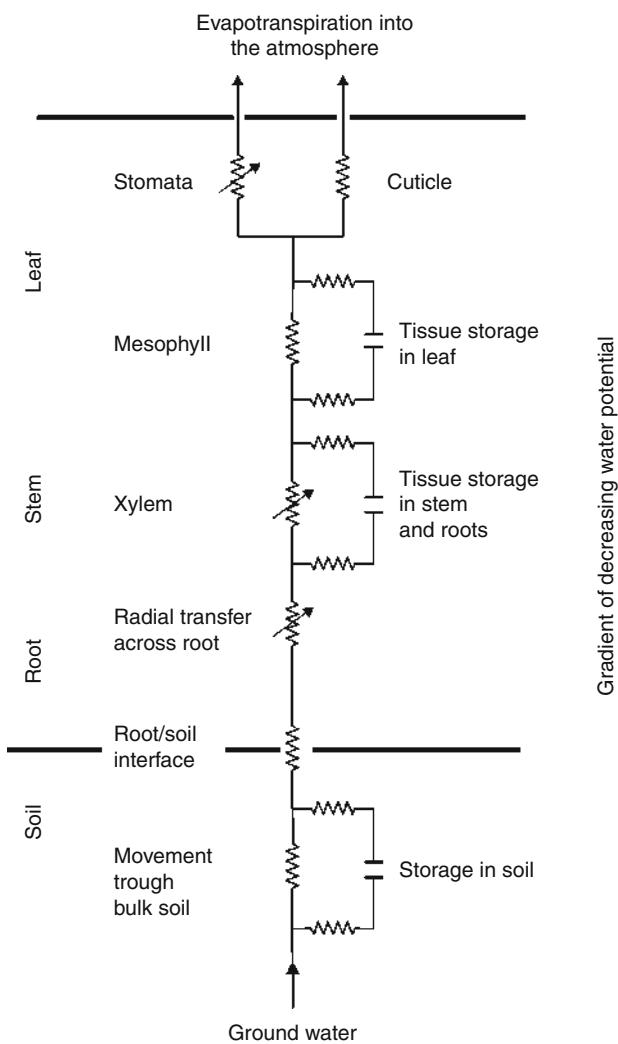

Mathematical models can be divided into mathematical–physical, statistical–physical, and mathematical–statistical models. They may be used for different applications – from pure modeling of transport phenomena in soil to crop growth and yield prediction.

A typical example of mathematical–physical model is the mass and energy transport through the soil–plant–atmosphere system (see *Soil–Plant–Atmosphere Continuum*) as a principal agrophysical phenomenon. It results from a combination of various mechanisms and includes molecular liquid diffusion, molecular vapor diffusion, capillary flow, convective transport, evaporation–condensation, pure hydrodynamic flow, and movement due to gravity. This transport can be described by 3D nonlinear differential equations with coefficients that can be determined experimentally. Water movement through the system was presented as a series of interrelated, independent processes which can be treated as analogous to the flow of electricity through a conducting system (Figure 6).

Complex mathematical–physical models are developed to describe soil, atmosphere, and plant processes responsible for biomass increase, using constitutional mathematical–physical equations (e.g., van Genuchten, 1980). The equations are resulting from the conservation laws, describing a chosen phenomenon in this system, e.g., transport of water, salt, and heat in the soil; soil deformation; and stress as a result of agricultural machines and cultivation tools reaction (Haman and Pukos, 1983; Pukos, 1994; Walczak et al., 1997; Konstankiewicz and Pytka, 2008).

Other examples of mathematical–physical models are models using the discrete element method (DEM) and finite element method (FEM) for modeling physical processes in various media (e.g., grain silos) (Holst et al., 1999a, b).

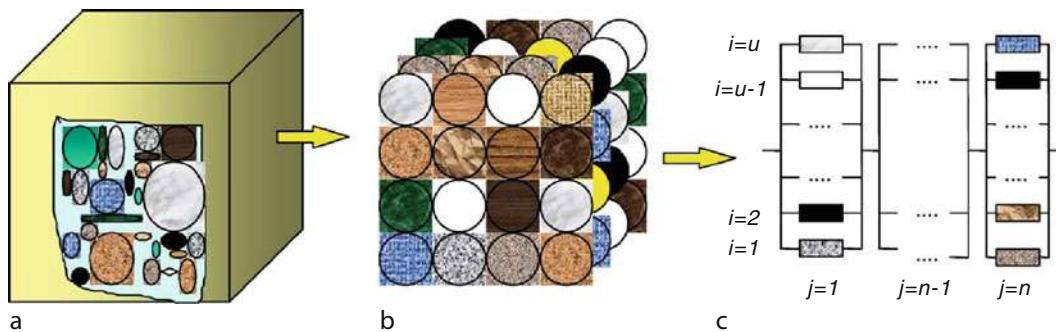

An example of a statistical–physical model is the model of soil thermal conductivity proposed by Usowicz et al. (2006). The model is expressed in terms of heat resistance (see *Ohm's law* and *Fourier's law*), two laws of Kirchhoff, and the polynomial distribution. The volumetric unit of soil in the model (Figure 7a) consists of solid particles, water, and air, and is treated as a system made up of regular geometric figures, spheres, filling the volumetric unit by layers (Figure 7b). It is assumed that connections between the layers of spheres and the layer between neighboring spheres will be represented by serial and parallel connections of thermal resistors, respectively (Figure 7c). Comparison of resultant resistance of the system, with consideration of all possible configurations of particle connections together with a mean thermal resistance of given unit soil volume, allows estimating the thermal conductivity of soil ($\text{Wm}^{-1}\text{K}^{-1}$).

Agrophysics: Physics Applied to Agriculture,
Figure 6 Diagram of water flow from soil to the atmosphere through plants (Adopted from Russel, 1977).

An example of mathematical–statistical models are pedotransfer functions (PTF), being equations or algorithms expressing relationships between soil properties different in the difficulty of their measurement or their availability. PTFs are vital tools to translate data that we have to data that we need in agrophysical research and management applications (*Pedotransfer Functions*). They were extensively used to predict soil hydraulic properties (retention curve, hydraulic conductivity) from basic soil properties such as particle-size distribution, organic matter, and bulk density.

Global warming resulting in climate change and its possible effects on the soil environment and the economy yielded the creation of simulation models concerning also predicted changes of soil parameters. The model of soil water balance, being a combination of mathematical–physical and phenomenological models, was elaborated

Agrophysics: Physics Applied to Agriculture, Figure 7 Schematic diagram of structure of the statistical model where (a) is a unitary volume of soil, (b) is the system of spheres that forms n layers, and (c) is a representation of contacts in layers by u parallel connection of resistors (Usowicz et al., 2006).

for the territory of the European Community within the ACCESS project (Agro-climatic change and European soil suitability – a spatially distributed soil, agro-climatic and soil hydrological model) (Loveland, 1996). One of its submodels on bypass flow in cracking soils was done and experimentally verified (Armstrong et al., 1996; Ślawiński et al., 1996; Walczak et al., 1996; Fernandez et al., 2004).

Mathematical modeling contributes to better understanding of the complex and variable effects of soil and subsoil compaction (Lipiec et al., 2003). Frequently, mechanistic and deterministic models were used. Root growth is often predicted as a function of mechanical resistance and water status of soil and crop yield from interactions of soil water and plant transpiration and assimilation. Modeling of the movement of water and chemicals is based on the Darcy/Richards one-dimensional flow equation. The effect of soil compaction is considered by changing hydraulic conductivity, water retention, aeration, and root growth. The predictability of some models was improved by considering macro-porosity and strength discontinuity (spatial and temporal variability of material parameters) and the relative compaction instead of bulk density. Scarcity of experimental data on the heterogeneity is a constraint in modeling the effects of soil compaction. Further work is needed to develop modeling approaches with consideration of soil structural discontinuities and spatial variation of the input parameters resulting from compaction.

Soil erosion models broadly fit into two groups: empirical and process-based models (see *Soil Erosion Modeling*). The Universal Soil Loss Equation (USLE) (Wischmeir and Smith, 1978) is the most dominant empirical model to predict field-scale erosion rates.

Crop models are mostly based on physiological and climate data without consideration of soil structure (Walczak et al., 1997). To bridge this gap, investigations were carried out in 1992–1995 within the framework of international multilateral projects between Austria, Czech Republic, Hungary, Poland, and Slovak Republic on the role of soil structure functions for sustainable agricultural

biomass production and soil protection (International Agrophysics, Special issue, 1993, Vol. 7, Nos 1–3 and Special issue, 1997, Vol. 11, Nos. 1–2). From the analysis of the models considering soil processes, it resulted that the soil structure parameters appearing most frequently in them are soil water retention, root system parameters, soil compaction and porosity, and unsaturated and saturated water conductivity. Generally, models of plant production include two groups of parameters: soil parameters and plant parameters. At least growth stage and rooting depth are necessary as plant parameters if crop growth should be coupled with soil structure effects. Modeling showed clearly that the effect of the saturated water conductivity and bulk density on crop yield alone was not significant. But, as soon as root distribution was introduced as a plant parameter, a strong effect on the plant growth was detected as an overall consequence of the soil structure status. Physical soil parameters provide the same kind of methodological troubles as all other scientific measurements. But, there is an additional difficulty, which is the fact that structure-dependent parameters cannot be determined from composite, disturbed samples. Each core sample or each in situ measurement has to be treated separately. This creates very specific problems of sampling. However, almost all crop production models assume that soil is a homogeneous substrate. Therefore, it is very important to develop models which also consider soil heterogeneity, time, and spatial variability of soil parameters at various scales.

Food processing technology using innovative strategy needs support from models. Within the EU 7th Framework Program, the multidisciplinary European DREAM project (Design and development of REAListic food Models with well-characterized micro- and macrostructure and composition) is being created at INRA (France) (Ad Litteram, 2009). The physical and mathematical food models developed as a result of the project will serve “as standards that can be applied across all major food categories to facilitate the development of common approaches to risk assessment and nutritional quality for food research and industry.” Also post-harvest and processing

technologies need mathematical models and optimization methods (De Baerdemaeker and Vandewalle, 1995; Agbashlo et al., 2009).

Even models which describe correctly the physical processes in modeled object may not yield accurate results when reliable values of the physical parameters of modeled object are not known. Even if the model has been widely used, uncertainties still arise when it is applied to conditions different than those for which the model was previously tested. Therefore, experimental verification of the model is very important (Fernandez et al., 2004).

Monitoring

Monitoring is the collection of data that allow to determine temporal and spatial variations of physical conditions in agriculture and the environment (see *Monitoring Physical Conditions in Agriculture and Environment*). The increasing pressure on natural resources, sustainability and exhaustion of nonrenewable resources need monitoring which should provide sufficient data for the decision makers. Advances in sensors, computers, and communication devices make it easier to collect useful information about physical conditions in agricultural and natural environment.

Recently, remote sensing technology is rapidly developing for monitoring the world's agricultural production including crop identification, acreage, vigor, density, maturity, growth rates, and yield forecasting, as well as soil physical properties and water availability and quality (see *Remote Sensing of Soils and Plants Imagery; Soil Physical Degradation: Assessment with the Use of Remote Sensing and GIS*).

Research needs and challenges

We present some research needs and challenges to improve agrophysical knowledge and applications.

Soils

Capture the dynamics of soil structure effects and improve quantitative description of surface roughness, crusting, bypass flow, infiltration, deformation resistance (mechanical impedance, crop establishment).

Estimate of the effective soil physical properties of heterogeneous field soil profiles. Integration of directly measured data and indirectly estimated information derived from new noninvasive techniques such as neutron and X-ray radiography, magnetic resonance imaging, electrical resistivity tomography, ground penetrating radar. Microwave remote sensing seems promising for this.

Quantify the size, continuity, orientation, and irregularity of pores by means of image analysis for a broad range of agrophysical applications including water movement and solute transport following human activity.

Visualize and quantify the complex geometry of the pore network and soil structure in 3D on various scales, thus enhancing understanding of the multiple interacting

soil physical, biological, and biogeochemical processes, including flux phenomena.

Quantify coupled soil heat and water transfer (particularly vapor flow components) and associated implications at various scales.

Integrate soil mechanical and conductive (hydraulic) processes affecting the time-dependent strain and the alteration of pore functioning, e.g., aeration and water fluxes. Precompression stress reflects well the stress and strain state for a given predrying intensity and helps the specification of appropriate agricultural machinery to avoid excessive soil and subsoil compaction.

Develop noninvasive soil sensors to alleviate the difficulty in researching below-ground processes (e.g., root development, water movement etc.).

Soil–plant relations

Explain perception of soil physical stress by plants (or plant roots) and the conversion of physical and chemical phenomena into physiological responses.

Determine the combined effects of multiple stresses such as water stress, oxygen stress, and mechanical stress, salinity, and temperature extremes on plant performance.

Develop emerging area of 3D soil–plant functional interactions modeling based on root architecture which allow better understanding of the complex mechanisms controlling water and nutrients fluxes in the soil–plant continuum and increase root uptake efficiency. Advances made in noninvasive measurement techniques can be useful for this.

Evaluate coating effects of increasing temperature and associated changes in soil moisture and rising atmospheric CO₂ on SOM and plant productivity, due to future climatic change.

Manage landscape structure to optimize the use of solar energy, heat and water balance of agricultural areas toward increasing potential for sustainable production of biomass.

Breed plants to develop crop varieties for physically stressed environment, e.g., lodging.

Agricultural products and foods

Determine optimal physical conditions to increase the utility (technological) value during processing and storage.

Improve technology of harvesting, storing and processing to decrease qualitative and quantitative losses using physical methods and modeling approaches.

Deepen knowledge on physical properties through description of macroscopic and microscopic structures and processes.

Technology

Save energy during various technological processes used in agriculture.

Improve construction of machines and devices (equipped with electronics) used in agriculture in terms of effective energy use and environmental protection.

Data use

Develop complete and reliable databases of agrophysical data – a challenging task. They are an invaluable resource for researches, educators, practitioners, and policy makers, and present great opportunities to translate the existing data to the data we need using cost-effective pedotransfer functions (or model approaches).

Develop modeling approaches with consideration of structural discontinuities and spatial variation of the input parameters.

AIR ENTRY VALUE

The value of water content or potential at which air first enters a porous media.

AIR FLUX (RESISTANCE) IN PLANTS AND AGRICULTURAL PRODUCTS

Agnieszka Kaleta, Krzysztof Górnicki
 University of Life Sciences (SGGW), Warszawa, Poland

Synonyms

Airflow–pressure drop relationship; Resistance to airflow

Definition

The resistance, which has to be overcome by air flying through porous media such as plant tissues and a packed bed of plants and agricultural products (e.g., bulk grain), is defined as a pressure drop per unit depth.

When air is forced through a layer of porous materials, resistance to the flow, the so-called pressure drop, develops as a result of energy lost through friction and turbulence. The prediction to airflow resistance is necessary, for example, to the fan selection for grain drying and aeration systems.

Ergun's model is the most comprehensive model to be used for airflow–pressure drop calculations. Ergun assumed that the pressure loss can be treated as the sum of the viscous and kinetic energy losses. The model is

the sum of equation for laminar flow (this term is a linear function of airflow rate) and equation for turbulent flow (this term is a function of v_0^2) and has the following form:

$$\Delta P = 150 \frac{v_0 \mu}{d_e^2} \frac{(1 - \varepsilon)^2}{\varepsilon^3} + 1.75 \frac{\rho v_0^2}{d_e} \frac{(1 - \varepsilon)}{\varepsilon^3} \quad (1)$$

where ΔP is the pressure drop per unit height, v_0 is the superficial velocity, d_e is an equivalent particle diameter, ε is the bulk porosity, μ is the dynamic viscosity of air, and ρ is the air density. The factors that affect the resistance of porous materials to airflow are among others: material porosity, size distribution of particles and pores, irregularity in particles and pores shape, surface roughness characteristics, orientation of the particles, and tortuosity. Such variables are extremely difficult to measure. For this reason, an empirical approach is often used.

Factors in Ergun's model other than airflow can be lumped into two parameters, so the model becomes an equation with the following form:

$$\Delta P = A_1 v_0 + B_1 v_0^2 \quad (2)$$

where A_1 and B_1 are product-dependent constants obtained from the experiment. When the velocity is small enough ($v_0 < 0.01 \text{ m s}^{-1}$), viscous forces dominate the flow and the equation reduces to Darcy's Law ($\Delta P = A_1 v_0$). The Shedd's equation represents the airflow resistance data over an airflow range of $0.005\text{--}0.3 \text{ m s}^{-1}$ and has the following form:

$$\Delta P = A_2 v_0^{B_2} \quad (3)$$

where A_2 and B_2 are product-dependent constants obtained from the experiment. The constant B_2 lying between 1 and 2 is a compromise between the velocity (v_0) and the (v_0^2) terms in Ergun's model. Hukill and Ives' equation:

$$\Delta P = \frac{A_3 v_0^2}{\ln(1 + B_3 v_0)} \quad (4)$$

where A_3 and B_3 are product-dependent constants obtained from the experiment, is valid for airflow range of $0.01\text{--}2.0 \text{ m s}^{-1}$.

Effects of process parameters on the resistance of, for example, bulk grain and seeds to airflow are generally the following: (1) the resistance to airflow decreases with an increase in product moisture content, (2) dense filling results in an increase in pressure drop, (3) the resistance to airflow through a bed of product in the horizontal direction is, in most cases, smaller than in the vertical direction, (iv) a product mixed with foreign materials offers more resistance to airflow than cleaned one.

Further details are given by Smith (1995) and Pabis et al. (1998).

AIR HUMIDITY

The amount of water vapor within the atmosphere.

AIR POROSITY

A volume of a material (e.g., soil, plant) that is occupied by pore spaces.

ALGAE, THE POTENTIAL SOURCE OF ENERGY

Magdalena Frac
 Department of Plant and Soil System, Institute of Agrophysics Polish Academy of Sciences, Lublin, Poland

Definition

Algae are a large and diverse group of simple photosynthetic microorganisms. They live in different environments: such as water, soil, but also on snow, and on ice. Algae are very sensitive to different factors, so they can be used as biological and pollution indicators. Algae are useful as fertilizer, important source of food – especially in Asia – and in bioremediation applications. They contain very important chemical compounds, so can be used in industry, especially for cosmetics and pharmaceuticals.

In aspect of the potential energy source, microalgae are sunlight-driven cells that convert carbon dioxide to potential biofuels and high-value bioactivities. Microalgal biomass contains three main compounds: carbohydrates, protein, and natural oils and can provide several different types of renewable biofuels:

- Methane produced by anaerobic digestion of the algal biomass
- Biodiesel derived from microalgal oil
- Ethanol produced by fermentation
- Photobiologically produced biohydrogen

Economics of the fuel production from algae demands that all the biomass is utilized as efficiently as possible. The most simplistic method is methane gas production. Biological and thermal processes are involved in gasification of organic carbon into methane. Ethanol production is most effective for conversion of the carbohydrate fraction. Biodiesel production applies to the natural oil fraction.

The idea of using microalgae as a source of fuel is not new, but it is being taken seriously because of the escalating price of petroleum. The production of microalgal biomass is carried out in closed photobioreactors or in open ponds. Closed photobioreactors have the benefits of better control over environmental conditions (pH, temperature) and biological contaminants and higher cell concentrations.

ALKALINITY, PHYSICAL EFFECTS ON SOILS

Lajos Blaskó
 Karcag Research Institute of Centre for Agricultural and Technical Sciences, Debrecen University, Karcag, Hungary

Synonyms

Basicity; Sodicity

Definition

Alkali or *alkaline soils* have been defined as soils with high pH-value, which is caused by excessive (usually more than 15% of the exchange sites) amount of exchangeable sodium ions or/and soluble salts capable of alkaline hydrolysis. The most injurious alkaline sodium compounds in the soils and irrigation waters are Na_2CO_3 (sodium carbonate) or NaHCO_3 (sodium bicarbonate).

Introduction

Natural and man-induced salt accumulation in the soil profile is a major environmental threat with dramatic negative impacts on agricultural production and sustainability, especially in the arid and semiarid regions of the world.

Alkalinity problems are more common in clay soils than in soils with low colloid content. As a consequence of the relative preponderance of sodium on exchange sites of colloids, the alkaline reaction of the liquid phase and the swelling/shrinking clay minerals, the low fertility of these salt-affected soils, in most cases, are closely related to their unfavorable physical and hydrophysical properties and their extreme moisture regime (Várallyay, 1981).

The sustainable use and management require adequate understanding of the processes causing structural, water regime, and water transport problems of these soils.

Indicators of alkalinity

Exchangeable sodium percentage is for characterizing the relative ratio of sodium in the exchangeable cation complex (ESP). It is defined as

- $\text{ESP} = (\text{exchangeable Na} \times 100 / \text{cation exchange capacity})$
- $\text{ESP} = (\text{exchangeable Na} \times 100 / \Sigma (\text{exchangeable Ca} + \text{Mg} + \text{K} + \text{Na}))$

The exchangeable cations and the exchange capacity are expressed in milliequivalent per 100 g.

The sodium adsorption ratio (SAR) is for characterizing the sodicity of the soil solution or applied irrigation water. It is defined as

$$\text{SAR} = [\text{Na}^+] / ([\text{Ca}^{2+}] + [\text{Mg}^{2+}])^{1/2}$$

The cations in liquid phase of soil or in irrigation water are expressed in milliequivalent per liter.

Besides the widely used alkalinity indicators, the direct determination of soda alkalinity (Soda%) is used for the examination and the qualification of salt-affected soils containing considerable amounts of salts capable of alkaline hydrolysis. The determination is carried out with a suspension of soil in distilled water. The suspension is titrated with 0.1M KHSO_4 till the red color of phenolphthalein disappears. The pH-value can also be an indirect indicator of sodicity. The finely dispersed calcium carbonate may cause slight phenolphthalein alkalinity up to pH 8.5, and above this value, the alkalinity is probably caused by sodium carbonate or bicarbonate (Darab and Ferencz, 1969).

Change of soil physical properties under the influence of alkalinity/sodicity

The influence of sodicity on physical properties varies with clay content and clay mineralogy. In soils with higher content of swelling/shrinking clay minerals, lower exchangeable sodium percentage (ESP) or soda content can cause a more significant physical effect (Shaw and Thorburn, 1985; Várallyay, 1981).

Soil structure properties

There is a general agreement among the soil scientists, that spontaneous clay dispersion and swelling are the major factors that disintegrate the structure of sodic soils.

The increasing dispersion and swelling of bentonite caused by sodium carbonate solution was demonstrated in laboratory experiments (Darab and Ferencz, 1969; Szabolcs et al., 1969). An important conclusion of these experiments is that swelling reached its maximum at a relatively low concentration of sodium carbonate (0.1% m/m), while at a higher concentration it assumed a nearly constant lower value.

The effect of increasing alkalinity (pH) or Sodium Adsorption Ratio (SAR) on clay dispersion was confirmed by several experiments (Chen and Banin, 1975; Frenkel et al., 1978; Bauder and Brock, 2001). While there is an agreement on dispersive effect of sodium on clay minerals, the combined effect of organic material and ESP on the dispersion of clay has been the subject of discussion. Emerson (1954) demonstrated the dispersive effect of organic material in soils with high ESP. Oades (1984) explained the dispersive effect of organic colloids by decreasing the activity of calcium through complexation, and by increasing the negative charge on soil colloids. There are several positive results of experiments where organic materials such as green manure or compost have been used to improve the structure of sodic soils (Chand et al., 1977; Robbins, 1986; Singh and Singh, 1989; Barzegar et al., 1997). Solving this problem needs further researches because of the contradictory results regarding the effect of organic colloids on clay dispersion.

McNeal (1968) revealed that the swelling of soil colloids can be evaluated as an opposite effect of ESP and the salt concentration of the soil solution (EC). The increase of ESP or the decrease of EC causes the increase of the swelling factor. The effect of sodium salt is double. As electrolytes, the neutral sodium salts (NaCl , Na_2SO_4) coagulate the colloids. However as an exchangeable cation, sodium tends to favor dispersion. For the simultaneous evaluation of effect of sodicity and salinity the electrochemical stability index (ESI) was developed. ESI has been suggested as a good measure of dispersive behavior of soils (Hulugalle and Finlay, 2003).

We have only a few data relating to the direct measuring of the change in the pore volume and its distribution under the influence of increasing alkalinity.

Józefaciuk et al. (2002) investigated the effect of alkalization on the pore properties of the soil with sodium hydroxide solution of increasing concentration from 0.001 to 1 mol dm^{-3} . The macropore volume and radius, in general, increased with the increasing alkali concentrations. The mesopore volume in most cases decreased due to the treatments. In general, the average mesopore radius increased under lower concentrations of sodium hydroxide and decreased under higher concentrations.

Lebron et al. (2002) using thin-section-techniques established that the area of the aggregates decreased steeply in the ESP range of 0–5. In the ESP range of 6–55, the area of the aggregates did not change.

Várallyay (1981) investigated the effect of Na_2CO_3 on the water retention of soil. Due to the effect of Na_2CO_3 , the water retention increased with the increasing alkali concentration within the whole suction range. The available moisture range (AMR) – calculated as the difference between the field capacity and the permanent wilting point – increased with the higher ESP values. From the results he concluded that in such cases the main limiting factor of the availability of water is not the low AMR, but the limited water transport.

Transport processes in soils

Surface sealing and crusting are the first impeding factors of water infiltration into the soil. Soil crusting is related to soil texture, organic matter, and sodium content. In arid and semiarid regions, the presence of crusted salt and sodium-affected soils is very common (Bauder and Brock, 1992).

There are several studies in which the decrease of saturated hydraulic conductivity (K) has been related to the increasing Na content (McNeal and Coleman, 1966; Frenkel et al., 1978; Várallyay, 1981; Shainberg and Letey, 1984; Suarez et al., 1984).

Lebron et al. (2002) measured a steep decrease of hydraulic conductivity in the ESP range of 0–5, over this ESP range the hydraulic conductivity did not change. Crescimanno et al. (1995) pointed out that could not be defined a critical ESP threshold relating to the effect of ESP on water transport properties, since there were an almost linear relationships between the soil physical properties and the ESP.

Várallyay (1981) measured the influence of Na_2CO_3 on the unsaturated water conductivity of the soil. The influence of Na_2CO_3 was stronger in the low suction range. The influence of Na_2CO_3 solution decreased with the increasing suction.

Rajkai et al. (1993) measured by means of tension infiltrometer much lower hydraulic conductivity on soil with ESP 15 than on soil with ESP 2 in case of similar clay content. In line with Várallyay's result, the water conductivity difference between sodic and non-sodic soil was higher at low than at high tension.

Consequently it can be established that infiltration and leaching (wet condition, low gradient) are more limited than the upward capillary flow (dry conditions, high gradient) promoting the salt and sodium accumulations in these soils in case of a shallow, saline groundwater.

There are only a few data relating to the effect of alkalinity on gas transport in soils. Stępniewski et al. (1992) measured the oxygen diffusion coefficient and air permeability at different moisture tension of clay soils and at different exchangeable sodium content. These aeration-related soil properties were much worse in the natic B, than in the A horizon. However, an exact quantifying of the relationship between alkalinity and aeration properties needs much more data.

Conclusions

Alkalinity indicates very unfavorable physical properties of soils, especially in soils with high smectite-type clay content. The alkaline pH range and the ESP cause increasing dispersion and swelling of clay minerals. The role of organic colloids in the dispersion processes is not fully clarified. The structural deterioration in sodic soils causes a very limited water transport in the matrix of the wet soil. Salt accumulation can hardly be reversed due to the limited leaching in wet state of the soil. To the contrary, an accelerated bypass water movement can occur in dry state

of the sodic soil due to crack formation. The structural and water movement properties of sodic soils are intensively investigated, but clarifying of some special transport properties (i.e., transport through the cracks and soil aeration properties) needs further researches.

ALTERNATIVE SOURCES OF ENERGY FROM AGRICULTURE BIOMASS – A EUROPEAN PERSPECTIVE

Piotr Kowalik
 Department of Sanitary Engineering, Gdańsk University of Technology, Gdańsk, Pommerania, Poland

Introduction

Energy is the capacity of a physical system to perform work. Energy appears in many different forms, including chemical energy of fuels, heat, mechanical energy, and electricity, among others. These are related by the fact that conversion can be made from one type of energy to another.

Biomass is a renewable energy resource in the form of solid, liquid, or gas energy carriers. Solid biomass is used mainly for heat, liquid biomass for transport, and gas for electricity production. Biomass is regenerated by energy from the sun and through societal metabolism. In this context, biomass is material originating from vegetation (wood, straw, lignin liquid waste as black liquor, waste paper), from animals (municipal sewage sludge, manure,

dung), and from substances that produce biogas (from anaerobic digestion of manure, sewage sludge, or organic solid waste on the sanitary landfills), bioethanol (from alcoholic fermentation of potatoes or crops), or pyrolytic gas (produced from wood or sewage sludge).

Organic waste material originating from animal metabolism may include biogas from the anaerobic digestion of animal manure or dung, biogas from anaerobic fermentation of sewage sludge in wastewater treatment plants, or biogas from anaerobic digestion of waste on the sanitary landfills. Organic material may be transformed into pyrolytic gas (mainly during the process of gasification of wood), and this pyrolytic gas may drive gas engines for electricity production or may be used in gas boilers for heat production.

Biomass is accumulated mainly in the place of production or processing of the plant material (e.g., surplus straw during the production of grain, waste wood in timber processing, and pulp in the paper industry), or it may be the plant material produced only for purpose of energy, for example, on the fast-growing, short-rotation tree plantations of selected poplar or willow clones.

Biomass is divided into two types of resources:

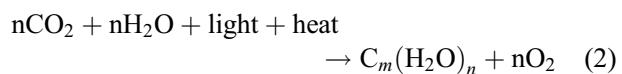

- Primary energy resources, including wood, straw, and sewage sludge (analogous to peat).
- Second-generation biomass that is a processed energy resource, upgraded into the form of biocarbon, biogas, bioethanol, biohydrogen, and pyrolytic gas.

Energy from photosynthesis

Plants have the ability to incorporate atmospheric carbon into biomass through photosynthesis. These molecules can then be used for fuel. This process is roughly exemplified by the following equation:

where PAR is the photosynthetic active radiation (visible light) and 8 quantum of light is needed for transformation of 1 atom of C. The equation takes the form:

The first “block” in building the biomass of plants is glucose, $\text{C}_6\text{H}_{12}\text{O}_6$ ($m = n = 6$), followed by more complex substances like polysaccharides ($m = n = \text{tens/thousands}$), cellulose ($m > n = \text{hundreds/thousands}$), and lignin ($m < n = \text{hundreds/thousands}$).

In the past, black coal $(\text{CH}_2)_n$ was derived from biomass, but today, biogas $(\text{CH}_4)_n$, methanol $(\text{CH}_3\text{OH})_n$, and biohydrogen (H_2) are derived. About 2 Mg of dry wood or straw are equivalent of the energetic value of 1 Mg of black coal. A fossil fuel like black coal has the parameters 25/22/0.8 (25 MJ/kg, 22% ash, 0.8% sulfur), but biomass from plant material (wood or straw) has the parameters 13/3/0.03. Dry sewage sludge has the parameters 14/45/0.8, which is similar to the contents of the coal

waste mud produced during the process of washing of black coal or to the contents of low-quality lignite (brown coal) or dry peat. But in energy production such a material may be utilized, meaning that coal waste mud, low-quality lignite, peat, or dry sewage sludge are considered an energy resource in local solutions.

Energy crops

Energy crops can take many forms and can be converted to a number of different products (Canell, 2003; Sims et al., 2006). Many crop species are multipurpose in that they can be used to produce more than one type of energy product like oil, ethanol, and solid biomass, and they are classified as follows:

1. Oil crops (e.g., rapeseed, linseed, field mustard, hemp) – Vegetable oils can be used directly as heating fuel or refined into transport biofuels such as biodiesel esters.
2. Cereals (e.g., barley, wheat, oats, maize, rye, triticosecale) – Grain can be used to produce ethanol and the straw can be used as a solid fuel (after pelleting, if possible), or for biogas production from feedstock.
3. Starch and sugar crops (e.g., potato, sugar beets, Jerusalem artichoke) – Ethanol can be produced by fermentation, and then is used mainly in blends with gasoline.
4. Cellulose crops (e.g., straw, grass, wood, short-rotation coppice) – The hemicellulose can be reduced to sugar by acid or enzymatic hydrolysis and then fermented to produce ethanol in blends with gasoline or biogas (to produce electricity).
5. Solid energy crops (e.g., whole-crop maize, reed canary grass, silvergrass, willow, poplar) – These crops can be utilized as a whole to produce heat and electricity directly through combustion or indirectly through conversion for use as biofuels like methanol or ethanol.

Such classifications are very useful in the evaluation of the recent biomass market.

In agriculture, solid biomass can be produced from traditional crops like the straw of wheat, rye, or rapeseed, and from grasses. In the timber industry, sawdust and wood chips and shavings are used for biomass (wood used for fuel is usually smaller branches of trees and low-quality timber). From agribusiness, mill cake, brewery grains, pomace of apples, bagasse, beet pulp, fruit stones, husks, molasses, paper, and pulp residues can be obtained.

More than 350 oil-bearing crops have been identified (Demirbas, 2007). Vegetable oils can be used directly or refined to biodiesel. The cereal grains can be used to produce ethanol, and straw can be used as a solid fuel. Sugar and cellulose crops can produce ethanol by fermentation, which is then either used directly or blended with fossil oil. Solid energy crops can be utilized only indirectly through conversion to biofuels. Some of the more common energy crops have been listed by Sims et al. (2006) and Tuck et al. (2006). Discussed here are crops already being grown in Europe or those, although allochthonous,

with potentially high bioenergetic performances. Energy crops are annual and perennial plants, herbaceous or arborescent. Annual crops are mainly cereals or oilseed crucifers of the genus *Brassica*. Less important in terms of cultivated hectares in the EU are sugar beet (*Beta vulgaris* var. *saccharifera*), soybean, hemp, and flax. Perennial crops are herbaceous (e.g., silvergrass, Jerusalem artichoke, giant knotweed), shrubs (e.g., *Rosa multiflora*), or trees (e.g., willow *Salix spp.*, poplar *Populus spp.*, black locust *Robinia pseudoacacia*).

Biomass as a liquid transport biofuel in the form of oil or ethanol is very common. Two technologies exist on the market today. The first is the production of esters from rapeseed oil, creating so-called biodiesel. The second is the production of alcohol in the form of dewatered bioethanol mixed with ordinary gasoline (3.5% bioethanol, 96.5% gasoline) and distributed in the gasoline stations.

Liquid biofuels are produced from crops rich in oil, sugar, or starch. First-generation biofuels were produced as bioethanol from fermentation of maize or potatoes, or as the vegetation oils from rapeseed or soybean. Bioethanol with oil can be used to produce biodiesel, an ester of oils. The second-generation production of bioethanol is based on perennial plants (Reddy et al., 2008) such as switchgrass and silvergrass – these can provide 260% more ethanol per hectare than maize (Heaton et al., 2008) – or microalgae (Schenk et al., 2008) (see *Algae, the Potential Source of Energy*). The global yield for all biomass crops (both herbaceous and woody) ranges from 8 to 22 Mg of dry matter per hectare per year (Ragauskas et al., 2006).

The second generation of biofuels is biogas and biohydrogen. Biogas may be produced by anaerobic digestion in sewage sludge, animal manure, or solid waste dumps.

Biomass for energy in the European Union

According to terminology introduced in the European Union (Grassi et al., 1992; THERMIE, 1995), biomass includes all organic material of biological origin (mainly from vegetation), which may be produced on special energy plantations, or may come from the residues and waste products of forestry, timber production, municipalities, agriculture, and agribusiness (mainly the food-processing industry).

The sources of biomass in the European Union are wood from the fast-growing tree plantations, wood residues from forestry and timber production, manure and dung from animal production, straw produced along with grain, and organic waste in agribusiness during food processing. Organic material in the sewage sludge produced in the municipal wastewater treatment plants is also considered to be biomass. The producers of biomass for energy are agriculture (straw, biogas from animal manure), the forestry and wood processing industry (solid fuel wood), municipalities (waste paper, biogas from the sanitary landfills, or biogas from the wastewater treatment

plants), or industry (residues from the paper and pulp industry, textile industry, food processing industry, etc.).

In the European Union, biomass has been identified as a vast potential reservoir of energy, comprising various organic raw materials of plant origin: forestry production, specific crops, and recycled agricultural, industrial, and household waste. Worldwide, it represents the fourth biggest energy resource (14% of global consumption) (see *Biomass as an Environmentally Benign Energy Source*). However, apart from Austria, Finland, and Sweden, where it plays a significant role, biomass accounts for only 2% of Europe's energy production. Biomass energy can be stored and does not fluctuate, and it has numerous advantages. It is neutral in terms of the greenhouse effect when used for electricity; plants give off the carbon dioxide that they took in while they were growing. A robust biomass industry has considerable potential for job creation and would provide a rationale for developing a common agricultural policy (European Commission, 2006, 2007).

Various European research projects involving conversion technologies (thermochemical, chemical, and biological processes) offer potential for diverse end-users, either as a source of heat and power or in the form of biofuels. Nevertheless, there are logistical problems involved in processing the large volumes of raw materials required to obtain sufficient and economical energy sources. At present, the cost of the energy produced is too high for many applications.

Oilseeds, cereals, starch crops, and solid biofuels will probably increase their growth in northern Europe by 2080, due to increasing temperatures, and will decrease in southern Europe due to increased drought (Tuck et al., 2006). These predictions indicate that the choice of bioenergy crops in southern Europe will be severely reduced in the future unless measures are taken to adapt to climate change.

Conclusion

Barriers to the use of biomass as an energy resource exist, including:

1. Lack of knowledge that the production of heat energy and electricity from cheap residual biomass is very economical and easily competes with conventional fossil fuels.
2. Low prices of conventional fossil fuels that don't account for the negative effects of coal, oil, and natural gas on the environment and human health.
3. Slow progress in the technological development of the most efficient production of heat and power from biomass.
4. Difficulties with the distributing the produced biogas or heat energy and electricity to the state-controlled gas pipe grid or electrical grid or to the district heating distribution pipes.
5. Lack of experience in implementing renewable energy in local energy plans for communities. The dissemination of knowledge about existing pilot programs

and demonstration solutions is important. Until now, there have been a limited number of the success stories and positive solutions, but in the future there will be more examples of installations and commercial applications.

Production of heat and power from biomass is very promising if we take into account the existing positive demonstration plants. Biomass is much more environmentally friendly than any fossil fuel. The technical parameters of the boilers, the positive economical results and relatively short time to payback on investment, and the ecological benefits due to the low level of emission of pollutants into the atmosphere support the increased use of biomass as an energy source.

ANISOTROPY OF SOIL PHYSICAL PROPERTIES

Xinhua Peng
Institute of Soil Science, Chinese Academy of Sciences,
Nanjing, P.R. China

Definition

Anisotropy is the property of being directionally dependent, as opposed to *isotropy*, which means homogeneity

in all directions. It can be defined as a difference in one soil physical property along different directions.

Anisotropic soil does not have the same physical properties when the direction of measurement is changed. Commonly it is used in reference to soil structure, soil strength, and soil permeability changes with direction of measurement.

Causes

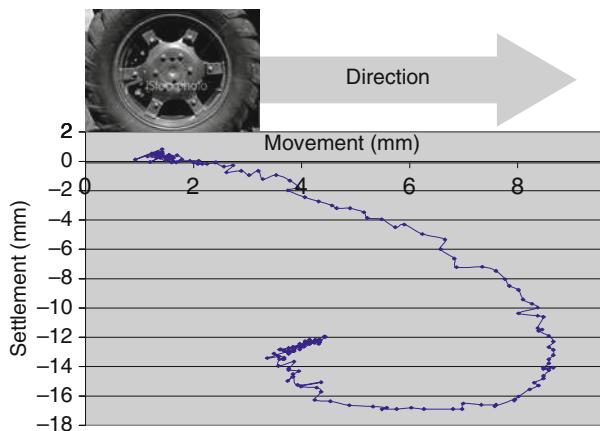

The anisotropy of soil physical properties may be primarily derived from natural pedogenesis. Due to the weathering of rock materials and the input of organic matter into soils, soil profiles can be, in general, defined as a humus-enriched mineral horizon (A), a leached horizon (E), an accumulated horizon (B), and a parent material horizon (C) from the topsoil downward to the less-weathered underlying material. The horizontal layers contain directly dependent soil properties. Human activity may be the secondary factor. Tillage creates a plow layer and a plow pan, which both exaggerate the predominantly horizontal-dependent soil properties. Soil cracks induced by soil shrinkage and swelling and biochannels may be another cause for a vertical-dependent soil structure and the permeability of gas and water. Soil physical properties, which are anisotropic, include soil structure (Pagliai et al., 2004; Dörner and Horn, 2006), soil strength (Peng and Horn, 2008), soil shrinkage and swelling (Bronswijk, 1990; Peng and Horn, 2007), and soil permeability of gas and water (Mualem, 1984; Dabney and Selim, 1987; Dörner and Horn, 2006), and so on. These properties, however, are further interacted each other. For example, the anisotropy of soil structure may result in the directionally dependent soil strength, soil permeability, and soil shrinkage and swelling.

Soil structure

Hydraulic stress by natural wetting and drying cycles and mechanical stress by human tillage management always propagate three-dimensionally through the solid, liquid, and gaseous phases and result in a rearrangement of aggregates, their reformation, or complete destruction. In such case, the stress propagation is linked to an alteration of pore structure and excess soil water is drained off. During the natural wetting and drying cycles, new aggregate formation always starts with a prismatic structure of strongly vertically anisotropic behavior, later followed by a polyhedral and subangular blocky structure with a slight vertical anisotropic to isotropic behavior (Hillel, 1998; Horn et al., 2003). But, after tillage compaction, a platy structure can be formed (Pagliai et al., 2004; Dörner and Horn, 2006).

Soil strength

Mechanical stress from tractor wheeling causes a “kneading effect” of tires, which furthermore enhances an anisotropic soil structure (Figure 1). Aggregates or particles simultaneously move forward and downward. Therefore, the responses of pore structure and soil strength

Anisotropy of Soil Physical Properties, Figure 1 Particles move forward and downward simultaneously during tractor tire running.

to tractor wheeling resulted in anisotropic soil properties. Peng and Horn (2008) reported that agricultural machinery caused soil strength to be more anisotropic in conservation tillage than in conventional tillage.

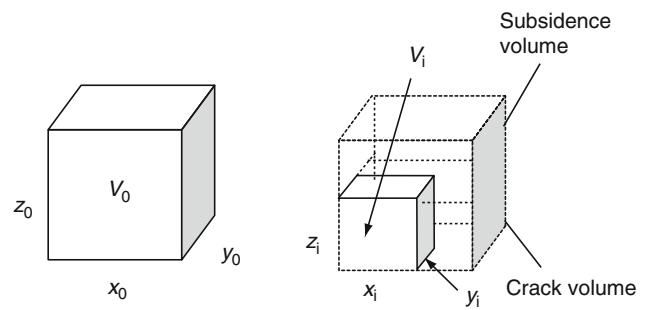

Soil shrinkage/swelling

The anisotropy between the vertical and horizontal deformations during shrinkage and swelling was described by Bronswijk (1990) with the dimensionless geometry factor (Figure 2), r_s , defined by

$$r_s = \ln \frac{V_i}{V_0} / \ln \frac{z_i}{z_0} \quad (1)$$

where V and z are the volume and height of the soil, with the subscript 0 being the initial conditions and subscript i representing the i th step. There are five cases to describe their relationships: (1) $r_s = 1.0$, only vertical deformation; (2) $1.0 < r_s < 3.0$, predominant vertical deformation; (3) $r_s = 3.0$, isotropic deformation; (4) $r_s > 3.0$, predominant horizontal deformation; (5) $r_s \rightarrow \infty$, only horizontal deformation.

Based on the geometry factor, the anisotropy of shrinkage and swelling, increased with water loss and decreased upon wetting (Garnier et al., 1997; Chertkov et al., 2004; Peng and Horn, 2007). A conceptual model about the anisotropy of shrinkage and swelling was proposed by Peng and Horn (2007). At the beginning of drying, water is first drained from macropores by gravity, resulting in a small capillary pressure. The geometry factor shows only vertical shrinkage. As the soil dries further, water is removed from finer pores, causing greater capillary stress and both horizontal and vertical shrinkages. Vertical shrinkage dominates until the soil is dried intensively and only part of the very fine micropores still contains water. At this stage, the heterogeneous distribution of water preferably within soil aggregates and electrostatic attraction produces highly

Anisotropy of Soil Physical Properties, Figure 2 Volume change in vertical and horizontal direction by soil shrinkage.

consolidated platy units. Due to the stress history on the soil the horizontal shrinkage becomes dominant instead of vertical shrinkage, while r_s is a little larger than 3. During swelling, however, the impact of overburden stress on vertical swelling results in the geometry factors exceeding 3.0 during the whole wetting process. At the beginning of wetting, the previously oriented platy soil particles, caused by the shrinkage history, produce the geometry factor greatly exceeding 3.0. If we evaluate the alteration of soil structure during wetting and drying, the shrinkage and swelling processes should be isolated.

Soil permeability

One of the consequences of anisotropic soil structure is a directly dependent permeability of gas and water. Earthworm and roots channels in the plowed layer both cause a preferential flux in a vertical direction (Wiermann et al., 2000; Peng and Horn, 2008). Vertical soil cracks also lead to a vertical predominance of soil permeability, whereas platy soil structure compacted by agricultural machinery induces a mainly horizontal flux (Dörner and Horn, 2006; Horn et al., 2003; Pagliai et al., 2004).

Summary

Anisotropy of soil structure induced either by pedogenesis or by human activity is a basic soil property in nature. However, its consequences have not yet received much attention, particularly when modeling the permeability of gas and water it is often simplified as isotropic. The concept and principle of anisotropic soil physical properties will improve our understanding of dynamic of soil structure and permeability and soil sustainable agricultural management.

Synonyms

Backscatter

Backscattering (or backscatter) is the reflection of waves, particles, or signals back to the direction they came from. Backscattering is defined also as the phenomenon that occurs when radiation or particles are scattered at angles to the original direction of motion of greater than 90°. It is a diffuse reflection due to scattering, as opposed to specular reflection like a mirror. The term is used in several fields of physics, as well as in photography, telecommunication, computer network security, security imaging systems, and e-mail. Backscattering has also important applications in astronomy and medical ultrasonography (Wikipedia).

The incoming waves or particles can be scattered by quite different mechanisms:

- Rayleigh scattering of electromagnetic waves from small particles, diffuse reflection from large particles, or Mie scattering in the intermediate case, causing alpenglow and gegenschein, and showing up in weather radar
- Inelastic collisions between electromagnetic waves and the transmitting medium (Brillouin scattering and Raman scattering), important in fiber optics
- Elastic collisions between accelerated ions and a sample (Rutherford backscattering)

- Bragg diffraction from crystals, used in inelastic scattering experiments (neutron backscattering, X-ray backscattering spectroscopy)
- Compton scattering, used in Backscatter X-ray imaging

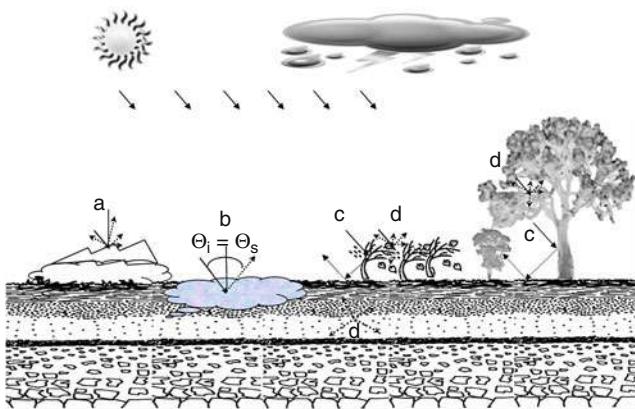

The scattering of rays or particles is more or less isotropic, that is, the incoming rays, particles are scattered randomly in various directions, with no particular preference for backward scattering. In these cases, the term “backscattering” just designates the detector location chosen for some practical reasons (backscatter):

- In X-ray imaging, backscattering means just the opposite of transmission imaging.
- In optical fibers, light can only propagate forward or backward. Forward Brillouin or Raman scattering would violate momentum conservation, so inelastic scattering in optical fibers cannot be anything else but backscattering.
- In inelastic neutron or X-ray spectroscopy, backscattering geometry is chosen because it optimizes the energy resolution.

In other cases, the scattering intensity is enhanced in backward direction. This can have different reasons:

- In alpenglow, red light prevails because the blue part of the spectrum is depleted by Rayleigh scattering.
- In gegenschein, constructive interference might play a role.
- In multiple scattering from suspensions like milk, the enhancement of backscattering is connected with weak localization.

Backscattering occurs in the environment at quite different physical forms and is the result of complex interactions between electromagnetic waves and the land surface, as

Backscattering, Figure 1 Complex interactions between electromagnetic waves and the land surface: (a) diffuse, (b) specular, (c) corner reflection, and (d) volume scattering (Θ_i and Θ_s are incidence angle and reflection angle).

Synonyms

Plant deflection; Plant flexure

Definition

Bending of plants and their parts is understood as a flexure process in which there is a change in the curvature of the plant part. Different views can be used for the

classification of plant bending: Shape and structure of the deflected part

- one-dimensional homogeneous rod (beam) type
- one-dimensional inhomogeneous rod (beam) type
- planar thin (membrane) type
- planar thick homogeneous plate type
- planar thick inhomogeneous plate type

Location of the loading forces

- local forces
- continuous loading

Duration of loading (*Rheology in agricultural products and foods*)

- short-time loading
- long-time loading
- alternating (dynamical) loading

State of plant part (*Drying of agricultural products*)

- natural
- dried
- thermal processed
- chemical processed

Introduction

The bending properties of plants are being studied for a long time, because during plant cultivation and processing, the plants and/or their parts frequently bend. Among the most important properties of this type, are tree windbreak and plant lodging (see [Plant Lodging, Effects, and Control](#)). The physical property connected to both windbreak and lodging resistance is the stem toughness. It plays an important role in harvesting (e.g., hay bailing and fruit shaking harvest) and processing technologies (wood rods and beams, see Kollmann et al., 1968).

Plant bending represents a complicated physical problem, difficult to solve in its complexity. For this reason, plant inhomogeneities are excluded in the actual cases and the problem is solved by methods usually used in material sciences (Boal, 2002).

Theoretical considerations for ideal beam: static elastic case

Theoretical methods describing plant bending follow the methods developed for stress evaluation in beams and plates (Timoshenko and Goodier, 1970; Timoshenko and Woinowsky-Krieger, 1959).

We limit our considerations to a very simple case, where the beam cross section does not change by external loading perpendicular to the beam longitudinal axis. The beam cross section is the same over the whole length of the beam with the same modulus of elasticity E and the second moment of cross-sectional area I to centroidal axis perpendicular to the external forces (the axis lies in the neutral plane). The product EI is then also constant over the whole longitudinal beam axis and is termed bending

toughness T . The Euler Bernoulli's equation for the deformed beam can be written as follows:

$$EI \frac{d^4 u}{dx^4} = w(x) \quad (1)$$

where $u(x)$ is the beam deflection (deformation) in direction perpendicular to the beam longitudinal axis, $w(x)$ distributed load (longitudinal force distribution, in N.m^{-1}), and x is longitudinal beam coordinate. The bending toughness includes information on the beam dimension (second moment of the cross section) and on the beam material (modulus of elasticity see also *Physical Properties of Raw Materials and Agricultural Products*).

In many cases, we can simplify beam loading by external forces taking into account only loading by the bending moment M omitting the shear stresses produced by gradients of the external forces. In this case, the normal stresses σ (in tension and in compression) in a loaded beam can be expressed as follows:

$$\sigma = \frac{My}{I} = E y \frac{d^2 u}{dx^2} \quad (2)$$

where y is the distance of the analyzed point from the neutral plane. Equations 1 and 2 can be integrated depending on the boundary conditions and the relations between external and internal quantities can be obtained as follows for two important cases (see also Mohsenin, 1986):

Type of loading	Beam maximum deflection	Stress
<i>Cantilever</i>		
A beam with one fixed and one free-loaded end F – loading force, l – length of beam	$y = \frac{Fl^3}{3EI}$	$\sigma = \frac{My}{I}$ see Equation 2
<i>Three point beam bending</i>		
A beam supported on the ends and loaded in the center of the beam by a perpendicular force F – loading force, l – length of beam	$y = \frac{Fl^3}{48EI}$	$\sigma = \frac{My}{I}$ see Equation 2

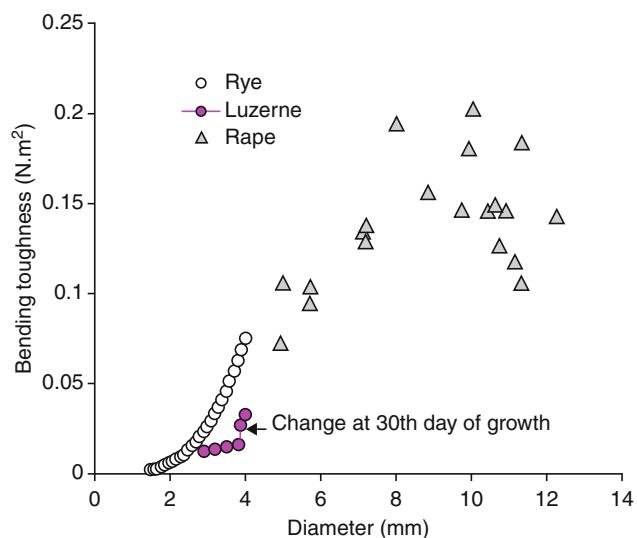

The second moment of the cross section area I depends on the shape of the cross section. For rectangular shape $I = bh^3/12$, where b is the length of the edge perpendicular to the loading force. For circular cross sections, $I = \pi d^4/64$.

The simple formulas in the above table are complicated in more real cases by the direct influence of external "feed" forces that change the stress field in the loaded beam and moreover change the shape of the cross section area (Skubisz, 1982). This type of change is observed at bending of cereal stems similar to thin wall tube. The given formulas can be used only to test very long beams at low levels of loading.

Mechanical properties of plant stalks and trunks

Bending tests of real plant stalks give variable results (see *Plant Biomechanics; Grass Fibers, Physical Properties*). The bending toughness for cereal stalks (rye), rape stem, and the lucerne stalks are given in Figure 1. The figure shows that bending toughness increases with increasing stalk diameter in most cases. For rye, nearly an exact relation was found even if the toughness depends not only on the diameter but also on the thickness of the stem wall and its modulus of elasticity. The results obtained on raw lucerne stalks show that in this state toughness is lower than in the dry state (see *Drying of Agricultural Products*) and illustrate the influence of stalk lignification. The results obtained on the dry rape stems illustrate limitations on the trend of increasing of stem toughness with increasing diameter. The increase in diameter of the rape stem is usually related to the increase of the soft aerenchyma (see *Microstructure of Plant Tissue*) in the stem, which leads to a decreasing mean value of the modulus of elasticity and a decreasing value of the bending toughness. Moreover, the rape stem aerenchyma is frequently destroyed by insects with consequence of toughness decrease, mainly in thick parts of the stems (Skubisz and Blahovec, 1997; Skubisz et al., 1989).

Modulus of elasticity of young soft plants is 1–2 GPa (lucerne) and moves up to values of about 10 GPa for dry cereal stalks and/or stems. This quantity could reach values of 20–30 GPa for special sclerenchymatic parts of the dry stalks (Razdorskij, 1949, *Microstructure of Plant Tissue*). These results are in agreement with the module of elasticity of wood, as obtained in bending test. For moist natural

Bending Properties of Plants, Figure 1 Plot of bending toughness versus diameter for some field plants: dry cereal stem (rye), raw lucerne stalk, dry rape stem (Blahovec, unpublished results). For rye it is quasi-theoretical formula $T = 0.0000995d^4 + 0.00114d^3 - 0.00157d^2 + 0.000504d - 0.0000801$, where d is in mm and T in N.m^2 . At lucerne the effect of its stalk lignification is displayed.

wood, the results are well below 10 GPa (Skubisz et al., 2001; Kollmann et al., 1968) whereas for dry wood ($MC\ d.b. = 12\%$) the values are usually higher than 10 GPa.

Bending tests give data suitable for strength limit estimation. Our unpublished results give 40–50 MPa for dry cereal stalks.

Stationary vibrations of plant stalks

Stationary natural vibration of an elastic beam is given as follows:

$$\omega_i^2 = k_i \frac{EI}{S\rho l^4} = k_i \frac{EI}{ml^3} \quad (3)$$

where ω_i is a natural angular frequency of the mode i with the characteristic constant k_i , S cross section of the beam area, ρ density, l length, and m mass. The characteristic constant is given by fixing of the beam and it is related to different harmonics of the vibration. Equation 3 shows that natural frequencies are proportional to the bending toughness of a beam. Experimentally determined natural frequencies of plant beams can be used to calculate their bending toughness. The natural angular frequencies of wheat stalk internode are about 40 s^{-1} (Dunca, 2008).

Bending of processed plant stalks and their parts

Plants and their parts are frequently bent in basket making, matting, and joinery. In most cases, the plants are processed before bending. The processing is very variable but generally it consists either in separation of the fibrous parts (Microstructure of Plant Tissue; Grass Fibers, Physical Properties) that can be well bent or hydrothermal or chemical modification of the plant parts to increase their inelastic deformability. For hydrothermal processing, hot water or steam is used to increase the temperature of the processed medium up to temperatures between 90°C and 98°C (for details see Kollmann et al., 1968).

Conclusions

The key problem of plant bending is related to rod bending that is modeled by beam bending. A big part of the problems is of elastic character that can be solved in the frame of the theory of elasticity either as a static or as a dynamic problem. Static bending is based on the term “bending toughness” with two subcomponents: the modulus of elasticity and the second moment of the cross-sectional area. The dynamic bending is tightly connected with beam natural frequencies.

Other bending problems have to be solved by numerical methods. Some of the problems are connected with deep changes in plant properties during processing and have to be solved experimentally.

BIOCHEMICAL RESPONSES TO SOIL MANAGEMENT PRACTICES

Jan Koper¹, Małgorzata Brzezińska²

¹Department of Biochemistry, University of Technology and Life Sciences, Bydgoszcz, Poland

²Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland

Definition

Biochemical response: Change in the activity of enzymes induced by external and internal signals.

Soil management: The combination of all tillage operations, cropping practices, fertilizer, lime, and other treatments conducted on or applied to the soil for the production of plants (Glossary of Soil Science Terms, SSSA, <https://www.soils.org/publications/soils-glossary>).

Introduction

Soil provides a habitat for numerous and diverse species of bacteria, fungi, and microfauna and can be viewed as a huge heterogeneous collection of microsites throughout which microorganisms are unevenly distributed (McCarthy et al., 2005). Agricultural management changes soil physical conditions (e.g., aggregate stability and air-water status) and the quantity and quality of plant residues entering the soil, thus strongly modifying the habitat of soil microbes.

Soil biochemical activity

All functions of a cell are based on the fine-tuned action of enzymes that are part of regulatory networks. Owing to the possibility of metabolism regulation, soil microbes persist in changing soil environment. Central to cell regulation is the ability of a cell to adopt the activity of enzymes in response to external and internal signals. In a broad sense, enzyme regulation operates at two main levels, either by changing the enzyme concentration (mechanisms used often for long-term adaptations) or by altering the activity of preexisting enzymes (a quick response to stimuli, allowing short-term changes in the rates of biochemical reactions) (Krauss, 2003).

Enzymes in soil are produced mostly by bacteria, fungi, and plant roots. They are active in soil both intra- and extracellularly (Burns, 1978), and are similar to enzymes in other systems, in that their level and reaction rates are markedly dependent on pH, temperature, redox potential, ionic strength, presence of inhibitor or substrate, etc. (Gliński and Stępniewski, 1985; Dick and Tabatabai, 1993). At low nutrient concentrations, soil microbes may maintain viable populations by growing slowly or by sustaining periods of starvation interspersed by rapid proliferation and increase in metabolism intensity when nutrients become available (McCarthy et al., 2005).

Despite major amounts of introduced enzymes are inhibited by soil constituents or rapidly degraded by soil proteases, the enzymes synthesized by plants, and added to soil with plant residues, may remain active. Thus, it is not surprising that the type of vegetation added to soil can greatly affect soil enzyme activity (Dick and Tabatabai, 1993). Plants also indirectly influence soil biochemical activity. Enzyme activity is considerably greater in the rhizosphere of plants than in bulk soil due to either a specific microflora or the plant root or to both (Nannipieri et al., 2007).

Effect of agricultural management on soil biochemical activity

Biochemical activity of soil organisms is involved in both the stabilization and degradation of soil structure. Agricultural production causes an alteration of natural ecosystems and produces disturbances in abiotic and biotic components (Schjønning et al., 2002; Liu et al., 2006; Melero et al., 2009). There is worldwide interest in assessment of management effects on soil quality. Soil physical, chemical, and biological properties are involved in soil functioning and all have been extensively used to measure soil quality. However, physical and chemical properties usually change very slowly and at a temporal scale are not suitable for short-term management purposes. By contrast, soil biochemical properties respond most rapidly to small changes in soil, and, because are directly related to soil organisms involved in biogeochemical cycles of C, N, P, and S, thereby are considered to be appropriate indicators of soil quality or early indications of soil alteration in both natural and agroecosystems (Pankhurst et al., 1997; Gil-Sotres et al., 2005; García-Ruiz et al., 2008).

Many publications over the last decades have dealt with modification of soil biochemical activity by soil management practices (a few of them are listed in Table 1).

In general, a decline of soil biochemical activity can be observed following soil cultivation with respect to adjacent soils in continuous grass and pasture (Bandick and Dick, 1999; Caravaca et al., 2002). Numerous experiments confirmed that intensive and even reduced tillage resulted in lower enzyme activities than a no-tillage system. Nevertheless, conservation tillage system is still far from reaching the quality levels of the adjacent soils under native vegetation (Roldán et al., 2005). Trasar-Cepeda et al. (2008) observed a much lower biochemical status of 45 cultivated soils than those corresponding to soils under oak forest (*climax* soils), i.e., natural soils of the highest possible quality. However, when the biochemical properties were expressed per unit of organic C, the values for both types of soils were very similar, and for some properties, the values for the cultivated soils were even higher.

The no-tillage system, which allows a great surface accumulation of crop residues, is the most effective for improving soil biochemical status. In cultivated systems, enzyme activity is higher where crops or organic residues were added as compared to treatments without amendments (Bandick and Dick, 1999). Change in the quantity and quality of plant residues in the soil profiles under different practices strongly influences soil microbial processes, and an effect of management practices may vary among different soil depth (Friedel et al., 1996; Kandeler et al., 1999; Geisseler and Horwath, 2009).

The study of Eivazi et al. (2003) was designed to examine the long-term effects of various cropping and management practices (since 1888) on five soil hydrolases. With regard to tillage practice, activities of all tested enzymes were significantly higher for continuous corn

Biochemical Responses to Soil Management Practices, Table 1 Soil enzymes used in studies of the effect of agricultural practices on soil biochemical activity

under no-tillage than for continuous corn under conventional tillage. All enzymes showed significantly higher activity in plots that received manure applications since 1888, regardless of crop type as compared with inorganic fertilization. The highest enzyme activities were found in the 3-year rotation plot which received manure as only source of fertilizer since 1888, and the lowest values in the plot under continuous soybean grown under conventional tillage. The lower activities of soil enzymes in the monoculture than in the rotation system indicates that substantial disturbances occur in the microbial activity under the monoculture (Dick, 1992; Koper and Piotrowska, 1998; Gajda and Martyniuk, 2005).

Animal manure and plant residues usually stimulate soil biochemical activity (Bandick and Dick, 1999; Schjønning et al., 2002; Koper et al., 2004). However, after slurry and FYM application, a specific response was also observed, depending on tested enzyme (Koper and Piotrowska, 1999). Although inorganic fertilizers can increase soil biological activity because of an increased plant biomass production, some evidence suggests that repeated applications of inorganic fertilizer nutrients can suppress production of certain soil enzymes that are involved in the cycling of a given nutrient (Dick, 1992; Nazarkiewicz and Kaniuczak, 2008), or the changes can be negligible (Koper et al., 2004). The intensity of the effect of NPK-fertilization on enzyme activities may differ for rhizosphere and non-rhizosphere soil (Skwaryło-Bednarz and Krzepiło, 2009).

Marx et al. (2005) assessed the effect of long-term nitrogen fertilization on distribution and kinetics of six hydrolases in four particle-size fractions. For non-fractionated soils, N management had a considerable

effect on all enzymes, with the fertilized system having a higher activity than the non-fertilized system. At higher resolution, in the particle size fractions from both fertilizer systems, the same observations were made, except in the coarse sand fraction ($>2,000 \mu\text{m}$), where activities were not significantly different. Soil hydrolases showed a significant fertilization effect in the smaller size fractions, while both clay-size fractions displayed no change in their contents of C_{org} and N_{tot} . This shows that the variation in enzyme activity cannot be solely explained by changes in the organic matter status. What seems clear, at least in the clay-size fraction (2–0.1 μm), is that the enzyme activity is more sensitive as an indicator of treatment effects than are C and N contents. It is unclear, however, whether the higher catalytic potential in the high N system can be attributed to a larger accumulation of enzymes or a more advanced enzyme system with higher activity rates. The same values of Michaelis constant (K_m) were found in the same fractions from the soil under two contrasting fertilizer management regimes, indicating that the K_m was unaffected by soil changes caused by N fertilization (Marx et al., 2005).

The usefulness of soil enzymes as indicators of soil quality has also been criticized because of their seasonal changes and inherent differences in the activity, and sometimes little or inconsistent responses across soil management practices (Wick et al., 1998; Geisseler and Horwath, 2009). However, the enzyme activities show higher sensitivity to soil management practices than do other soil properties. In a long-term study, Kandeler et al. (1999) found that enzyme activities significantly increased in the top 10 cm of the profile after only 2 years of minimum and reduced tillage compared to conventional

tillage. In contrast, significant effects of tillage treatments on microbial biomass, nitrogen (N) mineralization, and potential nitrification were not observed until after 4 years. Besides, soil enzymes are strictly related to nutrient transformations and are easy to measure. Thus, soil biochemical activity is commonly used for assessing the quality or sustainability of agricultural ecosystems (e.g., Roldán et al., 2005). Another option for the evaluation of the impact of soil management on soil ecosystem is to use complex indices calculated by the combinations of different biochemical and physico-chemical soil properties (Koper et al., 2003; Koper and Piotrowska, 2003; Puglisi et al., 2006; Bastida et al., 2008).

Summary

The use of land for agricultural purposes is one of the main causes of soil degradation, and there is therefore worldwide interest in quantifying the loss of soil quality generated by agricultural operations. Soil enzyme activities are increasingly used as indicators of soil quality because of their relationship to decomposition and nutrient cycling, ease of measurement, and rapid response to changes in soil caused by both natural and anthropogenic factors. The enzyme activities show higher sensitivity to the agricultural practices than do physical-chemical properties, and, thus are useful for monitoring of the trends in soil over time and as early indicators of management-induced changes in soil quality. Numerous experiments show that the traditional soil cultivation generates many changes in soil properties and the associated changes in biochemical activity. In quantitative terms, the enzyme activities in soils under intensive cultivation are lower than in soils from undisturbed ecosystems. Soil biochemical activity reflects not only soil properties but also tillage operations, cropping practices, fertilization, liming, and other agricultural treatments.

Bacteria; Organic colloids; Protozoa; Viruses

Definitions

Colloids: Particulate matter between the sizes of approximately 10 µm to 1 nm of organic (e.g., viruses, bacteria, microemulsions, nonaqueous phase liquids) or inorganic (e.g., clay particles, mineral precipitates) nature.

Biocolloids: A colloidal entity of organic nature including bacteria, viruses, protozoa, and their respective exudates.

DLVO theory: A balance of van der Waals and electric double layer forces set to describe the stability of colloidal particles in suspension.

Stability: In colloid systems, it is the state in which particles resist flocculation or aggregation for an extended period of time.

Colloid facilitated transport: Typically used to describe the enhanced movement of otherwise immobile contaminants that sorb onto colloid surfaces and therefore travel much further and faster than traditional solute transport models predict.

Why we look at colloid/biocolloid transport in soils

The transport and retention of colloids and biocolloids in soils is of significant interest from the standpoint of groundwater protection, bioremediation of subsurface contamination, and wastewater and drinking water treatments (Ginn et al., 2002; Keller and Auset, 2007). In terms of water treatment, colloidal-sized contaminants need to be removed from wastewater prior to discharge, and biocolloid concentrations must meet drinking water standards for potable water. However, despite the importance of this topic, the transport of pathogens through porous media is still poorly understood.

Colloid systems have special properties that allow them to resist flocculation and aggregation, and will thus remain in a stable suspension for very long periods of time. Due to their particle size, colloids are characterized by a high surface-to-volume ratio, which promotes complexation and sorption of a variety of substances onto their surface. Thus, the hydrological pathways of the soil water in which colloids are suspended/advection, as well as their surface chemistry properties are crucial parameters that determine the fate of colloids in soils.

Most research on biocolloid transport in the subsurface has been focused on the movement of disease-causing

contaminants to drinking water aquifers. The phrase “biocolloid contaminants” is generally used to refer to human pathogens such as viruses (e.g., Hepatitis A, non-A, and non-B) and enterobacteria (e.g., *Escherichia coli*, *Salmonella*, and *Campylobacter*). These pathogens generally enter the soil environment via land-applied wastes and leaking septic systems at or near the soil surface (Steenhuis et al., 2006). The distribution of coliform bacteria in soils often follows the direction of groundwater flow from leaking septic tanks and sewer lines, where a steady supply of nutrients and favorable growth conditions encourage greater bacterial penetration and proliferation (McCarthy and Wobber, 1993). Precipitation facilitates the transport of these pathogens even further, as rainwater infiltrates the soil and carries suspended biocolloids to depths that can reach groundwater aquifers. Although the soil matrix acts as a natural filter for percolating water, the flux of bacteria through soils is governed by a complex set of interrelated physical, chemical, and biological processes, which in turn control cell growth, survival, attachment, and detachment.

Currently, available understanding on the processes that control the transport and retention of colloid particles in soils is being applied toward the advancement of colloid-based strategies for subsurface contaminant mitigation and remediation. Several strategies that rely on effective colloid manipulation include (1) Improved delivery of specific microbes with the ability to scavenge and transform toxic compounds into benign substances, (2) Increased mobility of colloids to change the soil’s permeability to create an *in situ* barrier that will isolate the region of concern, (3) Introduction of surface-active colloids to promote contaminant sorption onto their surface, allowing the colloid sorbed contaminants to move with the flowing groundwater and be more efficiently extracted by pump-and-treat systems (McCarthy and Wobber, 1993).

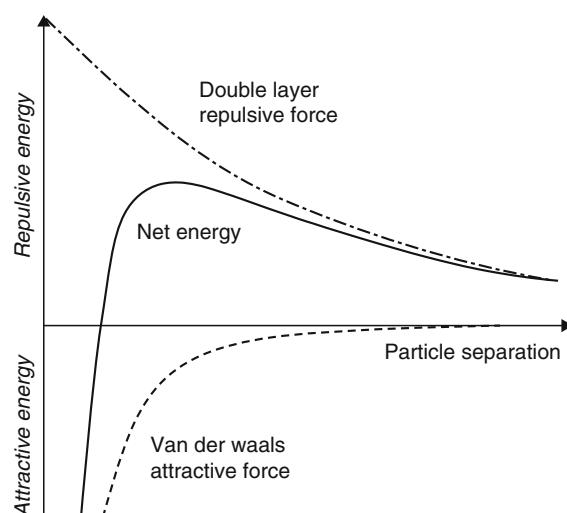

Thus, in cases when biocolloids are either accidentally or purposefully introduced into soils, understanding transport and retention of biocolloids is critical to effectively predict the load and timing of biocolloids arriving to a particular aquifer or contaminated site. To date, accuracy of predicted concentrations is a major challenge in environmental engineering; especially in terms of protecting drinking groundwater resources that become unsafe with minimal biocolloid contamination. In the following sections, a brief review of the primary transport and retention mechanisms of colloids/biocolloids is provided, though it is important to mention that it is an active research area that is constantly advancing our understanding of this complex topic.

Transport and retention processes of biocolloids in soils

Water is the primary carrier of colloids/biocolloids in soils. During transport, colloids can become permanently retained or retarded by a number of physical and chemical mechanisms that affect the behavior of colloids with each

other and the soil media. In addition, colloids tend to be excluded from soil pores in which they physically do not fit, and thus travel mainly through larger pores. For this reason, colloids can reach velocities that are orders of magnitude larger than the average velocity of solutes. Although several theories have been put forward to explain energetically how colloids behave in soils and their likelihood of becoming retained, none of them are found without shortcomings; especially in calculations that aim to predict colloid transport through unsaturated soils where water, air, and soil phases coexist.

Colloid retention in porous media is partially dependent on surface interactions between a colloid and the solid–water interface (SWI), colloids with each other, or a colloid and the air–water interface (AWI). As a colloid or a colloid aggregate collides with an immobile surface in the soil, the probability of attachment is determined by a balance of electrostatic and van der Waals forces between the colloid(s) and the retention site. These surface interactions are calculated by the Derjaguin–Landau–Verwey–Overbeek (DLVO) theory of colloidal stability. The van der Waals and electric double layer energies in DLVO theory are calculated as additive forces that decay with separation distance between charged surfaces/particles (Figure 1). The net energy potential indicates whether the interaction between the two particles will be repulsive (i.e., favorable colloid stability) or attractive (i.e., favorable colloid aggregation and/or surface attachment). Because the classic DLVO theory assumes conditions that are too simple to account for the complexity of natural systems, a significant amount of work has been done to elucidate a more complete set of dominant forces, including hydrogen bonding, hydrophobic effects (i.e., Lewis acid

Biocolloids: Transport and Retention in Soils,

Derjaguin–Landau–Verwey–Overbeek (DLVO) energy
potential of two approaching colloidal particles.

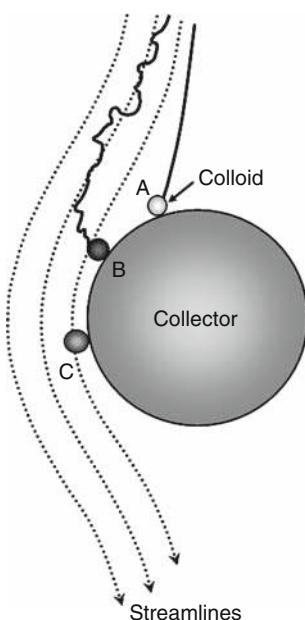

base interactions), and steric interactions (van Oss, 1994; Grasso et al., 2002), often referred to as extended-DLVO forces. However, the applicability of a combination of these additional forces to any colloidal system remains a topic of controversy, and more work on the matter is still needed to specify the dominant mechanisms that control colloidal stability of complex natural systems.

Although DLVO theory has been widely employed to account for the behavior of many colloid systems, the main assumptions of DLVO theory (colloid sphericity, uniform charge density, and impermeable surfaces) are promptly violated when applied to describe biocolloid stability. Biocolloids are inherently nonspherical, soft, deformable, have nonhomogeneous surfaces, and respond to chemical changes in the environment (Ginn et al., 2002; Tufenkji et al., 2006). Thus, biocolloids require an additional set of interaction forces to describe the mechanisms that affect their transport behavior.

The clean bed filtration theory derived by Yao et al. (1971) is the most commonly used approach for predicting particle deposition in a saturated and homogeneous porous media (Rajagopalan and Tien, 1976; Tufenkji and Elimelech, 2004; Tien and Ramarao, 2007; Cakmak et al., 2008). This theory describes the removal of suspended particles onto a single collector surface (i.e., soil grain). According to the theory, a particle moving through a porous medium will collide with a collector by one of three mechanisms (Figure 2): (1) interception, dragging colloids along streamlines; (2) gravitational settling of colloids or aggregates that are denser than the fluid; or (3) Brownian motion of particles. Nonetheless, filtration theory inaccurately predicts the amount of colloids that will become retained in the presence of an energy barrier between the colloid particles and the charged porous medium due to its simplistic pore geometry assumptions (Johnson et al., 2007; Bradford and Torkzaban, 2008). This discrepancy in deposition has more recently been explained with additional retention mechanisms (e.g., colloid wedging between grain-to-grain contacts) in pore structures made up of multiple collectors and the flow dynamics associated with them (Johnson et al., 2007).

A substantial fraction of research to date has focused on colloid transport in saturated porous media; though attention is quickly shifting toward the more complex – and perhaps more important to understand – transport in unsaturated porous media. Interest in unsaturated porous media transport has grown because the vadose zone is the critical connection between surface and shallow contaminant sources and the deeper groundwater (McCarthy and McKay, 2004). In addition to the above-mentioned characteristics that control transport in saturated soils, transport in unsaturated soils is further complicated by the presence of air. This third phase greatly affects colloid partitioning between the water phase, the soil surface, and the interfacial regions in between (e.g., AWI, SWI, and air–water–solid interface), which often act as additional sites for colloid retention (Crist et al., 2005; Zevi et al., 2005; Bradford and Torkzaban, 2008; Gao et al., 2008; Morales et al., 2009; Zevi et al., 2009). Experimental observations indicate that colloid retention in unsaturated soils is generally enhanced, though the mechanisms responsible for retention at the observed sites are still under debate. In addition to the moisture content of the porous medium, wetting history and changes in solution chemistry significantly contribute to the retention mechanisms of colloid transport through soils (DeNovio et al., 2004).

Predictive simulation studies aim to model biocolloid behavior under sets of measurable deterministic field conditions. For simplification purposes, colloids are typically modeled as inert particles suspended in fluid that can be represented with a modified convection–dispersion equation (CDE) containing systematic terms to account for attachment, detachment, and die-off of biocolloids (Elimelech et al., 1995; Tufenkji, 2007). While colloid transport models for saturated porous media are relatively effective and well developed, currently available models for unsaturated porous media are limited and need further improvement (Flury and Qiu, 2008).

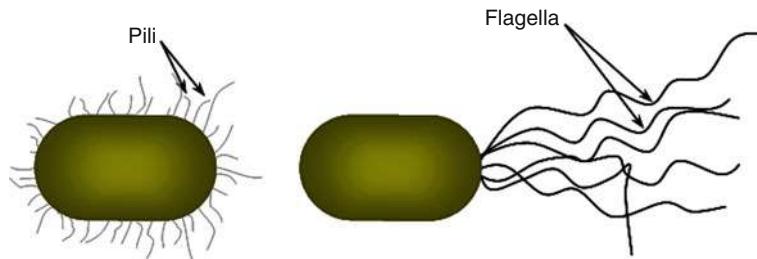

Biocolloids: Transport and Retention in Soils,

Figure 2 Schematic of filtration theory demonstrating colloid sedimentation (A), diffusion (B), and interception (C) onto a single soil-grain collector.

Effect of biofilms and extracellular appendages on biocolloid transport

Biofilms play an important role in the retention of colloids in the subsurface, as they are the prevailing lifestyle of most soil bacteria. Moreover, biofilms promote biocolloid

Biocolloids: Transport and Retention in Soils, Figure 3 Generic bacteria with pili and flagella appendages.

retention by anchoring cells of a colony to soil surfaces (Or et al., 2007), and often act as a nucleation site for suspended biocolloids (Keller and Auset, 2007).

Extracellular appendages or surface structures such as flagella, pili, curli, and polysaccharides are suspected to also play a key role in bacterial transport and retention through soils (Stevik et al., 2004). Short extracellular structures like lipopolysaccharides, curli, and pili (Figure 3) are typically associated with strains that are easily retained in soils, as it is hypothesized that the small appendages are used as sticky arms that help cells hold on to surfaces while biofilm is synthesized to attach the cells more permanently (Rijnarts et al., 1995; Walker et al., 2004, van Houdt and Michiels, 2005). In contrast, structures like flagella and cilia (Figure 3) increase cell motility, and are typically associated with more mobile strains that favor a nomadic lifestyle. As such, biocolloids with these characteristics are carried in suspension by the flowing soil water.

In addition to surface structures, different bacterial strains have diverse physicochemical properties that influence the cell's "stickiness" and ability to form biofilms (Keller and Auset, 2007), and subsequently affect biocolloid transport and retention. Other biological factors that may also affect attachment of microorganisms to immobile surfaces, but which are difficult to monitor in situ include cell growth, death, predation, and biofilm sloughing. Recent research is focused heavily on understanding the factors that support long-term survival of biocolloids in soils and the conditions that induce cell detachment from soil grains, which are related aspects of biocolloid transport that are still not well understood.

Conclusions

This chapter provides an overview of the transport mechanisms that allow biocolloids to move through soils. A vast amount of work has been done to further our understanding of the physical and chemical mechanisms that drive biocolloid transport through porous media. However, one major drawback to currently available knowledge is the accuracy with which models can predict the arrival time and concentration of biocolloids to specific locations in the subsurface, which are critical for protecting groundwater aquifers from contaminants and

for effective bioremediation strategies. In order to address this knowledge gap, basic research is constantly being carried out to discern interrelated effects that are not accounted for with classic DLVO and filtration theory calculations. In addition, technological advances constantly increase our ability for collecting data with improved temporal and spatial resolution, so that the necessary information can be assembled to refine predictive models and effectively monitor biocolloid transport in soils.

BIOFILMS IN SOIL

Mette Burmølle, Annelise Kjøller, Søren J. Sørensen
Section of Microbiology, Department of Biology,
University of Copenhagen, Copenhagen K, Denmark

Definition

A biofilm is commonly defined as “a structured community of bacterial cells enclosed in a self-produced polymeric matrix and adherent to an inert or living surface” (Costerton et al., 1999), but this definition has been modified to also include that the cell attachment is irreversible, and that the bacteria living in the biofilm exhibit an altered phenotype with respect to growth rate and gene transcription (Donlan and Costerton, 2002).

Introduction

Biofilms are characterized by being composed of cells that are organized into matrix-enclosed structures that vary in size from smaller microcolonies to large and sometimes “mushroom-shaped” structures, which allow nutrient supply and waste product removal for cells placed in the deeper biofilm layers (Costerton et al., 1987; Donlan and Costerton, 2002; Stoodley et al., 2002; Jefferson, 2004). The biofilm matrix consists of extracellular polymeric substances (EPS), mainly exopolysaccharides, and also of proteins and nucleic acids, and contains up to 97% water (Sutherland, 2001; Stoodley et al., 2002).

It has been estimated that “99% of all microbial activity in open ecosystems is stuck (in biofilms) to surfaces (Potera, 1996)”. Furthermore, bacteria are believed to obtain several advantages by living in biofilms (Jefferson, 2004). Therefore, understanding of biofilm structure, dynamics, and function has become a crucial part not only of microbiology but also of many more or less related research areas. Despite this, little is known about biofilms in soil, which may be due to the difficulties involved in the study of this structurally complex environment at the microscopic scale without disturbing the soil- and biofilm structures.

Bacterial distribution in soil

Bacteria are not evenly distributed in the soil environment. The highest bacterial densities are found near nutrient sources, i.e., on roots or decaying organic material (Foster, 1988; Pearce et al., 1995; Nunan et al., 2003) (see [Microbes, Habitat Space, and Transport in Soil](#)). In the bulk soil, bacteria are found in patches or microcolonies containing low cell numbers, often composed of different bacterial species (Nunan et al., 2003; Grundmann, 2004). However, when exposed to nutrient sources, these microcommunities have the potential of developing into multispecies biofilms with high bacterial density (Nunan et al., 2003). This biofilm-associated fraction may represent the stage of the bacterial life cycle in soil, characterized by metabolic activity, whereas the microcolony

stage is a dormant/survival stage with low activity. If so, cell division and interactions with other bacteria in the active biofilm stage must be of major importance for bacterial adaptation and proliferation in soil.

Why form biofilms in soil?

The physical and chemical conditions faced by bacterial cells in soil may change dramatically over very short time periods, which is why the ability of adaptation and self-protection is crucial for the survival of soil bacteria. Due to the embedment of cells in the biofilm matrix, the biofilm-associated cells are surrounded by a more constant environment than that outside the biofilm (e.g., in the soil water) and may better resist these dramatic changes.

A highly varying parameter in soil is the water content, and soil bacteria are often exposed to drought. However, it has been demonstrated that a soil *Pseudomonas* sp. produced more exopolysaccharides when subjected to desiccation (Roberson and Firestone, 1992) and that biofilm forming (mucoid) strains of different species survived desiccation better than isogenic non-mucoid mutants (Ophir and Gutnick, 1994). These results strongly indicate a protective effect of the biofilm toward desiccation, which is likely to be caused by the moist nature of the biofilm matrix (Sutherland, 2001; Jass et al., 2002).

Another challenge met by soil bacteria is the exposure to antibiotics, which are naturally produced by microorganisms in soil (Hansen et al., 2001), or to heavy metals and other toxic compounds present in plant material (Verbruggen et al., 2009). Generally, bacteria are more resistant to a wide range of antibacterial compounds when present in biofilms, compared to the free-living, planktonic state. This has been attributed to several factors including reduced permeability of the EPS matrix to some compounds and a changed gene and protein expression patterns that up-regulate the stress response (efflux pumps, EPS production, and stress factors) and lead to the formation of the more resistant “persistor cells” (Mah and O’Toole, 2001; Gilbert et al., 2002; Jefferson, 2004). A similar protective effect of biofilms in soil was indicated in a study by Almås et al., where it was demonstrated that the tightly bound bacterial cells (i.e., those present in biofilms or very small soil pores) were more susceptible to trace metals, which indicates a previous protection from the metals in the soil (Almås et al., 2005). The biofilm environment may also serve as protection against protozoan grazing, which is considered to be a very important constraining factor for bacterial growth in many environments, including soil (Ekelund and Rønn, 1994).

Finally, soil bacterial biofilms consist of a mixture of multiple species interacting metabolically and socially, whereby the present bacteria gain several selective advantages (Jefferson, 2004). The fact that different species are present in a high cell density environment increases the possibility of horizontal gene transfer (Sørensen et al., 2005) and this process may be further stabilized by the structural nature of the biofilm. Thus, by organizing in

biofilms, the cells increase their possibility of receiving genes from other bacterial cells – genes that usually encode traits, conferring selective advantages (Sørensen et al., 2005; Burmølle et al., 2008). Hereby the cells adapt even further to the versatile soil environment. The biofilm environment may also offer optimized conditions for quorum sensing, whereby bacteria regulate gene expression according to the cell density. We have demonstrated that intraspecies communication, based on *N*-acyl homoserine lactones, occurs in soil (Burmølle et al., 2005) and inter-species communication, based on universal signal compounds (such as AI-2, Xavier and Bassler, 2003), are likely to play a role in the development and physiology of multispecies biofilms. Additionally, multispecies biofilms are even more resistant to antibacterial compounds than those composed of single species (Burmølle et al., 2006) and the biofilm environment may also serve protection of species that would otherwise be outcompeted (Stewart et al., 1997; Klayman et al., 2009).

Thus, there are many selective advantages gained by soil bacteria by organizing into biofilm communities. From an evolutionary perspective, these may result in an improved fitness for the biofilm-associated bacteria, and it seems likely that the selective pressure in soil has favored bacteria capable of biofilm formation to such extend that the species surviving in the soil are those capable of biofilm formation when exposed to nutrient availability.

How to study soil biofilms

As previously mentioned, *in situ* studies of soil biofilms are complicated because of the complex structure of the soil environment. This, combined with an astonishingly high bacterial number ($\sim 10^9$ cells/g soil) and diversity ($\sim 10^6$ species/g soil) (Torsvik et al., 1990; Gans et al., 2005), imposes challenges and difficulties on such studies. Microscopic analysis of ultrathin soil slices provides information on the distribution of bacteria in the soil (Foster, 1981; Foster, 1988; Nunan et al., 2003), but not on the nature or function of these bacteria. One way to circumvent this is to study aspects of biofilm formation and physiology in the laboratory by use of model systems composed of one or more soil isolates, similar to the studies of the bacterial response to desiccation mentioned above (Roberson and Firestone, 1992; Ophir and Gutnick, 1994). A very commonly used model system is flow cells, where the biofilms are established on glass surfaces and continuously studied by confocal scanning laser microscopy (Møller et al., 1997; Stach and Burns, 2002). This technique has been adapted for studies of soil conditions by addition of sand grains to the medium (Rodriguez and Bishop, 2007). Biofilm establishment in culture tubes allows high-resolution microscopy of structural aspects of biofilm growth (Baum et al., 2009).

Attempts have been made to better mimic the conditions in the soil by establishment of biofilms in different types of bioreactors (Holden et al., 1997; Karamanov et al., 1997; von Canstein et al., 2002; Dunsmore et al., 2004;

Jean et al., 2004). Analysis of the composition and function of the community is then performed with microscopic, molecular methods or by detection of production/removal of various compounds. von Canstein et al. (2002) used a bioreactor to demonstrate that multispecies biofilms were more efficient in reducing mercury than those consisting of only one species. We have, in our group, developed a flow biofilm system, based on isolation and growth of soil bacteria on agar-covered glass slides and supplied with autoclaved soil water as nutrient source, thereby avoiding plate cultivation-dependent isolation and artificial growth medium (Burmølle et al., 2007, Figure 1). The system allowed identification of the dominating species present and studies of biofilm succession. Lünsdorf and co-workers isolated biofilm-forming bacteria on specific slides and showed by microscopy that the cells were organized into small “clay hutches,” possibly serving different functions including protection against protozoan grazing (Lünsdorf et al., 2000, 2001).

These model systems provide important knowledge on biofilm structure, function, diversity, and physiology that are essential in understanding soil biofilms. However, many aspects of how the complexity of soil and diversity of species affect the biofilm are still missing. Regardless of how well the model system is refined, it is impossible to create conditions perfectly reflecting those in soil. Still, we depend on these systems in order to gain more knowledge on soil biofilms.

Succession and diversity of soil biofilms

Biofilms in natural environments are primarily composed of bacteria attaching to surfaces in soil or water, but also fungi, algae, and protozoa are common inhabitants. Most

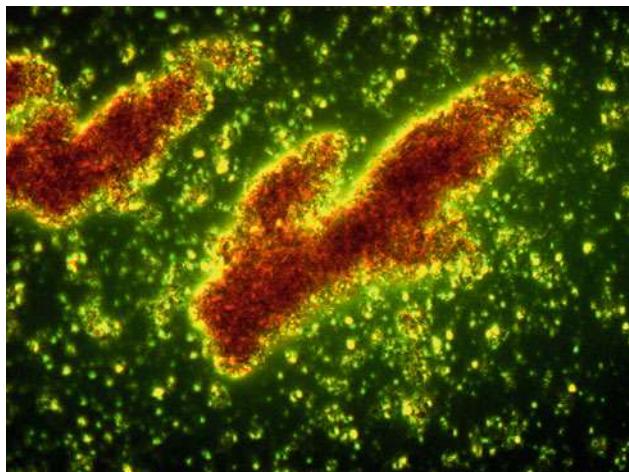

investigations concentrate on bacterial biofilms, but the other taxonomic groups also contribute to the function of the biofilm. Based on experimental work, Jackson (2003) suggested a general model for the development of bacterial biofilms. The species diversity will increase initially but decrease at a later stage when less-competitive species disappear. With time, the resource diversity will increase and competition become less important. At a later stage, interaction between bacteria and predation by protozoa will affect the biofilm diversity (Jackson et al., 2001; Jackson, 2003). By use of the flow biofilm system described above, we followed the succession in an early multispecies biofilm. The observed succession pattern could not be explained by the conceptual model, but we were able to distinguish early, intermediate, and late colonizers in the species present. We also showed that the ability of single species biofilm formation was reflected in the time of appearance in the multispecies biofilm, but that this was not the case for the planktonic growth rate. Thus, it seems that the ability of cell attachment and single species biofilm formation was essential for successful implementation in the multispecies biofilm consortium (Burmølle et al., 2007).

In the few studies of the bacterial species diversity of soil biofilms, a dominance of Gram-negative species was observed (Burmølle et al., 2007), and a similar tendency has been observed in aquatic systems (Hu et al., 2003; Martiny et al., 2003). However, some of these results could be artifacts caused by the fact that the methods used for growth and DNA extraction are optimized for Gram-negative bacteria.

Function of soil biofilms

Biofilms play a dominating role in degradation of decaying organic material in soil. As such degradation usually depends on extracellular enzymes, it makes sense for the degrading organisms to cover the material as much and tight as possible. By nutrient induced establishment of biofilm in soil on or near a degradable source (litter, roots etc.) the bacteria involved have a great advantage compared with the unattached bacteria as they have altered growth rate, physiological capabilities, and metabolic activity (Jass et al., 2002). In the biofilm, bacteria and microfungi act simultaneously in the degradation process; both bacteria and fungi are able to produce a variety of extracellular enzymes to degrade organic matter in soil, e.g., pectinase, amylase, xylanase, cellulase, protease, and lipase (Nannipieri et al., 2002); only fungi are able to attack and degrade recalcitrant ligninolytic compounds (Baldrian, 2006). The resulting soluble nutrients from the different enzymatic processes are later available both for bacteria and other microorganisms.

The bioremediating potential of several soil biofilm consortia has been evaluated. As described above, a multispecies soil biofilm effectively reduced mercury under changing environmental conditions (von Canstein et al., 2002). It has also been demonstrated how a biofilm

Biofilms in Soil, Figure 1 Micrograph showing the morphology of a multispecies biofilm composed of soil bacteria. The biofilm was established by immersion of agar-coated glass slides into soil slurry for 7 days. The attached biofilm was rinsed in a saline solution, stained with crystal violet, and rinsed again, followed by an examination by light microscopy. See Burmølle et al. (2007) for further details.

culture, composed of soil bacteria, were more diverse, both at the species and molecular level, compared to enrichment cultures (Stach and Burns, 2002). In the biofilm, more different polycyclic aromatic hydrocarbon (PAH) degrading species were present, and additionally, a higher diversity of genes involved in PAH degradation was observed. In line with this, bacterial degradation of fenemiphos was demonstrated only to take place within a mixed consortium of six Gram-negative bacteria, and only in the presence of soil particles in the growth medium (Ou and Thomas, 1994). Also, toluene diffusion was facilitated by a *Pseudomonas putida* in an unsaturated biofilm reactor (Holden et al., 1997). In fact, it has been suggested that the biotreatment of soil is improved by immobilization of soil and bacteria in a soil bioreactor, allowing the bacterial cells to form biofilms (Karamanov et al., 1997). Thus, bacterial soil biofilms may be very efficient in bioremediation, which could rely on several factors including the presence of multiple species and the bacteria-surface/soil particle interaction.

Pathogenicity and biofilms in soil

Many opportunistic pathogenic bacteria including *Burkholderia*, *Pseudomonas*, *Salmonella*, *Listeria*, *Campylobacter*, and *Legionella* are naturally occurring in the soil environment (Winfield and Groisman, 2003; Berg et al., 2005; Gray et al., 2006). However, the characterization of these bacteria has focused on their biology and population dynamics in human hosts or in hospital environments, ignoring the impact of the external (non-host) environment. Recent research suggests that the bacterial pathogenicity is greatly affected by the time and conditions faced by the bacteria in these external environments, of which soil is of major importance (Wilson and Salyers, 2003; Walther and Ewald, 2004). As stated above, soil conditions may select for biofilm formation and attachment, which unfortunately also enhance the potential pathogenicity of these bacteria. Additionally, species incapable of surviving in the soil environment on their own may become part of soil biofilms wherein they persist and evolve. This is of particular interest – and concern – with respect to pathogenic bacteria.

Perspectives

There are many reasons for soil bacteria to organize into biofilm communities: They obtain increased protection toward the harsh conditions faced by soil bacteria, they obtain a surrounding environment as stable as possible and, finally, they increase their potential of fast adaptation and maximum nutrient gain. We therefore hypothesize that the biofilm mode of growth is the preferred life style for active bacteria in soil due to evolutionary selective forces.

Studies of soil biofilms are complicated and we depend on ecologically relevant model systems for such studies. These are very fundamental tools for expanding our knowledge of the bacterial life in soil – knowledge useful

for exploiting the potential of bacterial bioremediation and for surveying the development of new aggressive pathogenic bacteria that may become less harmful when we are prepared for their arrival.

Microbial attachment in the food environment

Definition

Biofilms are currently defined as microbial communities (composed from one or many genus of microorganisms), surrounded by self-produced exopolymers and adherent to abiotic and/or biological surfaces (Costerton et al., 1995).

Introduction

In the majority of natural ecosystems, microorganisms have a tendency to adhere to solid surfaces. Following adhesion to a surface, cells may proliferate, form colonies, produce exopolymers (EPS), and finally develop a biofilm. The ability of microorganisms to adhere to solid surfaces has important economic consequences in many fields (contamination of food processing equipment, contamination of biomaterials in medicine, biofouling of marine materials, and wall growth in fermentation processes). Microbial biofilms play a crucial role in a variety of disciplines, including biotechnology, immunology, and biodeterioration. Biofilms are a serious problem in food processing environments. In the food industry, bacteria colonizing the processing equipments are a potential source of food contamination by spoilage or/and pathogenic microorganisms. Biofilms cause serious economical problems such as increase resistance in the liquid flow and heat transfer and increase the corrosion rate on the surface, leading to product and energy losses. In the food industry, bacteria in both biofilms and suspended forms are exposed to stresses such as high or low temperature, dehydration, pressure, and antimicrobial agents. Biofilm formation is a part of the survival strategies of microorganisms in adverse environmental conditions.

Mechanisms of biofilm formation

Biofilm formation is a dynamic process that includes the following steps: initial adhesion (reversible), specific adhesion (irreversible), formation of microcolonies (early stages of biofilm formation), growth of biofilm and finally, detachment of microorganisms from peripheral parts of biofilm. Sometimes, reversible adhesion is

preceded by conditioning of a surface. In the food environment, some organic and inorganic molecules like proteins, carbohydrates, and other constituents may adsorb to the surface, forming conditioning film. There is no clear evidence that microorganisms better attach to the conditioned surface. It depends on the kind of surface and its microtopography. The next step of biofilm formation is the initial attachment of microorganisms to the surface. This process may be active or passive and depends on various factors like microorganism's motility, growth stage, nutrient supply in surrounding environment, and physicochemical properties of the cells. This weakly interaction between surface and microorganisms are referred as reversible adhesion. In irreversible adhesion, hydrophobic/hydrophilic interactions, covalent and ionic bonding, and dipole–dipole interactions play a significant role. The irreversibly attached cells grow, divide, and form microcolonies. During this phase, microorganisms produce extracellular polymers, which help in the anchorage of the cells to the surface. The exopolymer molecules play crucial role in biofilm formation process. They promote specific adhesion, formation of microcolonies, and more advanced stages of biofilm development. The extracellular compounds are responsible for both adhesion and cohesion of microorganisms. Exopolymers strengthen the interactions between the microorganisms themselves (formation of cell aggregates) and between the microorganisms and surface. In the literature, there are clear evidences that the biosynthesis of extracellular proteins and exopolysaccharides are responsible for the morphology and three-dimensional architecture of the biofilms and take part in maintaining structural integrity of biofilms. As the biofilm ages, the attached microorganisms are able to detach and disperse from the biofilm and colonize new niches (Costerton et al., 1995; Lee Wong, 1998; Jefferson, 2004; Branda et al., 2005).

Factors affecting the adhesion of microorganisms to solid surfaces

The process of biofilm formation is dictated by a number of variables including: physico-chemical properties of solid surfaces, hydrophobicity of solid materials and cell surface, extracellular production of polymeric substances (mainly polysaccharides and proteins), environmental factors (temperature, pH, type of media, ionic strength), and other factors (species of microorganisms, microbial growth phase, cultivation conditions, nutrient supply, viability of cells, microbial competition, presence of signaling compounds). A lot of disagreements appeared in the literature relating to factors and its affecting to the adhesion of microorganisms to solid surfaces. These antitheses probably result from species of microorganisms being examined, methods used to detect the attached bacteria to the surfaces, solid surface properties, and differences in experimental conditions (Lindsay et al., 2000; Liu and Tay, 2001; Cabanes et al., 2002; Czaczyk and Myszka, 2007; Fuster-Valls et al., 2008). Recently, scientists have

paid attention to the molecular and genetic basis of biofilm formation. Analysis of expressed genes in response to a specific environment in which microorganisms form a biofilm will help in the production of good quality products.

Problems caused by biofilm in food industry

The biofilm formation on the food products or food contact surfaces leads to serious hygienic problems. A number of reports demonstrate the possibility of biofilm development process by foodborne pathogens like *Salmonella* sp., *Listeria monocytogenes*, *Yersinia enterocolitica*, *Campylobacter jejuni*, *Pseudomonas aeruginosa*, *Legionella pneumophila*, *Escherichia coli* O157:H7, and *Staphylococcus aureus* (Kumar and Anand, 1998; Lee Wong, 1998; Shi and Zhu, 2009). The presence of pathogenic bacteria on the surfaces of food processing equipment is a potential health risk for consumer. The adhesion of nonpathogenic microorganisms to the food products or food contact surfaces may lead to food spoilage. For example, biofilm formation in the dairy industry by nonstarter lactic acid bacteria is a common reason of cheese defects such as gas formation or undesirable flavors.

Studies carried out by different research workers present that biofilm may develop on various food contact surfaces. Microorganisms may be attached to rubber, polypropylene, Teflon, glass, stainless steel, aluminum, and other solid materials. In consequence, biofilm may develop on the floors, walls, water pipes, bends in pipes, conveyor belts, tanks, rubber or Teflon seals, and stainless steel surfaces. If the biofilm is not completely removed from surface, it may be a reason of food contamination by spoilage or/and pathogenic bacteria. Many researchers observed this process in poultry, meat, and dairy products. Biofilm is also responsible for cross-contamination and post-processing contamination (Bower et al., 1996; Kumar and Anand, 1998; Fuster-Valls et al., 2008).

In the food industry, biofilm formed on processing equipment reduces heat exchange, increases friction on movable elements of enginery, and causes limitation in liquid flow, filter blocking, and finally, equipment breakdown. The microbial attachment in drinking water distribution systems decreases water velocity and carrying capacity, causes clogging of pipes, and decreases efficiency of operations. The presence of sulfate-reducing or acid-producing bacteria in biofilms causes corrosion of metal surfaces. All these adverse technological effects have an economic impact on the food industry (Bower et al., 1996; Branda et al., 2005; Shi and Zhu, 2009).

Resistance of biofilms to antimicrobial agents

Resistance of bacterial biofilm to toxic compounds is a very serious problem of modern medicine and industry practice. Microorganisms forming biofilm initiate multilevel resistance mechanisms that protect the cells against antibacterial substances. Biofilms can tolerate antimicrobial agents at concentrations of 10–1,000 times that needed to inactivate genetically equivalent planktonic

bacteria (Jefferson, 2004). Inefficiency of antibacterial compounds on attached cells depends on biofilm structure, environmental factors in which biofilm is formed, the presence of capsule of bacteria, production of degrading enzymes, changes of the molecular targets of the biocides, and the activity of “efflux pumps” proteins. The exopolymers produced by microorganisms in biofilm may bind the disinfectants and prevent its penetration through biofilm (Bower et al., 1996). The process of formation and secretion of signal molecules to the medium by bacteria is also a very relevant aspect. Furthermore, microorganisms deeply embedded in biofilm receive less oxygen and nutrients than cells in suspension. In consequence, they alter physiology (quasi-dormant state) and become less sensitive to sanitizers, antibiotics, and surfactants (Shi and Zhu, 2009).

Removal of biofilms from food contact surfaces

The complete removal of attached microorganisms from food contact surfaces is a very difficult and demanding task. It requires time- and cost-effective cleaning and sanitizing procedures. The effective methods of biofilm removal are combination of mechanical, thermal, chemical, and biological processes. Traditional cleaning of food contact surfaces starts with physical removal of attached bacteria. This is scraping, brushing, or circulating turbulent solutions through the equipment to detach the biofilms. New physical methods are also being developed for the control of biofilms. They include high-pulsed electrical fields, super high magnetic fields, ultrasound treatment, and low electrical fields. The effectiveness of these techniques is high, especially when they are used in combination with organic acids, antibiotics, and other biocides. The chemical methods that are used to remove biofilm from food contact surfaces include the usage of typical groups of disinfectants such as alcohols, aldehydes, oxidizing agents, phenolic, quaternary ammonium compounds, and others. Studies demonstrate that peracetic acid, chlorine, iodine, hydrogen peroxide, and monolaurin are the most efficient in biofilms removal. It has been known that before using chemical sanitizers, mechanical elimination of microorganisms is required. When no mechanical treatment is applied, the effectiveness of disinfectants is not so high. The exopolysaccharides prevent the penetration of these substances through the biofilm by binding them, making it impossible for them to get into the cells. Detergents containing chelating agents like ethylenediaminetetraacetic acid (EDTA) or ethylene glycol tetraacetic acid (EGTA) also improve biofilms removal from food contact surfaces. They bind calcium and magnesium ions and destabilize the microorganisms' outer membranes. New biological strategies for biofilm control have also been devised. They include the usage of biological active compounds like bacteriocins (e.g., nisin) or exopolysaccharide degrading enzymes (Bower et al., 1996; Kumar and Anand, 1998; Burfoot and Middleton, 2009).

Preventing microbial adhesion

Methods of preventing microbial adhesion in food contact surfaces include applying antimicrobial agents, modifying surface hydrophobicity, and designing food contact equipment. Some surfaces impregnated with biocides may prevent microbial colonization for as long as the antimicrobial agents are being released from these materials. Antifoulant paints, which are used to protect the hull of ships from fouling, may be also used to control of biofilm formation on food contact surfaces. For example, antifoulant paints containing silver ions have been successfully applied to control mixed biofilms containing *L. pneumophila*. It has been reported that the applications of lactic acid bacteria cultures, its cell-free supernatants, and bacteriocins prevent the adhesion on the surface of different spoilage and pathogenic microorganisms. In the recent years, food packaging materials containing active compounds have gained practical significance in control of spoilage microorganisms and foodborne pathogens on food surfaces. These active antimicrobial substances incorporated in the packing materials migrate to the food surface and microbial contamination is eliminated (Le Magrex-Debar et al., 2000). Hydrophilic materials such as glass or stainless steel are known to reduce microbial adhesion, and therefore they are often used as food contact surfaces. It is caused by the low interfacial energy characteristic for such materials, and the fact that the cells and surfaces are similarly charged. The low-affinity contact surfaces may be obtained by attaching to them some passivating compounds. It is made by the derivation of the surfaces with polyethylene oxide, noncovalent attachment of some proteins (e.g., milk protein albumin), or treatment materials with surface active or nonionic compounds. The proper design of food contact equipment plays an important role in preventing biofilm formation. Materials which are used as food contact surfaces should be smooth (without any cracks, starches, and topographical defects), resistant for corrosion and damage. Equally important in food equipment design is the cleanability of the surfaces (Bower et al., 1996; Kumar and Anand, 1998; Branda et al., 2005).

Beneficial aspects of biofilms in the food environment

Not all biofilms cause problems in the food industry. They are applied in the production of some food products. Bio-reactors with biofilms (biofilms represent a natural form of cell immobilization) are used to obtain acetic acid, citric acid, ethanol, and polysaccharides. Human gastrointestinal tract is colonized by lactic acid bacteria and *Bifidobacterium* sp., protecting against colonization by pathogenic microorganisms. An appropriate number of these microorganisms creates a healthy equilibrium between the beneficial and potentially harmful microflora in the gut. This probiotic effect is also observed when various fermented foods are consumed. Biofilms are applied in municipal and industrial sewage treatment plants.

Present microorganisms in biofilms biodegrade many compounds (also toxic ones) and minimize the buildup of pollutants. Mixed microbial consortia are used in fluidized beds and trickling filters for wastewater purification. It is important for highly harmful sewage from the food industry (Kumar and Anand, 1998; Morikawa, 2006).

Conclusions

In the last few years, extensive studies have been carried out on various aspects of biofilms in the food environment. Results of these investigations will help fully understand the interactions between microorganisms and biotic or abiotic surfaces. The presence of attached cells or biofilms on food products and food contact surfaces plays a significant role in food safety, especially for minimally processed food and raw food. From this point of view, the increased resistance of microbial biofilms to antimicrobial agents, new strategies should be developed for the control of biofilms. It is found necessary to formulate new cleaning and disinfectant agents for effective biofilm removal.

A better understanding of biofilm formation and the factors affecting this process is needed for the production of microbiologically safe and good quality products in the food industry.

 Formerly Staff Member at the World Bank, Washington, DC, USA

Definitions

Biomass. Any living or dead matter from plants and animals, excluding fossils.

Biomass energy. Energy from living or dead plants and animals in unprocessed or processed forms, excluding fossil fuels.

Introduction

All animals depend on biomass for their direct energy requirements, and since time immemorial biomass has been used to provide energy services to humankind. Biomass energy includes fuelwood, crop residues, leaves, grasses, and dung, plus solid, liquid, and gaseous products

derived from them. About 70% of the population in less developed countries (LDCs) – half the world's population – is dependent on biomass for cooking and water/space heating, the principal uses of household energy. Recently, there has been an upsurge of interest in motor ethanol and biodiesel as a result of concerns about global warming and the increased price of oil.

Biomass is an important fuel in the service and industrial sectors especially in rural areas of LDCs. It is used for: baking, beverage and alcohol preparation, ceramic manufacture, crop drying, food processing, cooking, and in many other formal and informal enterprises. According to the International Energy Agency (IEA, 2009), biomass energy accounts for an estimated 10% of primary energy supply in 2008 for the world as a whole (51.4 ExaJoule (EJ) – 10^{18} J – of which 43.0 EJ are in LDCs). Because of conversion losses, final energy consumption is only about 70% of energy supply. According to the *Renewable 2010 Global Status Report*, and the IEA, final renewable energy consumption accounts for 18% of total energy use in 2008 (63.5 EJ) of which 13% or nearly three quarters (44.8 EJ) is traditional biomass of which 34.9 EJ (78%) is in LDCs (IEA, 2009; Ren21, 2010). Hence, in most developing countries it dominates with over 50% of total energy use. And although much of it is used by the subsistence sector, in many countries it is the most important traded fuel both in terms of employment and value.

Why has so little attention been paid to biomass energy? For energy planners in LDCs, the reliance on unprocessed biomass fuels is a sign of under-development. Biomass is considered a “traditional” fuel that requires relatively more time to use and is more difficult to control than “modern” fuels such as petroleum base energy and electricity. Biomass, especially unprocessed biomass has a relatively low energy value per unit weight unlike fossil fuels (Table 1).

Generally, biomass is unsuited to provide large-scale motive power, heat and illumination – regarded as essential ingredients in the development process. Apart from small energy plantations including palm oil and sugar estates, biomass energy production is very scattered, difficult to monitor and measure, and in many instances it grows despite, rather than because of, “human” intervention. On the other hand, petroleum products and electricity are manufactured in discrete large-scale units that can be controlled and for which special skills and training are required for production and maintenance.

Thus, development agencies, governments, and the private sector often pay scant attention to biomass energy because its production does not lend itself to large, capital-intensive projects. Nor in most instances is its production recorded or its consumption metered and the mechanics of marketing are poorly understood.

Energy terminology

The use of the term “commercial” energy only to describe products of fossil fuels, electricity, and more recently

Biomass as an Environmentally Benign Energy Source, Table 1 Energy value (EV) of biomass, its products, and fossil fuels

Fuel	Unit	Energy value MJ	Unit	EV – MJ
Methane (natural gas) (CH_4)	m^3	35.8	kg	50.1
LPG (propane/butane)	m^3	33.9	kg	47.5
Kerosene, diesel, petrol, etc.	l	32.2 to 37.2	kg	43.5 to 45.0
Coal (brown coal to anthracite)			kg	10.0 to 30.0
Steam coal			kg	26.2
(Electricity)	kWh	3.6		
Crop residues (15% mcwb; 10% ash)			kg	13.0
Dung (15% mcwb; 20% ash)			kg	14.1
Wood (15% mcwb, 1% ash)			kg	15.5
<i>Green biomass</i> (45% mcwb)			kg	8 to 10
Densified wood (7.5% mcwb, 1% ash)			kg	17.0
Wood charcoal (5% mcwb; 4% ash; 85% carbonized)			kg	29.0
Biogas (60% methane) (CH_4 , H_2 , CO_2 , NO_x)	m^3	22.6	kg	30.5
Producer gas (CO , H_2 , CH_4 , CO_2 , NO_x)	m^3	3.6 to 5.5	kg	10.6 to 16.2
Methanol (wood alcohol) (CH_3OH)	l	15.8	kg	20.0
Ethanol ($\text{C}_2\text{H}_5\text{OH}$)	l	21.6	kg	26.9
Gelfuel (ethanol/cellulose mix, + 10% H_2O)	l	18.0	kg	22.3
Plant oil (<i>Jatropha curcas</i> oil)	l	37.4	kg	40.7
Black liquor (pulp mill waste)	l	11.8 to 12.2	kg	12.5 to 13.0

Note: mcwb = moisture content wet basis: wet weight – dry weight/wet weight.

Source: (Openshaw, 1986) revised and updated.

renewable energy from solar, wind, and water is very misleading and ignores the role biomass plays in the monetary economy of developing countries. Charcoal and liquid fuels such as methanol (wood alcohol), ethanol, and now biodiesel have always been commercial products and increasingly, fuelwood, crop residues and dung are being traded. Also, biogas (60% methane) is being produced commercially. Granted, the bulk of rural people in LDCs still collect biomass, principally fuelwood, but many of these same people collect surplus fuel to sell to urban households or rural industries and for these people it is a very important source of income.

While employment figures for fuelwood and charcoal trading are scarce, a survey undertaken in Malawi in 1996/1997 (Openshaw, 1997a, b) estimated that 93,500 full-time people were employed in tree growing/management, production, transport and trade of which 64,530 supplied all urban areas. Household supply accounted for 84,000 for the country and 58,000 for all urban areas. This should be compared to those employed in kerosene, LPG, and electrical production, transport or transmission, and trading for the household sector, an estimated 350–500 people. A repeat survey was undertaken in 2008 (BEST, 2009). This found that full-time employment in growing, production transport and trade was an estimated 133,000 of which 122,000 served the household sector. Thus, woodfuel was and still remains the dominant “commercial” household fuel in Malawi. This is true for many sub-Saharan African (SSA), Latin American, and Asian countries. While there are no definite worldwide estimates, nearly 30 million people may be involved in the commercial production, transport and trade of biomass energy worldwide and it could generate in the region of

US\$ 20 billion annually (This estimate assumes that there are 3 billion biomass users worldwide. It is based on Malawi figures, which estimated that the woodfuel informal sector employs 1 person per 100 users of all biomass energy (purchased and collected). Each employed person generates about US\$ 650 per year. Besides cooking, biomass is used for household heating and by (rural) industries and the service sector. Some wood-rich Developed Countries also use biomass for heating and industrial purposes. So this employment figure and value may be underestimated). And as stated above in many SSA countries, the trade in household biomass energy is much greater than the sale of fossil fuels and electricity. In contrast, according to The Renewable Global Status Report, page 34 (Ren21, 2010), more than three million people are employed in all forms of “modern” renewable energy.

Again, the use of biomass has been widely disregarded by developing agencies. Indeed, the 2002 World Summit on Sustainable Development held in South Africa set a 2015 target for “renewable energy” in LDCs of 15% as part of the Millennium Development Goal (UNDP/WB, 2002). But the definition of renewable energy was mainly confined to solar, wind, and water, and completely ignored “traditional” biomass fuels, which were considered to be “unsustainable”! If biomass fuels are included, then already most LDCs have achieved the 15% renewable energy target.

There is reluctance in development circles to consider biomass as a legitimate energy form that can assist with poverty alleviation and sustainable development. Yet it is universally available, can be grown simply and cheaply close to where it is required, and has a sustainable supply several times that of the annual consumption of fossil fuels. Part of the reluctance to regard it as a viable form

of energy is that it is considered to impose an excessive burden on women and children who collect it and is a health hazard for the user, especially in a confined kitchen. The general consensus is that people who cook with biomass will remain in poverty. Until they use more convenient cooking fuels such as kerosene and LPG and until energy (electricity) access is improved, poor households will not be able to escape the poverty trap. Yet in most, if not all rural areas of the world, kerosene is available, but generally it is used sparingly for illumination purposes. Households are most reluctant to pay for fuel if they can collect it. In urban areas, most fuels are available, but many houses in “shanty towns” do not have grid electricity. It was proposed at the World Bank’s Energy Week in March 2004 (WB, 2004a) and again in March 2006 to subsidize kerosene and liquid petroleum gas (LPG) (WB, 2006) and to spend US\$ 120 billion over the next 10 years on rural electrification (WB, 2004b). (At the 2006 WB Energy Week meeting, it was stated by Prof. Robert Socolow of the Center for Energy and Environmental Studies at Princeton University (USA) that 35 kg of LPG per capita (1.65 GJ/c) should be sufficient to meet the yearly cooking requirements for the average household. Assuming the above figure, the delivered cost of LPG works out at about US\$ 100 for a family of six per year. For the world, about 500 million households containing three billion people cook with biomass (& coal). Thus, the yearly cost of LPG would be about US\$ 50 billion and the cost for a cylinder and 2-burner stove of US\$ 1.5 billion per year on average. This additional use of LPG would add between 82 and 90 million tons of carbon to the atmosphere each year. If past fuel subsidies are used as a pointer, free or subsidized kerosene will be sold as a diesel substitute, etc., and people will still cook with biomass: it will not ease the burden for women, nor reduce kitchen smoke. Also, would some of the US\$ 120 billion be better spent elsewhere on other energy and non-energy initiatives, such as improved stoves? The Global Alliance for Clean Cookstoves – a partnership between the US government and other nations along with charitable foundations – has pledged US\$ 60 million over 5 years to assist national cookstove programs in India, Mexico, and Peru [BBC (News 2010)]. While it is a step in the right direction, it is a paltry sum compared to the proposed investment in rural electrification!

At present a World Bank Group Energy Strategy Approach Paper has as its main thrust, improved energy (electricity) access for developing countries. “Traditional biomass” fuels are considered to be nonrenewable and to be substituted as quickly as possible (WB, 2009). By not treating biomass as a legitimate and renewable carbon-based fuel, an opportunity is being lost to provide employment for low-income rural and urban families.

Hydrogen has been touted as the new and renewable energy of the future, but its impact in LDCs will be negligible, especially in rural areas. Because hydrogen is difficult to handle, it has been suggested that methanol (CH_3OH) be the

“carrier” for hydrogen. Methanol can be produced from the dry distillation of biomass, therefore, why not use methanol directly rather than as a hydrogen carrier?

Each year, plants fix between 57 and 100 billion tons of atmospheric carbon through photosynthesis, of which about half is from land plants and thus potentially available for fuel before it decays and returns to the atmosphere (Hall and Rao, 1994; Sorensen, 1979). Wood is the most convenient form of biomass for energy purposes. For the world as a whole and for developing countries in particular, the annual growth of wood is 3–4 times annual demand (FAO, 1993; FAO, 2007–2009; Hosier, 1993; Openshaw, 1983, 2000a; Soussan, 1991; WB, 1994). It is not the use of wood that is causing “deforestation” but the clearing of land for arable and pastoral agriculture (and urbanization) as a result of population increase and the need to generate cash income. In 2008, about 8.0 billion tons of carbon were burnt in fossil fuels (IEA, 2009), thus even taking energy efficiency and conversion losses into consideration, there is considerable scope to consume much more than the current 1.4 billion tons of “renewable” carbon in biomass used for energy purposes (IEA, 2009). Burning renewable biomass does not add to the accumulation of atmospheric carbon dioxide because if biomass is not used it will decay and CO_2 will be returned to the atmosphere (the Carbon Cycle). If not properly prepared and burnt, biomass (and other fuels) generates products of incomplete combustion that can affect health and contain more damaging greenhouse gases (GHGs) such as methane and oxides of nitrogen. But these are technical problems that can and should be tackled at source rather than proposing alternatives such as fuel switching, most of which are financially and logically unattractive. Thus, biomass energy should be considered environmentally benign as it produces little if any net additional GHGs.

Biomass, rather than being treated as a fuel of the past, should be embraced as a legitimate, renewable, and versatile carbon-based fuel that can be and is used in the unprocessed and processed form or used as a feedstock for electrical generation. After all, all animals, including humans, rely on carbon-based fuel (food) for energy and there is no reason why biomass should not be a significant part of the world’s energy mix in future.

In the last 2–3 years, there has been an upsurge of interest in growing biomass for motor ethanol and biodiesel. The estimated consumption of motor ethanol in 2009 is 76,000 million liters (1,642 PetaJoules [PJ]) and that for biodiesel is 16,600 million liters (657 PJ) (Ren21, 2010), of which 50% is produced in Europe. In Europe, the EU has mandated that renewable energy, especially biofuels be increased significantly by 2020. The European Commission proposes the following targets in a series of documents representing the EU New Energy Policy (EU, 2001):

- Reduce greenhouse gas emissions by 20% in 2020, compared to the 1990 emissions
- Increase the share of renewable energy in the total energy mix from less than 7% in 2006 to 20% by 2020

- Increase the share of biofuels to at least 10% of the total energy content of transport fuels by 2020
- Reduce the global consumption of primary energy by 20% in 2020

Unfortunately, the UN Global Climate Summit in Copenhagen in December 2009 never reached an agreement on GHG reduction. One of the few positive outcomes was a pledge by Developed Nations of US\$ 30 billion over 3 years to help poorer countries mitigate climate change. Some of this money will go to REDD + (reduction of emissions from degradation and deforestation). However, clearing land for agriculture is a principal cause of deforestation. It is hoped that some will also go to help increasing agricultural productivity. With help and improved management, trees can be used to improve agricultural productivity and stabilize the environment, add to the store of organic carbon, and generate additional income; thus, expanded biomass use could be a key ingredient in the initiatives to alleviate poverty.

Carbon sequestration and greenhouse gasses (GHG)

Atmospheric carbon is stored in biomass, particularly woody biomass and in all types of soils. There is a greater accumulation of carbon in forest and woodland soils and to a lesser extent in grassland soils than in arable agricultural soils under similar conditions. Therefore, biomass can be used to sequester atmospheric carbon in the biosphere, while its annual production could be used, for example, as renewable energy or as a carbon store in wood products. There are proposals and actual schemes to sequester carbon dioxide from fossil fuel burning in caves, abandoned mines, porous rocks, and in the ocean to mitigate and eventually stabilize the “global warming effect.” But it may be easier, less costly, and safer to increase the carbon dioxide storage in biomass and soils, while at the same time increasing the supply of wood, etc., for biomass energy!

Unfortunately, because of population pressures, low (subsistence) agricultural productivity and the need to produce cash crops in LDCs, more forest land is being cleared than is being replaced by newly planted or naturally regenerated trees. Therefore, at present, more CO₂ is being released into the atmosphere from forest land clearing, the burning of wood in situ and from former forest soils, than is being sequestered. In order to reduce deforestation, apart from a vigorous policy to slow down and eventually reverse population increase, agricultural productivity, especially in LDCs, has to increase. In part trees and other forms of biomass can play a role. Many plants, including trees and shrubs, fix atmospheric nitrogen; thus nitrogen-fixing trees, judiciously spaced in fields can maintain if not improve agricultural productivity, while at the same time providing stick wood. Also, trees can provide browse and fodder for animals; the manure from these animals can be used directly or indirectly as fertilizer in place of being used as unprocessed fuel as happens in several countries such as India where wood is scarce. Also many countries

have biogas digesters to extract methane from manure. China has an estimated 25 million and India four million digesters (Ren21, 2010). Again, trees can reclaim marginal land and improve the local microclimate through shelterbelts and hedges on rainfed and irrigated arable lands and protect watersheds, thus benefiting lowland agriculture and hydro-dams amongst other things.

This is not to say that chemical fertilizers should not be encouraged. But such agencies as the World Bank are against subsidizing such fertilizers and they are promoting “market driven” solutions. Yet agricultural subsidies in developed countries (DCs) are depressing world market prices and this is leading to “subsidized” food from DCs competing with non-subsidized food from LDCs. The whole theory of comparative advantage is being corrupted by distorted agricultural policies in DCs especially in the EU, Japan, and the USA.

It is not that “traditional” collection and use of biomass energy is unsustainable, rather it is the policies of developed countries and one-sided “market” solutions that are unsustainable: this is accelerating deforestation and keeping many rural communities in poverty. A level playing field with regard to subsidies for agriculture (and energy) will do more for development than the current trade and aid policies. However in 2008/2009, the price of staples such as maize increased considerable because maize was being diverted for motor ethanol production and it had a knock-on effect regarding the price of rice. In the USA, the ethanol producers receive a subsidy and there is an import tax on ethanol produced in Brazil, a much cheaper fuel source. Also tropical forests were being cleared for palm oil production for biodiesel, although this has slowed down due to reduced palm oil prices.

Energy use

According to the International Energy Agency’s official statistics (IEA, 2009), biomass energy supplied 51.4 EJ (10%) of the world’s energy demand in 2008. This is up from the 1997 figure of 44.1 EJ (11%) (IEA, 1999). Many surveys in LDCs have shown that official figures underestimate actual consumption (Openshaw, 1978). Even in developed countries taken as the 29 OECD counties (footnote to Table 2), wood is used as a heating fuel during the winter months and much is not recorded. Therefore, in 2008, the actual primary energy supply of biomass energy may be in the region of 64 EJ or 12% of the energy consumption! Taking this adjustment into consideration, the average primary energy supply for the world in 2008 is 78.5 GigaJoules [GJ, 10⁹ J] per capita. In non-OECD countries, the percentage share of biomass energy rises from 15% to 18%, but the average per capita consumption is only 55 GJ – 29% of the average in OECD countries of 188 GJ/c. In sub-Saharan Africa, biomass fuels account for as much as 80% of energy consumption, but per capita primary energy supply is a low 36 GJ, less than half of the world average and 18% of that of developed countries.

Biomass as an Environmentally Benign Energy Source, Table 2 Estimated world primary energy supply 1997 and 2008
(Units: ExaJoules (10^{18} J) except where stated)

	OECD countries ^a		Non-OECD countries ^b		Total	
	1997	2008	1997	2008	1997	2008
<i>Population (billion)</i>	1.09 (19%)	1.19 (18%)	4.59 (81%)	5.51 (82%)	5.68	6.70
Natural gas	43.3	54.7	36.5	53.7	79.8	108.4

^aOECD Countries (29). Australia, Austria, Belgium, Canada, the Czech Republic, Denmark, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Japan, Luxembourg, Mexico, the Netherlands, New Zealand, Norway, Poland, Portugal, South Korea, Spain, Sweden, Switzerland, Turkey, the UK, and the USA.

^bThe non-OECD countries include all developing countries except Mexico and Turkey. All the former Soviet Union Countries are non-OECD, although Russia is developed. Likewise, the Gulf States are non-OECD countries, whereas in most, their per capita income is high and are classified as developed. In 1977, Albania, DPR Korea, and Vietnam (populations 103 million) were excluded. In 2008 they were included (populations 109 million).

^cThe biomass total for non-OECD is probably low due to under-recording. A more realistic figure for both time periods is 10 GJ/c or 535 kg in wood equivalent terms. This would increase the overall biomass share by about 3.5% in each time period. In 1997 biomass and waste energy is an estimated 45.9 EJ and 55.1 EJ in 2008 and the total energy consumption 405.5 EJ in 1997 and 525.8 EJ in 2008.

^dThis gives off 22.85 billion tons CO₂, equal to 6.23 billion tons C.

^eThis gives off 29.23 billion tons CO₂, equal to 7.97 billion tons C. There has been a 28% increase in CO₂ emission since 1997 – 2.4% increase per year.

IEAs statistics are in million tons of oil equivalent (TOE). 1 TOE = 41.868 GJ.

Sources: (IEA 1999, 2009).

At present the top 18% of the world's population consume about 44% of the world's annual energy demand and 3.6 times more in per capita consumption of fossil fuels. If the remaining 82% were to approach the energy use of the top 18%, then annual energy consumption would increase by 3.6 times. If this increase is mainly in the form of fossil fuels it could lead to serious if not disastrous environmental consequences. What is more, the world's population may swell to over nine billion by 2050. Therefore, even following the current energy use patterns may mean the world is sitting on an environmental time bomb. This is why trying to stabilize fossil fuel consumption at 1990 levels and having a vigorous policy to expand the use of renewable energy is so important. The Stern Review to the UK Government on the Economics of Climate Change emphasized this (Stern, 2006). But the December 2009 "Global Climate Summit" in Copenhagen did not reach any agreement on fossil fuel stabilization.

Clearly, the developing world must expand its (useful) energy consumption if it is to escape from the present

poverty and under-development traps. And just as important, the developed world must reduce its energy input of fossil fuels. Therefore, it is inappropriate environmentally and may be unwise from an economic standpoint for LDCs to follow the past energy strategies of the "West." Of course there are vested interests in promoting development with a reliance on "modern" fuels. Expanding the use of these fuels requires considerable capital investment. Indeed the World Bank Energy Workshop held in March 2004 proposed that US\$ 120 billion be spent on rural electrification over the next 10 years (WB, 2004a). However, only 3.2% of energy investment was for renewable energy, the bulk of which was for non-biomass energy (WB, 2004b). Developed countries promote capital-intensive energy programs because much of the equipment and technical know-how is supplied from the "West" (and of late from India and China). Also energy planners in LDCs favor such projects for they see them as the way to modernize the country by providing power at the flick of a switch. But in many instances, because of inadequate

tariff structures, poor maintenance, and unauthorized use, electrical supply is usually intermittent with considerable voltage fluctuations.

One justification for low tariffs in LDCs is to assisting the poor. But most poor households do not have electrical connections! Those that do, use electricity very sparingly. In Malawi in 2008, the average household tariff, including tax, was US cents 4.56/kWh. It was estimated that of the 31% of urban households with connections, the rich received a subsidy of about US\$ 638 per year, whereas the poor only got US\$ 44 (BEST, 2009). There is no reason why the rich and middle income households should be subsidized. If poor households need help, then a lifeline tariff is the most equitable way to help.

Similarly, subsidies on fossil fuels generally depress the price of competing (biomass) fuels. This lowers the opportunities for rural people to increase their earnings and increases the chance of the natural resource base being less well managed. In some cases, it leads to trees in watershed areas being felled to expand subsistence agriculture and to obtain cash from the sale of wood. In turn, this affects the water retention capacity and can lead to flash floods during the rainy season and little stream flow in the dry season. For countries with hydro-electricity generation, trash may block the inflow channels during the “flood” period and there may be too little water during the dry season. Thus, hydro-electrical production may be seriously affected.

Energy strategies for LDCs

In LDCs, what options and strategies could energy planners choose in preparing for an expansion of energy use? Can and should they follow the conventional path and mainly plan for the expanded use of fossil fuels and electricity using traditional generating options and switch to non-biomass fuels as quickly as possible? Or should they recognize that biomass is a legitimate, renewable indigenous resource and is one of several options that should be given the importance it deserves in the energy mix of individual countries? After all about 3 billion people cook with biomass and it will be decades, if ever, before a significant switch to non-biomass (cooking) energy is achieved, even if concerted efforts are made by countries and development agencies. And is this the appropriate option to pursue both economically and environmentally?

In most sub-Saharan African countries biomass energy accounts for over 80% of total energy demand. It is the dominant fuel in the household sector and is important in the service and industrial sectors. This same pattern is found in Asian and Latin American countries, although biomass energy use is not as dominant. Even so, biomass accounted for about half of energy consumption in the Philippines in 1989 – 87% in the household sector and one third each in the service and industrial sectors (ESMAP, 1991). There is little chance that this dominance can be replaced rapidly, nor in most cases, is this the best option. Yet governments in general and energy ministries in particular have little detailed knowledge either of the

biomass energy supply situation or the sector demand patterns. This leads to poor planning, misallocation of resources, and erroneous strategies.

Estimates of biomass availability, particularly wood, can vary by a factor of four or more. One estimate in Ethiopia indicated that the country was using considerably more than the annual growth of wood (TFAP, 1996). It was proposed that a massive countrywide plantation program should be undertaken to close the demand/supply gap and that other mitigation measures be undertaken. However, an inventory in 2003 showed that for the country as a whole, the annual growth of wood was more than annual demand (WBISPP, 2003). This inventory pinpointed areas of shortage and surplus. Programs were proposed in these specific areas to meet the shortfall through local community and farmer driven efforts and to increase the off-take of wood in surplus areas. Similar discrepancies were found in Malawi, the Philippines, and Uganda. A carbon sequestration study in 2000 undertaken for the Global Environment Facility (GEF) in Benin, estimated the store of carbon in wood and soils. An inventory of all woody live and dead biomass was undertaken (Openshaw, 2000a). It was determined that stem wood accounted for only 55% of aboveground weight. Therefore, basing the carbon store just on stem weight underestimates the aboveground carbon content in wood by over 80% and considerably underestimates the quantity of wood available for use. Again, in the Philippines, one estimate of sustainable wood supply indicated that there was an annual shortfall of 15 million tons of woodfuel to satisfy demand, whereas a later inventory estimated that there was a surplus of 44 million tons (ESMAP, 1991). This latter information led to a recommendation that biomass consumption should be expanded.

In these countries, the largest cause of deforestation is agricultural clearing. Indeed, an analysis undertaken in all sub-Saharan African countries indicated that 95% or more of deforestation was caused by clearing land for arable agriculture and that the annual growth of wood ranged from 2.6 times more than demand in Southern Africa to nine times more in Western Africa (Openshaw 2004). Therefore, without good supply/demand analyses and proper investigations into the causes of land degradation and energy access, etc., inappropriate and costly solutions are often proposed.

Promote rural electrification and switching from fossil fuels

While it is desirable for people to have energy at the flick of a switch or the turn of a knob, without the (rural) poor having money to pay for these fuels, even if they are subsidized, then it is unlikely that they will use such fuels for household purposes. Therefore, rural electrification should be first targeted for productive and/or health uses. Before village electrification is promoted, people have to be in a position to afford electricity. One way this can occur is to use more fully the natural resources that are available in the surrounding areas.

Electricity, with other forms of energy, can be an engine for growth in the non-household sectors of the economy. The “green revolution” in India was assisted by electrical pump sets that provided irrigation water enabling the growing of two and three crops per year. This provided money for farmers to pay for electricity. This is documented in a 2007 publication on the challenges of rural electrification. It provides pointers for successful rural electrification programs (Barnes, 2007). In future, much more emphasis has to be placed on supplying the increased demand for electricity, especially in rural areas, from renewable forms of energy such as wind, solar, micro-hydro, and biomass. Using biomass in stand-alone projects or as part of grid-based systems will provide jobs to rural people and help with poverty alleviation.

While LPG, natural gas (and biogas) are perhaps the “best” cooking fuels, kerosene is the only fossil fuel that is widely available in rural areas of developing countries. It is a more convenient cooking fuel to use than unprocessed biomass. However, from the many household surveys that were undertaken by the UNDP/WB: Energy Sector Management Assistance Programme (ESMAP), it was found that rural people in general and rural/urban poor in particular were reluctant to purchase fuel for cooking if biomass could be collected. Subsidizing kerosene (and LPG) generally did not lead to it being used for cooking. Rather, it was diverted to other neighboring countries and/or used as a diesel substitute. Where subsidies are proposed, they have to be targeted and the government has to make sure that the target group receives most of the benefit.

One renewable energy source that has been promoted for the last 40 years with little success is solar energy for cooking. A critical analysis was prepared for an *International Conference on World Solar Cooking and Food Processing* held in Italy in 1999. Solar stove initiatives were examined in Africa and India and it was concluded that they are, at best, only marginally successful and have not been cost-effective. Solar cooker initiatives neither solve indoor kitchen pollution nor contribute to the halt of deforestation (Openshaw, 1999).

Treat biomass as a legitimate resource for economic development and poverty alleviation

Biomass, particularly wood, is not only a fuel or a source of industrial wood products, but it has many other uses. Trees can be used to increase agricultural productivity through improved microclimate and/or fertilizer inputs. Many trees have multiple uses: they are used as a source of fodder and animal feed; trees are important for honey, nut, fruit, and medicinal/herbal production and are essential for environmental protection. This versatility is both a strength and weakness.

No single government ministry feels responsible for all the functions of trees and forests and in many instances no one takes responsibility for coordinating these various functions and uses. Forestry departments may undertake the management/inventories of forests under their control, but rarely

will they measure trees on forests and woodlands outside their control. Nor will they ever think about measuring trees (and residues) on non-forest land, particularly agricultural land. Yet these trees are an important source of wood and biomass energy, particularly for rural households; they may account for up to 85% of rural energy and generate income for local people when supplying biomass to industry, the service sector, and urban areas.

However, unless the growing stock and annual yield of trees and other forms of biomass are measured, it is impossible to undertake meaningful planning. Governments, development banks, and private companies would never finance natural gas or oil field development unless they knew the extent of the reserves, but this basic assessment is rarely, if ever, done for the dominant energy resource in many LDCs. This is extremely short-sighted for it can mean either the difference between using a resource that will last indefinitely or mining it over a limited time period with possible adverse environmental and agricultural effects. It may lead to inappropriate investments in tree planting. Therefore, it is important that governments, development agencies, the private sector and individuals co-operate to manage biomass resources sustainably and to target tree planting and other mitigation measures.

Promote sound environmental projects

Countries, development banks, especially the World Bank and the sister regional banks, plus other development agencies such as UNDP, the Global Environmental Fund (GEF), the Food and Agricultural Organisation (FAO) of the UN, the UN Clean Development Mechanism (CDM) and REDD + and the WB Prototype Carbon Fund could and should be strong influences in promoting poverty alleviation linked to sustainable development. Yet in the past and even today some are directly or indirectly supporting initiatives that are environmentally questionable and may be economically dubious. Development banks have long encouraged capital-intensive schemes in the electricity and petroleum sectors. Hydroelectric schemes were promoted without proper watershed protection and refineries were built because of prestige rather than viability. But several initiatives in the agricultural/natural resource sector are questionable. Vietnam was encouraged to grow coffee on a large scale. Many forest areas were cleared to plant the coffee bushes to the detriment of biodiversity and the carbon store and local people were moved from the area. However, the demand for coffee has increased at a much slower pace than the supply and depressed world prices: this adversely affecting all coffee producing nations and especially coffee farmers. In Indonesia, forest areas are being destroyed to make way for palm oil production, and in Brazil forests are cleared for soy beans and pastoral agriculture. Irrigation schemes have been badly planned leading to, for example, sterilization of the soil through surface salt deposits (Pakistan), drastic lowering of water tables (India) and abandonment because of excessive sedimentation in the water, destroying the water pumps (Bangladesh and Kenya).

Therefore, development must be attuned to the environment and its long-term sustainability.

There are many areas of marginal and abandoned agricultural land that can be reclaimed for “biomass crops” rather than clearing forests for oil crops, soy bean and pastoral agriculture. Areas of *Imperata cylindrica* grass an aggressive “weed” species can be reclaimed through the planting of nitrogen-fixing tree species such as *Gliricidia sepium* and *Leucaena leucocephala*. These trees rapidly suppress the weed and it dies, leaving little that can sustain a grass fire (NAS, 1979). The reclaimed land can be used for arable and pastoral agriculture, with some short-rotation trees left to provide mulch, shade and stick wood, etc. Again witchweed (*Striga asiatica*) attacks food crops such as maize and reduces yields considerably. It can be controlled naturally by planting tick-trefoil (*Desmodium sp.*) as a nitrogen-fixing understory. This can then be used as a green manure and/or as an animal feed (NAS, 1979).

Similarly, dry areas including deserts can be reclaimed with *Prosopis sp.* This provides stick wood; the milled pods are protein rich and are sold commercially as animal feed. There are many nitrogen-fixing plants including short-rotation trees that can be grown in all areas of developing countries that can be of environmental benefit and provide tree products (NAS, 1979).

Prospects for motor fuels from biomass in LDCs

An oil-bearing tree species, *Jatropha curcas*, which can be grown on marginal lands, is exciting much interest at present. It is being planted in Africa and Asia. Although it can be grown on dry marginal land, productivity is a function of water availability and soil fertility. *Jatropha* is not a nitrogen-fixing tree; indeed its seed cake is nitrogen-rich and can be used as a fertilizer. This implies that in order to maintain productivity, nitrogen fertilizer has to be added to the soil. *Jatropha* could be inter-cropped with a tree legume and/or NPK fertilizers could be added to the soil (Openshaw, 2000b).

While there are many motor ethanol plants, Brazil is by far the largest producer in LDCs. Out of a 2008 world total production of 67 billion liters, Brazil produces 27 billion liters and the USA 34 billion liters (Ren21, 2010). However, twice as much land is required in the USA to produce the same amount of motor ethanol as in Brazil. Sugar is the main feedstock in Brazil, whereas corn (maize) is the feedstock in the USA. The production cost in Brazil is an estimated US cents 29 per liter and the wholesale price is US 71 cents. About 1.35 L of motor ethanol are required per liter of gasoline. It is estimated that if crude oil prices remain above US\$ 35–40 per barrel (159 L), then ethanol production from Brazil will be competitive with gasoline [(Xavier, 2007); CBS (News, 2006)]. Moreover, bagasse (sugarcane waste) is used to raise heat and power for the factories and to provide surplus electricity to towns.

There are plans to make motor ethanol from wood waste and switch grass, etc., both raw materials being

cheaper than maize (corn). The cellulose in each product will have to be broken down into simple sugars before it is fermented into ethanol. It may be more cost-effective to produce alcohols and hydrocarbons, etc., directly by the dry distillation of cellulose or from the gasification of cellulose. There are pilot projects to produce biomass from algae, cyanobacteria, and artificial photosynthesis in ranaspumin based foam (NPR, 2010; Wendell and Todd, 2010). The biomass can then be turned into liquid fuels and used for motive power, but at present these systems are in the development stages and much more work has to be done to make them economically viable.

Biomass, especially traditional biomass, is the Cinderella of fuels

The production of liquid biomass fuels as substitutes for liquid fossil fuels is receiving considerable attention, but gaseous fuels from fermentation or gasification are also important. However, most energy ministries in LDCs pay particular attention to electricity and petroleum-based fuels. They may even have sections dealing with new and renewable sources of energy such as solar power, wind and water. Few, if any, devote much time to biomass fuels, especially “traditional” biomass use, because in general they assume that they cannot influence the production process and they wrongly think that using such fuels, especially wood, is a principal cause of deforestation. However, through systematic supply and demand surveys, governments can pinpoint areas of surplus and deficit, determine the root causes of deforestation, document current management, conversion and end-use practices, and investigate actual and potential end uses and barriers to promote renewable energy, particularly biomass. Development banks and aid agencies could and should help with such work. This information is essential for compiling meaningful strategies and proposing long-term development initiatives.

Today the main emphasis is on Renewable Energy, which mostly excludes biomass, except using “modern” biomass in discrete initiatives mainly in developed countries. It appears that rather than fostering poverty alleviation, development bodies are promoting rural backwardness and environmental degradation.

Apart from helping governments obtain good biomass supply/demand statistics, development bodies should assist them with rural development plans, especially improving agricultural productivity, promoting greater rural access, providing timely market intelligence, and increasing social services. Expanding biomass use, promoting specific vegetation types and encouraging species selection to improve agricultural and silvicultural production, decreasing the incidence of pests and diseases, and protecting biodiversity and watersheds should be an integral part of rural development. This could be done through training, demonstration and extension at all levels. Farmers, women’s groups, villagers and local entrepreneurs can be shown how better to grow, manage, produce and market their resources on all land use types. Housewives can be shown better kitchen

practices, and encouraged to obtain improved stoves, as part of enhanced village services. Generally, all these initiatives require outside assistance, albeit at a modest level. But usually such assistance will pay off many times over, both environmentally and socially. Also, from a financial standpoint it is mostly very cost-effective.

In some countries, charcoal producers are regarded as destroyers of the forests and woodlands, when in fact they are the producers of an important urban fuel that in many cases use resources that otherwise would ultimately rot or be burnt in situ. In some countries such as Ethiopia and Malawi, charcoal production is illegal. This leads to surreptitious (and generally wasteful) production methods and the fear of confiscation unless bribes are paid: all this adversely affects the price of charcoal and makes producers outlaws, rather than the providers of a demanded product.

Charcoal production can be improved and producers should receive training in woodland management, charcoal production, and in marketing. It should be treated as a legitimate activity that is supplying a renewable and convenient energy form, while generating employment in production, transport, and trading. There are petroleum engineers, electrical engineers, but there are few biomass production engineers (charcoal, methanol/ethanol, biodiesel, biogas/producer gas). Yet these are, or could be, important fuels and their status would be enhanced through systematic university/technical training in the production of these fuels.

The World Bank has stressed the importance of assisting the private sector, and biomass energy production is principally in the hands of the private informal sector and is a fuel consumed by the poor and rural industries. Yet very little help is afforded to such people. Development banks could assist through training, market intelligence, encouraging the removal of inappropriate bans and restrictions, improved infrastructure, and promoting a level playing field regarding fuel subsidies. If world bodies are serious about global warming, they should be promoting carbon taxes on fossil fuels (Stern, 2006).

Similarly, energy conservation is considered to be an important way to reduce fuel costs and decrease pollution. But relatively little effort has been put into improving end-use efficiencies in the household sector. Because biomass stoves are produced mainly by the informal sector, who can ill afford to undertake research and development, governments should assist in this effort, through targeting training in stove manufacture techniques, business management and marketing, providing loans for micro-enterprise development, testing stoves and materials, and undertaking quality control. Governments should also coordinate efforts of health departments and stove manufacturers to reduce indoor air pollution. Some effort is now being made and US 50 million has been proposed to improve stoves in three countries over the next 5 years [BBC (News, 2010)], but this is a meager sum compared to that proposed for rural electrification over the next 10 years – US\$ 120 billion (WB, 2004).

Sustainable development

Various authors have given estimates of the earth's carrying capacity for humans ranging from a low 0.5 billion to a high 14 billion, with the median ranging from 2.1 billion (low) to 5.0 billion (high) (Richards, 2002). The high estimates are based on a much increased use of the net primary production (NPP) from biomass. Already, the world's population may be greater than its carrying capacity and there are wars, fights and disputes over land and water resources.

This year, 2010, is the International Year of Biodiversity. It has been stated that our ecological footprint – what we take out of the planet – is now 1.3 times the biological capacity of earth. Habitats are being destroyed and species are being lost, because of population and economic growth leading to the destruction and degradation of forests, grassland, farmlands, wetlands, rivers, seas, etc. At present, only lip service is given to sustainable development, reclaiming areas that have been degraded, improving agricultural and silvicultural management and productivity, and the sharing of resources within and between countries. If the world is not overtaken by environmental disasters, by 2050, the human population may be 9.2 billion and by then people on average will be nearly three times as wealthy as today! (The World Bank Energy Strategy Approach Paper states that "The world economy is set to grow four-fold by 2050 and — energy-related carbon dioxide emissions will more than double" (WB, 2009). This translates to an overall increase of 2.9 times in per capita wealth assuming the world's population will reach 9.2 billion by 2050.) Their total energy demand, even taking energy efficiency and energy conservation measures into consideration, may be in the region of 1,000 EJ, nearly twice the amount used today (Table 2). By that time, the extraction of liquid fossil fuels may be uneconomic, if they have not been banned, and only coal will be available in quantity. But to foster truly sustainable development, such fossil fuels should not be used. All types of renewable energy and nuclear power will be needed to meet such a demand.

At present, electricity supplies an estimated 16.3% of the energy mix (OECD Countries 20.0%) (IEA, 2009). Of course, by 2050 electricity's share may increase considerably, but solid, liquid and gaseous fuels still will be required to meet the everyday needs of the population. As stated previously, all fossil fuels came from biomass, so biomass can be turned into similar fuels.

Every year plants fix between 57 and 100 billion tons of atmospheric carbon with Richards giving an estimate of about 80 billion tons of atmospheric carbon (Richards, 2002). In theory about half is available for use, before it rots or is burnt in wild fires, etc. The other half is produced in the seas and oceans. Now some of this may be farmed using algae (NPR, 2010). The present consumption of biomass energy is an estimated 55.1 EJ containing 1.5 billion tons carbon (Table 2). (This is the adjusted figure. The IEA figure is 1.4 billion tons of carbon.) Taking into account

the other uses of biomass including food, about 1.8–2.0 billion tons out of a possible 40 billion tons C are presently used. The carbon content in fossil fuels that are burnt annually is about 8.0 billion tons C. (IEA, 2009). Therefore, out of the approximately 38 billion tons C that is theoretical available, at least an additional 10 billion tons C in biomass could be used as fuel (26%); this could sustainably meet a considerable quantity of future energy demand. If the overall conversion efficiency to gaseous, liquid, and solid fuels is 50%, then five billion tons C would be available for motive power, power generation, process heat, and cooking. Thus, biomass energy could be an important and increasing renewable input to sustain development.

Conclusions

In summary, there should be no distinction between energy types. Energy planners and development agencies should attempt to quantify the supply and demand for biomass energy alongside other forms of energy. All fossil fuels came from biomass and thus it can be a feedstock to produce many kinds of renewable substitutes for fossil fuels. By doing this, the importance of the different types and uses of energy will be highlighted. It will bring home to governments not only the problems of quantifying biomass supply and demand, but also the opportunities that biomass presents in encouraging rural people to manage the resource sustainably, thus promoting rural development and poverty alleviation.

Second, because biomass production impinges on forestry, agriculture, energy, environment, industry and development, it is important to have a multidisciplinary approach so that planning and policy can be influenced by biomass energy specialists.

Third, it must be recognized that biomass is a versatile multipurpose commodity that can be turned into gaseous, liquid, and solid products both for energy and non-energy purposes or used directly as a fuel or feedstock for steam generation, process heat, and electrical generation. It can be produced indefinitely and, therefore, is a renewable *carbon-based fuel* that does not increase GHG: this cannot be overemphasized. The potential available carbon in the annual growth of biomass – 40 billion tons C – is many times that given off from the annual burning of fossil fuels (8.0 billion tons C). Thus, there is considerable scope to substitute much more biomass energy for fossil fuels, thereby reducing GHG accumulation.

Fourth, trees, shrubs, bamboo, etc., are a store of atmospheric carbon both in the living biomass and the soil beneath the biomass, as well as in wood products, etc. Such plants can be used to sequester more atmospheric carbon than at present. Wood is a convenient store of solar energy that can be used when required and/or left to perform other functions such as watershed management, habitat conservation, and environmental protection.

Fifth, biomass can be and is grown, managed, and used by rural people with little capital inputs, but with income

generating possibilities and to ensure energy availability nearby. Trees, etc., can assist agricultural productivity, land reclamation, and environmental protection. They can provide energy for industries and the service sectors, thus assisting sustainable rural development.

Sixth, global warming, mainly caused by burning fossil fuels, but exacerbated by deforestation, has to be checked through aggressive action by all nations of the world, especially OECD countries.

Seven, in order to slow down and eventually halt deforestation, agricultural productivity has at least to keep pace with population increase. However, it is important that action be taken to slow down and eventually reverse population increase. Already, with the present living standards, the earth's carrying capacity for the human population may be exceeded.

Eight, while the promotion of "modern" energy is receiving priority, it will do little to help the bulk of poor people living in tropical countries. Modest investments in time, money, good governance, and policy reform could reverse the deforestation trend. Bringing the poor into partnership with government and providing more opportunities to earn money from all aspects of tropical forests, plantations, woodlands, and trees outside the forest could reap great environmental and economic rewards and help alleviate poverty.

Finally and most importantly, biomass is a local resource that is environmentally benign. It is an important fuel in many developing countries, which can be produced indefinitely. Its importance is also increasing in developed countries that see it as a means of greenhouse gas mitigation. Because it is a renewable and versatile carbon-based fuel that can be grown universally, it should be promoted as a form of energy that truly can support sustainable development. This lesson could and should be followed especially by the developed and "emerging" nations of the world.

BIOSPECKLE

Artur Zdunek
Institute of Agrophysics, Polish Academy of Sciences,
Lublin, Poland

Definition

Biospeckle is phenomenon of interference pattern formation when a biological specimen is irradiated by a coherent light.

When a coherent laser illuminates a rough surface, the scattered light exhibits mutual interference and forms randomly distributed bright and dark spots of variable shapes called speckle pattern. When the laser coherent light impinges on the surface of biological material, it can pass through one or more layers (e.g., air space, skin, and cell walls), each of them will act as a stationary diffuser. If particles within the biological material are in motion, the speckle pattern exhibits spatial and temporal fluctuations and is said to “boil” or “twinkle.” This phenomenon is called biospeckle.

BIOTECHNOLOGY, PHYSICAL AND CHEMICAL ASPECTS

Zdzisław Targoński

Department of Biotechnology, Human Nutrition and Science of Food Commodities, University of Life Sciences, Lublin, Poland

Definitions

Biotechnology – any technical application that uses biological systems, living organisms, or derivations thereof to make or modify products or processes for specific use.

Bioprocess – any process that uses complete living cells or their components (e.g., bacteria, enzymes, chloroplasts) to obtain desired products.

Biorefinery – the coproduction of a spectrum of bio-based products (food, feed, materials, chemicals) and energy (fuels, power, heat) from biomass.

Physical aspects

Various definitions of biotechnology are known (Purohit, 2005); however, biotechnology is best defined as a process, which enables its exponents to convert raw materials into final products when the raw material and/or a stage in the production process involves biological entities. Most commercial processes used in the chemical industry are applicable to bioprocesses.

A bioprocess includes an upstream process, biological reaction (fermentation process), and a downstream process. An upstream process consists of various stages of processing and preparing biological materials before the production stage including organisms and enzyme screening, gene screening, cloning, transformation, cell line development, medium design, cleaning, sterilization, filtration, and feed control. The core, a biotechnological process, is a biological reaction in a bioreactor. The organisms require strict chemical and physical factors

in a bioreactor for growth as well as for the production of biomass and metabolites. The physical processes used in bioreactors are as follows: agitation, absorption and desorption of gas, oxygen transfer, and heat exchange. The goal of process control is the optimal utilization of biological systems for biosynthesis, transformation, and biodegradation. A variety of online sensors is used in bioprocesses, which are temperature, bioreactors back pressure, gas flow rate, agitation rate, dissolved oxygen and carbon dioxide, pH, redox potential, and optical density (Alford, 2006).

A downstream process consists of various processing stages that occur after the completion of the production stage and includes cell lysis, solid–liquid clarification, product isolation, product purification, formulation, and packaging of products (Misha and Dubrey, 2009). There are two methods of cell lysis that can be used: chemical (osmotic shock, addition of chemicals, detergents, enzymes) and physical (compression and/or shear, high pressures homogenizer, bead mill, ultrasonication). Biological products are separated and based on one or several physical or physicochemical properties, which are as follows:

- Size, for example, filtration, centrifugation, membrane separation, gel filtration
- Density, for example, flotation, centrifugation, sedimentation
- Diffusivity, for example, membrane separation, extraction
- Shape, for example, flocculation, sedimentation
- Polarity, for example, extraction, precipitation, crystallization
- Electrostatic charge, for example, adsorption
- Mobility, for example, electrophoresis
- Steric hindrance, for example, filtration
- Volatility, for example, distillation, pervaporation

In the formulation of the end product, lyophilization, adding of excipients and package are used as the main processes.

Chemical aspects

Chemistry has had a fundamental role in almost every aspect of modern society. However, the chemical industry has come under increasing pressure to make production more eco-friendly. Green chemistry is a chemical philosophy encouraging the design of products and processes that reduce or eliminate the use and generation of hazardous substances (Anastas and Warner, 1998). As for white biotechnology, it links green chemist and bio-based production. Also known as industrial biotechnology, it is the modern use and the application of biotechnology for the sustainable processing and production of chemicals, materials, and fuels (Hatti-Kaul et al., 2007). Biotechnology can both replace existing chemical processes and allow the production of new products. A concretization of white biotechnology is a concept of a biorefinery. A biorefinery is a facility that systematically obtains products such as

valuable chemicals, fuels, and materials through microbial fermentation of sugar produced by decomposing biomass as renewable resources (Kamm and Kamm, 2004).

Fossil reserves are finite and increasingly expensive as raw materials. A change in the feedstock from hydrocarbons to biological molecules will alter the technological basis of the world industry. Plants offer a sustainable solution; thanks to photosynthesis, complex products are renewable and can be obtained cheaply and in large quantities. Biomass will play a major role in the next generation of chemical industry which, contrary to petroleum refineries, does not use crude oil to obtain similar products. Biomass can be subdivided into several groups of substances, such as cellulose, starch, hemicelluloses, protein, oil, and lignin. The majority of all biomass found in nature is carbohydrates, which remain to be a flexible raw material. Biotechnological transformation, as well as classical chemical transformation, has also been explored. Nowadays, only a small number of chemicals are produced from renewable resources via fermentation (Haveren et al., 2008). The biotechnological production of lactic acid, acetic acid, and ethanol is a process that is currently applied on a technical scale, which can compete with petrochemical routes. Various technological processes used in the production of many chemicals such as butadiene, butandiol, acrylic acid, propane, and succinic acid from renewable resources are technologically feasible, yet, they remain uneconomical.

Biocatalysis is one of the branches of chemical biotechnology. The increasing contribution of biotechnology in industrial chemistry means discovering enzymes and new synthetic routes to fine and bulk chemistry (Arnold and Glieder, 2003). Current applications of enzyme biocatalysis are dominated by enantioselective bioconversion for fine chemical production. However, an enzyme can have other functions, including the production, degradation, and modification of polymers.

Chemical biotechnologists are generating new molecules with the aim of applying them to the production of foods, pharmaceuticals, materials, and consumer products. By cloning genes from different sources in new ways inside the engineered host, pathways to rare or even unknown metabolites have been found.

Summary

Biotechnology, being an interdisciplinary science, is largely based on physical and chemical processes used in the preparation of organisms and substrates for conducting a biological process as well as various individual operations with the aim of obtaining an end product. Bioprocess control is based to a considerable degree on sensors that use physical and chemical properties of specific media. Chemical biotechnology is going to play a more and more significant role in generating bioenergy and chemicals with the use of renewable plant biomass serving as raw material. The progress in metabolic paths is going to enable one to obtain compounds in a natural way – an innovation in the field of biotechnology.

BOWEN RATIO

An index that is proportional to the ratio of temperature gradient to vapor pressure gradient in the atmosphere above a field. It is relatively low when the field is wet and the evaporation rate is high, i.e., when the temperature gradient is small relative to the vapor pressure gradient. When the field is dry, the humidity gradients tend to be low and much of the received solar energy goes to warming the soil, hence the temperature gradients tend to be steep and the Bowen ratio becomes large.

BREADS: PHYSICAL PROPERTIES

Renata Różyło, Janusz Laskowski

Department of Equipment Operation and Maintenance in the Food Industry, University of Life Sciences, Lublin, Poland

Definition

Physical properties of bread – bread properties that can be measured or calculated from instrument readouts.

Introduction

Bread is one of the fundamental food products, necessary in human nutrition. It is produced through baking dough made of flour, water, possibly also salt and other additives. The dough is usually subjected to fermentation, either natural or with the help of leavening agents.

Depending on the basic material used, bread is generally classified as wheat bread, rye bread, mixed grain bread, and others – as pertains to the raw materials, the technology applied, etc. Bread quality depends on the properties of the raw materials and on the technological parameters applied in the process of production. The quality assessment of bread makes use of determinations of its physical properties, among which the most frequently tested are the volume, weight, and specific weight (true

density) of bread. Estimations of the quality of bread crumb take into consideration such features as its structure, moisture, and mechanical properties (firmness (hardness), gumminess, chewiness, cohesiveness, resilience, springiness, etc.). Whereas, estimations of the quality of bread crust are based on such parameters as color and mechanical properties of crust as determined in testing by means of a variety of instruments. The results of determinations of the physical properties of bread permit verification of the effect of the raw materials and the process parameters on the quality of bread.

Determination of physical properties of bread

Measurement of volume is used for the determination of the specific volume which is a quotient of volume and weight of bread, as well as for the determination of true density of bread, through division of its weight by its volume (Esteller et al., 2006). Bread volume measurement can be made in accordance with the methods consisting in bread volume measurement by means of granular materials, e.g., millet or rapeseed. Poppy seed is less frequently used for the purpose. The most commonly used devices operating on the principle of displaced seeds include the Fornet apparatus (Tamba – Berehoui et al., 2004), the Sa-Wa apparatus (Sadowska et al., 2003), very popular in Poland, and the Chopin apparatus (Carr et al., 2006).

Currently the latest generation apparatus for bread volume measurement have been introduced, where the object studied is scanned with the ultrasonic method or by means of laser beam.

The volume of bread is affected by the process of dough fermentation, during which carbon dioxide is released, leavening the dough and causing an increase in bread volume. Whereas, poorly risen dough subjected to baking will yield bread of small volume. Extended process of fermentation has a negative effect on the plasticity of gluten, yielding loafs of reduced volume. Extension of the time of dough kneading, up to a limit, permits obtainment of bread with large volume, while excessively long kneading will cause the bread produced to be of unsatisfactory quality.

Porosity is defined as the ratio of bread volume occupied by pores to the total bread volume. Determination of bread porosity can be performed with the help of so-called Dallman Tables (Błaszcak et al., 2004). Another method is based on determination of the difference in volume between undisturbed crumb and crumb with the pores eliminated through compression. Bread porosity can also be measured without destroying the bread structure, through the use of a gas multipycnometer in helium or toluene atmosphere.

Another tool for the estimation of bread porosity may be digital analysis of scanned image of bread crumb (Digital image analysis system) (McCarthy et al., 2005; Carr et al., 2006). (See [Image Analysis in Agrophysics](#)).

Porosity is a characteristic index of bread quality and it is related with bread volume. Porosity reflects the course of all stages of bread production, with special emphasis

on the process of dough fermentation and on the quality of materials used for baking (Bloksma, 1990).

Observation of crumb structure is performed with the use of various types of microscopes, including optical microscopes, scanning electron microscopes, cryogenic electron microscopes, confocal-laser scanning microscopes, as well as ultrasonic techniques.

The cellular structure of bread crumb has a considerable effect on its mechanical properties. Scanlon et al. (2000) observed that the microstructure features of bread crumb were related with the estimation of its texture.

Moisture of bread crumb, another important index of bread quality, is determined by drying a sample of bread to a constant weight. Apart from bread moisture measurement, water activity measurements are also made, with the help of special automatic gauges.

The mechanical properties of bread crumb are commonly determined in single or dual compression test (TPA test). Bread texture determinations, including the TPA test (Texture Profile Analysis), are very often based on earlier works by Szcześniak (1972) and Bourne (1978). Moreover, there is a number of various other methods for making such determinations. The measurements are made with the help of many different instruments – the TA-XT texture analyzer, the Instron apparatus, the Zwick strength tester, and the Stevens texture analyser. In the course of such measurements, a sample of bread crumb is compressed to various depths depending on the test method. The result of single compression tests is the value of firmness, and in dual compression tests the additional values obtained are those of cohesiveness, resilience, gumminess and chewiness. Additionally it is possible to determine the values of springiness and adhesiveness.

Apart from the bread crumb compression tests, also other tests are used, such as the shearing test (Fik and Surówka, 2002), tensile test (Zghal et al., 2002), penetration test (Fiszman et al., 2005), and indentation test (Liu and Scanlon, 2002). Bread crumb samples are also used for performing the relaxation tests (Mandala and Sotirakoglou, 2005), cracking tests, and hysteresis test (Scanlon et al., 2000). The measurements of flat extruded bread are made with the help of acoustic methods (Marzec et al., 2007).

The mechanical properties of bread crumb are related with those of the dough (Scanlon et al., 2000). Bread baked of dough characterized by high strength have crumb that is more compacted than bread baked of weak dough. A number of correlations between the alveographic properties of dough and the mechanical properties of bread crumb have been demonstrated by Dziki and Laskowski (2005).

Next to the raw material quality, the changes in recipe and the process parameters play an important role in the formation of the textural features of bread. For example it was demonstrated that the different water level (Rózyło et al., 2009) and the conditions of the fermentation process effect on breadcrumb texture (Gómez et al., 2008).

The textural features of bread may be modified through the application of natural additives – e.g., other cereals or

flours. Changes in textural features may also be caused by artificial additives.

Staling causes especially intensive changes in textural properties of bread. When gluten-free bread is kept in storage, there is an increase in crumb firmness, with simultaneous drop in crumb moisture and crust firmness (McCarthy et al., 2005). After 2 days of storage, such bread becomes brittle and crumbling, and its springiness, cohesiveness and resilience decreases (Moore et al., 2004). Storage causes a change in the textural properties of bread, crumb firmness being characterized by the highest percentage change as compared to resilience, cohesiveness, gumminess and chewiness, and therefore it can be accepted that firmness is that feature which reflects the degree of bread staleness the best (Rózyło et al., 2009).

Determination of crust coloring is an important parameter in the estimation of bread crust and can be performed with the use of a chromameter, spectrophotometer or calorimeter.

Estimation of the mechanical parameters of bread crust is highly significant in the determination of crust quality. Methods used for the determination include the penetration test (McCarthy et al., 2005), the crust puncture test (Mandala and Sotirakoglou, 2005), and the crust shear test (Fik and Surówka, 2002).

Conclusions

In view of the significant role of bread in the human diet, special attention should be paid to its quality features, and the physical properties – due to their relations with sensory assessment – appear to be the best indicators of bread quality. There are many factors that have a significant effect on the quality of bread. The qualities of raw materials, the recipe applied, production process parameters and storage conditions significantly affect the physical properties of bread. Therefore, knowledge of the physical properties of bread has a notable utility significance, permitting optimization of production in modification of existing products and processes as well as when introducing new ones.

BRIGHTNESS TEMPERATURE IN MONITORING OF SOIL WETNESS

Jerzy Usowicz
 Toruń Centre for Astronomy, Nicolaus Copernicus University, Toruń, Poland

Introduction

All bodies, including soil, consist of atoms and molecules. Any body at a final absolute temperature radiates

electromagnetic energy. This electromagnetic radiation is termed as a thermal radiation. According to quantum theory, the thermal radiation is always emitted when the atoms or molecules undergo transitions from higher to lower energy levels. The frequency of the emitted photon is given by the Planck's equation $\Delta E = h\nu$. There are three different kinds of energetic transitions: electron, vibrational, and rotational. Any system which contains a huge number of molecules is characterized by a large number of degrees of freedom. Molecules collide with each other due to their random motion. Every collision causes a change of their energy levels. Spectral lines emitted by such a system are very close to each other which results in a continuous spectrum of radiation. The collision rate depends on the kinetic energy of the random motion. It increases with the absolute temperature of the substance.

In 1900, Max Planck derived a new formula for the thermal radiation of a black body. It was a significant event for the birth and subsequent development of quantum mechanics. The Planck's law describes the relation between the temperature of a black body and its radiated power. It is given by the following formula:

$$I = \frac{2hv^3}{c^2} \frac{1}{e^{\frac{hv}{kT}} - 1}$$

where

T is the temperature, K

c is the speed of light, 2.99×10^8 m s⁻¹

h is the Planck's constant, 6.63×10^{-34} J s

k is the Boltzmann's constant, 1.38×10^{-23} JK⁻¹

I is the specific intensity, W m⁻² Hz⁻¹ Sr⁻¹

The specific intensity is expressed as a power per unit area per unit frequency interval and per unit solid angle.

The Rayleigh–Jeans law is a convenient and accurate approximation of the Planck's formula for $\frac{hv}{kT} \ll 1$. Expanding the exponential in the denominator of Planck's law in a Taylor series about zero argument, we obtain the following formula

$$I = \frac{2kTv^2}{c^2}$$

At this point, we have to invoke the Kirchoff's law which says that the emissivity ε of a body is equal to its absorptivity α . The absorptivity of a body is defined as the ratio of the total thermal energy absorbed by the surface to the total thermal energy incident upon it. By the definition, a black body has absorptivity $\alpha = 1$. Thus, a black body is also the most efficient radiator and has $\varepsilon = 1$.

In reality, bodies or substances emit less than a black body and the specific intensity emitted generally depends on the direction and the polarization. In passive remote sensing, microwave receiver measures the specific intensity $I_\beta(\theta, \phi)$ emitted by the given object, where β denotes

the polarization and $I_\beta(\theta, \phi)$ denotes the angular dependence. An equivalent radiometer temperature called the brightness temperature $T_{B\beta}(\theta, \phi)$ can be derived simply from the Rayleigh–Jeans law as follows:

$$T_{B\beta}(\theta, \phi) = \frac{I_\beta(\theta, \phi)c^2}{kv^2}$$

Assuming that the body has a uniform physical temperature T , the emissivity $\varepsilon_\beta(\theta, \phi)$ is defined as a ratio:

$$\varepsilon_\beta(\theta, \phi) = \frac{T_{B\beta}(\theta, \phi)}{T}$$

From this definition one obtains the fundamental equation used in passive remote sensing:

$$T_{B\beta}(\theta, \phi) = \varepsilon_\beta(\theta, \phi)T$$

According to this equation, the brightness temperature of a body depends on its emissivity and its physical temperature.

Soil can be regarded as a mixture of water and the bulk material which includes sand, silt and clay. The emissivity of soil depends on the effective dielectric constant of this medium (Monerris, 2009). The relationship between brightness temperature and soil emissivity is linear in general; however, the emissivity of water depends nonlinearly on its dielectric constant (Behari, 2005). The theory of microwave remote sensing of soil moisture is based on the large contrast between dielectric properties of liquid water (~ 80) and dry soil (~ 4). As the water content in soil increases, the dielectric constant of the soil–water mixture increases as well. Such changes are detectable by microwave radiometers in surface soil layer of 5 cm depth.

BUFFER CAPACITY OF SOILS

Mieczysław Hajnos

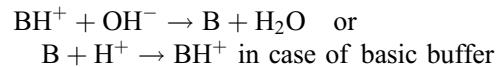

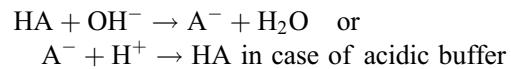

Institute of Agrophysics, Polish Academy of Science,
 Lublin, Poland

Definition

Buffer capacity of soil is defined as a soil's ability to maintain a constant pH level during action on it by an acidifier or alkalescent agent. A soil, considered a mixture of buffered systems, contains components, which have the ability to neutralize acids by bonding H^+ ions as well as bases by the release of hydrogen ions (Federer and Hornbeck, 1985). The effectiveness of soil buffering systems depends on numerous physical, chemical, and biological properties of soils.

Buffer capacity

A buffer solution is an aqueous solution consisting of a mixture of a weak acid and its conjugate base ($HA + A^-$) or a weak base and its conjugate acid ($B + BH^+$). It has the property that the pH of the solution changes very little when a small amount of acid or base is added to it because of the following reactions:

Buffer capacity is a quantitative measure of the resistance of a buffer solution to pH change on addition of hydrogen or hydroxide ions. It can be defined as follows:

$$\text{Buffer capacity} = \frac{dn}{d(pH)} \quad (1)$$

where dn is an infinitesimal amount (in moles) of added base or acid and $d(pH)$ is the resulting infinitesimal change in pH.

The capacity of soils to oppose an acid/alkaline reaction is called buffer properties of soils or soil buffer capacity. Buffer properties of soils are determined by their sorption capacity. The higher the sorption capacity of soil colloids the higher the buffer capacity of soil. Humus colloid fraction exhibits the strongest buffer activity among the soil colloids.

Buffer properties of soils are connected with the following processes: reactions of dissolution of calcium carbonate in weak acids or its total decomposition by strong acids; with weathering of primary silicates resulting in the release of basic cations; ion-exchange process in result of adsorption of hydrogen cations by organic and mineral components of sorption complex; bonding of H^+ by clay minerals' lattices, by hydroxyaluminium complexes or hydrated alumina; reactions of ferrous oxides and

hydroxides in result of which H⁺ cations are neutralized (Ulrich, 1986).

Buffering reactions with bonding or release of protons occur in soils also in the following processes: organic matter mineralization, mineralization and nitrification of organic nitrogen, mineralization and oxidation of organic sulfur, mineralization of organic phosphorous, complexing or releasing of metal cations, etc. (van Breemen et al., 1984).

Knowledge of buffering properties of soils is of great importance in respect to the estimation of a liming effect or influence of degrading factors on the soil environment (Jaworska et al., 2005).

BULK DENSITY OF SOILS AND IMPACT ON THEIR HYDRAULIC PROPERTIES

Shmuel Assouline

Environmental Physics and Irrigation, Institute of Soil, Water and Environmental Sciences, Agricultural Research Organization – Volcani Center, Bet Dagan, Israel

Definition

Density is the ratio of mass to volume, with a dimension of (ML⁻³). A soil sample at natural conditions consists, in most of the cases, in three phases, solid, gas, and liquid. The bulk density of a soil sample, generally represented by ρ_b , is a physical property defined as the ratio of the total mass of solids (M_s) to the total volume of the sample (V_t):

$$\rho_b = \frac{M_s}{V_t} \quad (1)$$

The bulk density of soils is generally expressed in units of g cm⁻³ or Mg m⁻³.

The bulk density of soils is related to additional physical properties, such as porosity, n , and void ratio, e :

$$\rho_b = \rho_s(1 - n) \quad (2)$$

$$\rho_b = \frac{\rho_s}{e + 1} \quad (3)$$

where ρ_s is the soil particle density defined as the ratio of the total mass of solids (M_s) to the volume of solids (V_s).

The bulk density is required to transform gravimetric water content, θ_g , into volumetric water content, θ_v :

$$\theta_v = \rho_b \theta_g \quad (4)$$

The normal range of ρ_b in natural undisturbed soils varies between 0.7 and 1.8 Mg m⁻³.

The bulk density: an integrative soil physical property

The definition of the bulk density in Equation 1, addressing explicitly the total mass of solids and the total volume it occupies, indicates that it is a physical macro-property related to both soil texture and structure. Soil texture corresponds to the relative amount of sand, silt, and clay components of the solid phase. These components affect the nature of the arrangement of the soil particles, and play a role in determining numerous soil physical, chemical, and biological properties, including porosity and bulk density (Rawls, 1983; Gupta and Larson, 2001; Martin et al., 2009). The nature of the specific relationships depends on the clay type, the presence of organic matter and cementing agents, and the ionic strength of the liquid phase. A special interest was given to the effect of organic matter content on ρ_b (Rawls, 1983; Soane, 1990; Arvidsson, 1998; Ruehlmann and Korschens, 2009).

Soil structure characterizes the spatial arrangement of the solid particles within the total volume, and will thus determine ρ_b . However, soil structure addresses also the specific void size distribution, and related state variables such as tortuosity and connectivity, within the soil sample under interest. It therefore affects basic hydraulic, electrical, mechanical, and thermal soil properties. Consequently, ρ_b is expected to be related to these important soil properties, and to affect water, heat, and gas exchange (Warkentin, 1971; Stepniewski et al., 1994), root growth (Voorhees et al., 1975; Dexter, 1987; Lipiec and Hatano, 2003), and crop production and environment quality (Håkansson et al., 1988; Soane and van Ouwerkerk, 1995; Dexter, 2004). In various regression equations aiming to predict hydraulic properties from available basic soil data, generally addressed as pedotransfer functions, bulk density is a key element of the input dataset (Gupta and Larson, 1979; Rawls et al., 1983; Pachepsky et al., 1998).

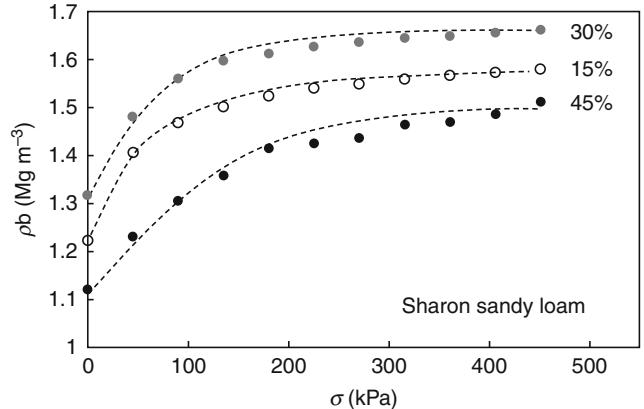

Soil bulk density can be measured using direct or indirect methods. The direct method consists in measuring the mass of the oven-dried soil sample and the volume it occupies (Equation 1). This measurement may be carried out using cylinders of a known volume (Blake and Hartge, 1986;

Campbell and Henshall, 1991). Although being quite simple and straightforward, the direct methods are prone to errors during sample extraction, transport, and handling in the laboratory. Indirect methods are based on measuring the attenuation in the intensity of gamma radiation emitted by a radioactive isotope due to the presence of the soil between the source and the receiver (Vomocil, 1954; Van Bavel et al., 1957; Freitag, 1971; Soane and Henshall, 1979). The attenuation in radiation intensity is related to soil bulk density and water content. Consequently, calibration is required to empirically relate the attenuation to ρ_b , and the soil moisture content has to be known. The disadvantages of the gamma-ray method are that devices are expensive and that their operations require nuclear safety-trained personnel. An additional indirect method relies on the correlation between soil penetration resistance, soil water content, and ρ_b . Soil penetration resistance can be estimated by means of cone penetration tests using penetrometers. Soil penetration resistance was found to increase with increasing ρ_b and to decrease with increasing soil water content. A combined penetrometer–moisture probe aiming to provide simultaneous soil moisture and penetration resistance measurements was developed by Vaz and Hopmans (2001). Penetrometer readings may be empirically related to ρ_b and θ_v . However, these relationships are specific to the soil type and the characteristics of penetrometers. A large number of models are available that relate penetrometers data to ρ_b estimates (Wells and Treesuwant, 1978; Jakobsen and Dexter, 1987; Ayers and Bowen, 1987).

Bulk density is not an intrinsic property of the soil but rather depends on external conditions. Increase in ρ_b occurs at a variety of scales and may result from various natural as well as artificial processes. It can occur around a growing root (Dexter, 1987; Bruand et al., 1996), during rainfall (Tackett and Pearson, 1965; Baumhardt et al., 1990; Bresson et al., 2004; Assouline, 2004), or during the passage of loaded wheels (Lindstrom and Voorhees, 1995; van Dijck and van Asch, 2002). Cycles of wetting and drying, and freezing and thawing, after tillage may also cause the soil bulk density to increase because of natural soil reconsolidation, thereby affecting the hydraulic properties of the soil profile (Mapa et al., 1986; Rousseva et al., 1988; Or et al., 2000).

Soil bulk density and compaction

Compaction is the process of reducing the volume of voids in a soil, mainly those filled with air, by packing the soil particles closer together. Consequently, ρ_b increases during compaction. Figure 1 depicts the increase in ρ_b resulting from the increase in the applied stress, σ , of three sandy loam soil samples at different initial saturation degrees during uniaxial drained compaction tests. Therefore, ρ_b is often used as an indicator to evaluate the impact of vehicular traffic or of tillage systems on the soil physical condition (Gupta and Larson, 1982;

Bulk Density of Soils and Impact on Their Hydraulic Properties, Figure 1 Compaction curves from uniaxial compression test on the Sharon sandy loam at three different initial saturation degrees, and the corresponding fitted model in Equation 5 (dashed lines).

Or and Ghezzehei, 2002). A degree of compactness, defined as the dry bulk density of a soil as a percent of a reference bulk density obtained by a standardized uniaxial compression test, was introduced to allow directly comparable values for all soil types (Håkansson and Lipiec, 2000).

A logarithmic model was generally used to mathematically describe the increase of ρ_b with the applied stress, σ (Bailey and Vanden Berg, 1967; Larson et al., 1980; Gupta and Larson, 1982). In the logarithmic model, ρ_b is undefined for $\sigma = 0$ and it continues to increase as σ increases (Assouline et al., 1997). Furthermore, it is not flexible enough to represent the variability of the compression curve shapes, which can range from nearly linear to sigmoidal curves (Fritton, 2001). Therefore, additional models involving exponential and power functions were developed to provide a reliable mathematical representation of the mechanical compaction process (Bailey et al., 1986; Assouline et al., 1997; Fritton, 2001). Assouline (2002) has generalized the model of Assouline et al. (1997) to account for preconsolidation effect:

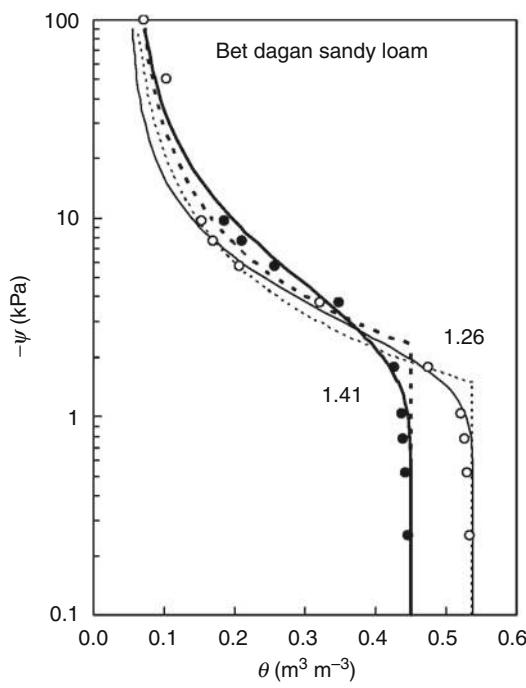

$$\rho = \rho_o + (\rho_{\max} - \rho_o)[1 - e^{-(\kappa\sigma)^{\omega}}]; \quad \omega > 0 \quad (5)$$

where ρ_{\max} , ω , and κ are considered as fitting parameters that depend on the initial soil water content, although ρ_{\max} could be fairly predicted by means of compression tests under laboratory conditions (Hartge, 1986; O'Sullivan, 1992). The model in Equation 5 fulfills the boundary conditions ($\sigma = 0$; $\rho = \rho_o$) and ($\sigma \rightarrow \infty$; $\rho \rightarrow \rho_{\max}$). The ability of the model in Equation 5 to describe compaction curves is illustrated in Figure 1. The expression in Equation 5 was fitted to the data in Figure 1, and reproduces quite accurately the different shapes as well as the effect of the initial water content. It can be seen also that maximum compaction is obtained for some optimal water content.

Effect of ρ_b on soil hydraulic properties

Soil bulk density affects many aspects of the soil–water–plant–atmosphere system. Appropriate quantitative tools with predictive ability are therefore essential to account for compaction effects on agricultural, hydrological, and environmental aspects. Change in ρ_b due to compaction represents the total change in the voids volume of the soil. Small changes in the voids volume distribution, tortuosity, or connectivity could still occur during compaction, especially during elastic deformation, without reflecting on measurable changes in ρ_b (Lenhard, 1986). Nevertheless, different studies have suggested that ρ_b is an appropriate independent variable to express the main effects of compaction on the soil hydraulic properties, that is, the water retention curve (WRC) and the hydraulic conductivity function (HCF) (Assouline et al., 1997; Ahuja et al., 1998; Stange and Horn, 2005; Assouline, 2006a, b).

The study of Assouline (2006a) has proposed quantitative expressions that relate the relative changes in the parameters for the WRC models of Brooks and Corey (1964) and Assouline et al. (1998) to the relative change in ρ_b . Consequently, the effect of the increase in ρ_b on the WRC could be predicted, given that the WRC for a reference bulk density is known. Figure 2 depicts measured WRCs for a sandy loam soil corresponding to

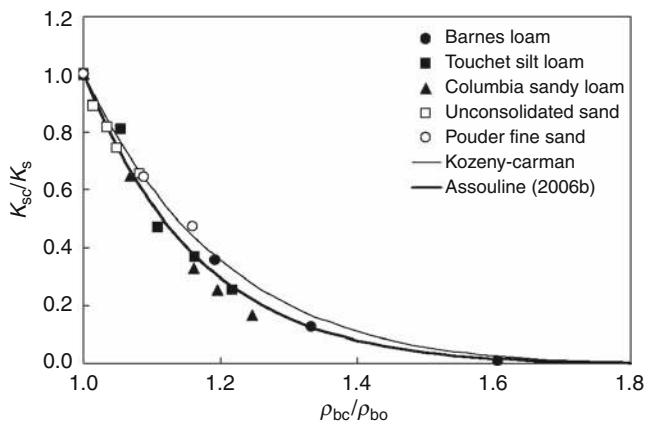

Bulk Density of Soils and Impact on Their Hydraulic Properties, Figure 2 Measured WRCs for a sandy loam soil at two bulk densities and the corresponding modeled curves following Assouline (2006a). The dashed lines correspond to the model of Brooks and Corey (1964) and the solid lines to the model of Assouline et al. (1998).

two bulk densities, 1.26 g cm^{-3} and 1.41 g cm^{-3} . Increase in ρ_b reduces the saturated water content, increases the air entry value, and increases the pore size distribution index. The thin dashed line represent the fitted model of Brooks and Corey (1964) and the solid one, that of Assouline et al. (1998), to the WRC at the reference state $\rho_{bo} = 1.26 \text{ g cm}^{-3}$. The thick dashed and solid lines represent the corresponding predicted curves according to the model of Assouline (2006a).

The impact of ρ_b on the HCF addresses the saturated state, and its corresponding saturated hydraulic conductivity, K_s , and the unsaturated one. The reduced relative part of the large pores in the soil when ρ_b increases (Lipiec et al., 1998; Häkansson and Lipiec, 2000), mostly determine the resulting reduction in K_s (Laliberte et al., 1966; Dawidowski and Koolen, 1987; Dębicki et al., 1993). A large body of studies has suggested quantitative relationships between K_s and ρ_b (Carman, 1937; Laliberte et al., 1966; Mualem and Assouline, 1989; Or et al., 2000; Green et al., 2003; Assouline, 2006b). A concise review of the different approaches developed to relate the permeability of porous media to porosity can be found in Assouline and Or (2008). Figure 3 presents the relative decrease in K_s versus the relative increase in ρ_b for various soil types, as well as the predicted relationship resulting from the Kozeny–Carman expression (Carman, 1937; Or et al., 2000; thin solid line) and from the model of Assouline (2006b, bold solid line).

Studies dealing with the unsaturated case are scarce. Most of these studies apply Mualem's (1976) model of the HCF (Or et al., 2000; Lipiec and Hatano, 2003; Morozumi and Horino, 2004). Assouline (2006b) has extended the HCF model of Assouline (2001) to account for changes in ρ_b . An interesting result of this study is that the relationship between the power parameter of the HCF model and the coefficient of variation of the WRC, which

Bulk Density of Soils and Impact on Their Hydraulic Properties, Figure 3 Measured and modeled relative decrease in K_s versus the relative increase in ρ_b for various soil types (the thin solid line corresponds to Kozeny–Carman expression and the bold solid line, to the model of Assouline (2006b)).

was found to be valid for a large range of soil types, still remain valid when these soils are compacted.

Soil bulk density generally presents some variation with depth within the soil profile under natural conditions as well as under tilled agricultural fields. This behavior, coupled with the relationship between ρ_b and HCF, induces a specific level of anisotropy to the soil profile. Assouline and Or (2006) have analyzed the saturated and the unsaturated anisotropy factors induced by ρ_b distribution with depth. The results indicated that the anisotropy factors can be related to soil texture, especially for fine-textured soils.

Summary

Soil bulk density is an integrative soil physical property containing valuable information on its porosity, level of compactness, and strength. It is a key state variable in the estimates of soil hydraulic properties, thus playing an important role in the definition of rainfall–infiltration–runoff–erosion relationships, heat and gas exchanges, seedling emergence, root growth, crop yields, and soil quality.

BYPASS FLOW IN SOIL

Horst H. Gerke
 Institute of Soil Landscape Research, Leibniz-Centre for Agricultural Landscape Research (ZALF) Müncheberg, Müncheberg, Germany

Synonyms

Funnel flow; Macropore flow; Preferential flow

Definition

Bypass flow. This phenomenon has been described also as short circuiting flow of water in soil, indicating a situation in which surface water is connected with water in the subsurface due to rapid infiltration. Here, infiltrating water is percolating along preferential pathways (i.e., macropores, cracks, fissures, decayed-root channels, or worm burrows) thereby bypassing most of the bulk soil volume.

Preferential flow. This is a general expression to describe water movement along preferred flow paths in soil.

Macropore flow. Preferential flow in structured soil along (large capillary- and) non capillary-sized macropores (i.e., cracks or biopores). The expression *macropore flow* is mostly used to indicate preferential flow in continuous root channels, earthworm burrows, structural fissures, or in shrinkage cracks in well-structured finer-textured soils. Here, flow paths are varying in type from individual macropores to a highly connected pore network. Pore geometries may range from cylindrical to platy and dimensions may vary from over-capillary-sized “macropores” to capillary-sized “mesopores” (for a definition of macro porosity in terms of a specific pore radius see, e.g., Luxmoore, 1981).

Funnel flow. This type refers to the lateral redirection or “funneling” of water in heterogeneously layered soil where water moves along the least resistance layer boundary to bypass less permeable layers.

Introduction

Bypass flow in soil describes the process of preferential water movement through a relatively small fraction of continuous macropores or highly permeable pore regions while most of the surrounding soil volume (i.e., the porous

matrix) is excluded. Nonuniform flow leads to spatially irregular wetting of the soil profile. This is in contrast to the standard uniform flow (e.g., Green and Ampt, 1911), which assumes stable homogeneous wetting fronts that move basically parallel to the infiltration soil surface. Nonuniform soil water flow has been recognized for a long time (e.g., Lawes et al., 1881, see Hendrickx and Flury, 2001). The phenomenon has increasingly gained attention beginning around the 1980s (e.g., see the review of Jarvis, 2007) mainly in the context of soil conservation and water pollution; this is because bypass flow creates highly nonuniform water infiltration and percolation fronts with characteristically differing flow velocities that allow infiltrating water and dissolved chemicals to reach the deeper subsurface environment nearly without any interaction with the bulk soil. In contrast to uniform flow, where water infiltration begins by filling first the smaller, and then successively the larger pores according to capillary forces, the larger pores start filling during bypass flow and conducting water (e.g., Youngs and Leeds-Harrison, 1990). It means that infiltrating water does not have sufficient time to equilibrate with resident water in the matrix during bypass flow. Such transient nonequilibrium condition in the pressure head between flow paths and bulk porous matrix is considered one of the most important features of preferential flow (e.g., Flühler et al., 1996).

Terminology

The term “bypass flow” reflects that large parts of the soil volume are simply bypassed through flow along preferred pathways (i.e., vertically continuous macropores or highly permeable pore networks). The synonymously used term “short-circuiting” (Bouma and Dekker, 1978; Beven and Germann, 1982) indicates that infiltrating water can immediately connect the surface hydrology with that of the subsurface. It is obvious that in this case, not only water but also dissolved chemical and colloids can directly be transported from the soil surface to the groundwater; it may reach the drainage system and eventually surface water bodies practically without any buffering by the soil matrix.

The occurrence of bypass flow requires a concurrence of several effects including sufficiently high infiltration rates (e.g., rainstorms, surface water ponding), a cracked or macroporous soil with proper vertically continuous larger pore system, a certain initial soil moisture regime, and other liquid and solid phase properties. Since myriad combinations are possible in natural soil, the complexity resulted in many different descriptions of observations of nonuniform flow and definitions for basically the same phenomenon.

Thus, the more general term “preferential flow” (Beven, 1991; Hendrickx and Flury, 2001) is frequently used that includes all different types of bypass flow such as *macropore flow* (i.e., preferential flow along continuous decayed-root channels, earthworm burrows, fissures, or cracks for well-structured mostly fine-textured soils), *unstable flow* (i.e., in mostly coarse-textured sandy soils

due to instabilities of the wetting front at fine-over-coarse textural layers (e.g., Dekker and Ritsema, 1994), and *funnel flow* (i.e., the lateral redirection and funneling caused by textural boundaries (e.g., Kung, 1990) along which water bypasses lower-permeable regions). Finger-like unstable flow patterns can result from soil water repellence (Bauters et al., 1998) or air entrapment (e.g., Ritsema and Dekker, 1994), and may lead to *distribution flow* (Ritsema and Dekker, 1995).

Experimental observations

Bypass or preferential flow has been observed in so many different soils that it seems to be the rule rather than the exception (Flury et al., 1994). Many reports are from arable field soils (e.g., Beven and Germann, 1982; Gish and Shirmohammadi, 1991) or unsaturated fractured rocks (e.g., Wang, 1991). *Fingering* has been observed in arable (e.g., Dekker and Ritsema, 2000) as well as in sandy forest soils under pines (*Pinus sylvestris*) (e.g., Ehwald et al., 1961) and in forest-reclaimed mine soils (Hangen et al., 2004). Bypass flow has even been observed in paddy soils (Wopereis et al., 1994; Sander and Gerke, 2007; Janssen and Lennartz, 2008) where surface water during ponding conditions can bypass the compacted plow pan through cracks and biopores thereby leading to water and nutrient losses.

Bypass flow has previously been defined as the flow of “free” (i.e., non- or over-capillary) water along macropores into and through an unsaturated soil matrix (Bouma, 1981; van Stiphout et al., 1987); in the field bypass flow often starts when water infiltrates into open macropores (e.g., Beven and Germann, 1982; White, 1985) at the surface or commences at the boundary between tilled subsoil and untilled subsoil (Quisenberry and Phillips, 1976). More recent tracer studies similarly indicate that the initiation and the degree of preferential flow depends either on deep penetrating macropores that are connected to the soil surface (Zehe and Flühler, 2001) or on the buildup of hydraulic pressure at the plow pan and subsequent infiltration into subsoil macropores (e.g., Kasteel, 1997). Bypass flow was spatially more variable when initiated at the soil surface than when initiated at the plow pan (Weiler and Naef, 2003) and was observed for relatively high (e.g., Granovsky et al., 1993) as well as for relatively low (e.g., Shipitalo and Edwards, 1996) initial water contents. An extensive review of the principles and controls on preferential flow and transport in soil has recently been published by Jarvis (2007).

The fraction of preferential flow increased with irrigation intensity (e.g., Kasteel, 1997) and was larger for ponded than for sprinkling irrigation (e.g., Hamdi et al., 1994). Liu et al. (1994) could demonstrate by means of nuclear magnetic resonance (NMR) technique that in a structured soil the water flow velocity in root pore channels was about 100 times larger than in the surrounding porous soil matrix. Velocities in macropores reached the transition between laminar and turbulent flow (e.g., Mori

et al., 1999; Maruyama et al., 2003). In other studies, bypass-flow velocities of $>500 \text{ mm day}^{-1}$ were determined using an isotope tracer (Deuterium) (Seiler et al., 2002) while matrix-flow velocities ranged between 0.7 m year^{-1} (Loess) and 1.2 m year^{-1} (tertiary gravels and sands) (i.e., $2\text{--}4 \text{ mm day}^{-1}$).

Soil structure

Structured soil consists of a diverse mixture of different and dynamically changing pores of differing sizes, shapes, and continuity, which serve as flow paths under certain initial and boundary conditions. Shrinkage cracks at the soil surface and worm burrows in the subsoil as two main types of relatively large macropores (Figure 1) are highly dynamical pore structures. Cracks appear after extensive drying (Figure 1a) and close during wet periods due to swelling; also, they are being destroyed due to soil cultivation. Although these cracks are clearly over-capillary in size, significant amounts of water are only able to enter the cracks after surface ponding of the soil matrix. In contrast, worm burrows are relatively permanent and mechanically stable macropores, at least those larger ones that extend into the subsoil. The picture (Figure 1b) indicates, however, that also the worm burrows can undergo alterations, for instance, by soil biological activities. Here the abandoned burrow was used as preferred channel for plant roots, and in some parts, it was loosely refilled with soil material. Such alteration, in turn, can drastically change the hydraulic properties of the macropores.

Besides the large macropores, which act as preferential flow paths when infiltration rates are high enough to produce ponding, in many soils, there exists a hierarchy of relatively fine-structured inter-aggregate networks, which form a system of different pore sizes where water retention functions could be determined. Continuous pores of the hierarchical crack network are still highly conductive but may not be denoted as macropores. Embedded within fine-textured soils, these “mesopores” (e.g., Luxmoore, 1981) may possibly form a secondary pore system and may act as preferential flow paths as well as larger macropores.

Basic model approaches

Obviously, there is no universal type of model that allows the quantitative description of bypass flow in soil. The applicability of the different models depends on the specific flow problem and the soil structure (a more detailed overview can be found in Gerke, 2006).

For flow in the above described structured soil, dual-permeability models assuming gravity flow in the macropore domain (MACRO, Jarvis, 1994) or a coupled set of Richards' equations (DUAL, Gerke and van Genuchten, 1993a) are currently applicable. The two “dual-permeability” models assume that water can flow in two separate but interacting porous domains. The models differ mainly in the descriptions of flow in the

Bypass Flow in Soil, Figure 1 (a) Shrinkage cracks of up to 5-cm width at the surface of a clay-loam soil in a wheat field and (b) cross section of a large vertical cylindrical macropore from a worm burrow of *Lumbricus terrestris* of about 0.7 cm in diameter in a silty loam gleyic Luvisol derived from Loess. Both pictures are from arable field soils located near the village of Neuenkirchen, near Schladen, south of the city of Braunschweig, Germany. The burrow section was from the B-horizon (about 55–95 cm soil depth). The abandoned worm burrow contained roots and some soil material, and showed darker-looking coatings along the surrounding matrix.

macropore domain and in the formulation of the inter-domain mass transfer terms.

Germann (1985) and Germann and Beven (1985) suggested using a kinematic wave equation to describe gravitational movement of water in macropores as follows:

$$\frac{\partial q}{\partial t} + v \frac{\partial q}{\partial z} + vr\theta_f = 0 \quad (1)$$

where r is the macropore “sorbance,” z is depth (L), t is time (T), and θ_f is the volumetric water content ($L^3 L^{-3}$) of the macropores, and where the volumetric flux density, q ($L T^{-1}$), and the kinematic wave velocity, v ($L T^{-1}$), are defined by

$$q = b\theta_f^a, v = \frac{\partial q}{\partial \theta_f} \quad (2)$$

in which a is a “kinematic” exponent and b a macropore conductance parameter ($L T^{-1}$). This approach neglects any capillarity (and water retention function) in the macropore domain.

This concept was utilized for the MACRO model, in which a unit hydraulic gradient for flow in the macropore domain (Jarvis, 1994) and an expression similar to the kinematic wave Equation 2 are used to describe gravitational movement of water as

$$q = b \left(\frac{\theta_f}{\theta_{sf}} \right)^a = b(S_{fe})^a \quad (3)$$

where θ_{sf} is the saturated water content ($L^3 L^{-3}$) of the macropores (i.e., macroporosity) and S_{fe} is the relative saturation (–) of the macropore domain. Since θ_f is scaled by θ_{sf} , the fracture conductance parameter b has the physical meaning of a hydraulic conductivity of macropores, K_{sf} ($L T^{-1}$), at full saturation. By assuming that the porosity of the macropore system, ϵ_f , is identical with θ_{sf} , a balance equation for flow in macropores is obtained:

$$\frac{\partial \theta_f}{\partial t} = -\frac{\partial}{\partial z} \left[K_{sf} \left(\frac{\theta_f}{\epsilon_f} \right)^a \right] - S_w \quad (4)$$

where S_w (T^{-1}) denotes water transfer from the macropores into the soil matrix. In the soil matrix domain (subscript m), flow and transport is described using the Richards equation as

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z} \left(K_m(\theta) \left(\frac{\partial h}{\partial z} - 1 \right) \right) + S_w. \quad (5)$$

where h is matric potential or soil water pressure head (L). Water flow between the two regions was described with a quasi-empirical equation using relative saturation as a driving force. An empirical threshold matric potential value, h_b (L), defines the matrix water content that is required for initiation of flow into the macropore domain. A threshold value of $h_b = -50$ hPa was calibrated to describe the measured preferential chloride transport using MACRO (e.g., Saxena et al., 1994).

A number of applications of the MACRO model revealed the usefulness of the approach for analyzing bypass flow in structured soil (e.g., Larsson and Jarvis, 1999). The MACRO model was further extended toward pesticide and particle transport (e.g., Jarvis et al., 1999) and improved identification of model parameters (Larsbo et al., 2005) among other aspects.

The numerical dual-permeability model (DUAL) of Gerke and van Genuchten (1993a) assumes that the properties of the total soil volume can be characterized by two local properties for porosity, water content, fluid flux density, q ($L T^{-1}$), by the relative volumetric proportion of the fracture pore system $w_f = 1 - w_m$, ($0 < w_f < 1$). Assuming applicability of Darcy's law, water flow in the fracture and matrix pore regions are described by a coupled pair of Richards' equations:

$$C_f \frac{\partial h_f}{\partial t} = \frac{\partial}{\partial z} \left(K_f \frac{\partial h_f}{\partial z} - K_f \right) - \frac{\Gamma_w}{w_f} \quad (6)$$

$$C_m \frac{\partial h_m}{\partial t} = \frac{\partial}{\partial z} \left(K_m \frac{\partial h_m}{\partial z} - K_m \right) + \frac{\Gamma_w}{1 - w_f} \quad (7)$$

where C is the specific water capacity $d\theta/dh$ (L^{-1}), z is depth taken to be positive downward (L), t is time (T), and Γ_w is the water transfer term (T^{-1}). Analogously to flow, coupled sets of convections-dispersion equations are used to describe preferential solute transport in structure soil (Gerke and van Genuchten, 1993a). The mass transfer term has been evaluated to include in a simplistic way the basic soil structural features (Gerke and van Genuchten, 1993b; Gerke and van Genuchten, 1996) such as structural geometries and a locally reduced permeability of clay coating. In this 1D model (DUAL) both, the coupled dual-permeability equation for flow and solute transport, are solved simultaneously using mass-lumped linear Galerkin finite element scheme with Picard iteration and adjustable time steps (Gerke and van Genuchten, 1993a). An alternative partitioned numerical solution treats each pore system separately followed by a sequential execution of the single-domain numerical schemes (Tseng et al., 1995). The DUAL model has been applied in 1D (e.g., Gerke and Köhne, 2004) and extended toward flow and transport in two spatial dimensions (e.g., Gerke et al., 2007) as well as used to analyze nonequilibrium flow conditions (e.g., Šimůnek et al., 2003).

The model approach VIMAC (i.e., Vertical Infiltration through swelling and shrinking MACroporous Clay soils) (Greco, 2002) for preferential flow in macroporous swelling soil considers three different pore domains. Besides the soil matrix, these are the dynamically changing shrinkage cracks and the permanent macropores, both regarded as separate flow domains in which over-capillary flow is described using a kinematic wave equation. This approach more realistically mimics basic soil conditions (cf., Figure 1) of natural field soils, while most of the model parameters can be derived from soil structural

information. It is still unresolved, whether the larger cracks can conceptually be regarded as a pore domain, and whether flow in the permanent macropore domain should always be treated as non-capillary.

Summary

Bypass flow in soil is a frequently observed phenomenon that describes rapid and nonuniform downward water movement along highly conductive pathways through the unsaturated soil. Such preferential flow is caused by a number of different mechanisms that originate primarily from local heterogeneities. In structured soils, vertically continuous earthworm burrows and root channels, or cracks and fissures of an inter-aggregate pore network mainly serve as preferential flow paths. The interrelations between flow and transport processes and soil structural properties under varying initial and boundary conditions are complex and process-based models need to be improved.

Current approaches for a quantitative description of preferential flow mostly assume that the structured soil consists of separate but interacting porous domains. The dual-permeability models assume two mobile flow domains. These models mainly differ in the description of flow in the preferential flow domain (i.e., either Richards' equation assuming capillarity or kinematic wave approach for gravity flow) and with respect to the mass transfer formulation (i.e., from pressure head or saturation-based first-order type formulations to more complex nonlinear formulations or numerical solutions of the local flow equation). Many challenges remain, in particular, how to capture dynamic soil structure effects and to improve quantitative descriptions of bypass flow.

A better understanding of the susceptibility of soils to preferential flow is of importance when studying problems related with unintended contaminations of ground and surface waters. At the same time, the quantitative analyses of water and element balances of ecosystems are methodologically problematic as long as preferential leaching rates cannot adequately be measured or calculated.

C

CAKING

Changing of a powder into a solid mass by heat, pressure, or water.

CALICHE (LIME-PAN)

(I) A zone near the surface, more or less cemented by secondary carbonates of Ca or Mg precipitated from the soil solution. It may occur as a soft thin soil horizon, as a hard thick bed, or as a surface layer exposed by erosion.
(II) Alluvium cemented with NaNO_3 , NaCl and/or other soluble salts in the nitrate deposits of Chile and Peru.

CARBON LOSSES UNDER DRYLAND CONDITIONS, TILLAGE EFFECTS

Félix Moreno, José M. Murillo, Engracia Madejón
Instituto de Recursos Naturales y Agrobiología de Sevilla
(IRNAS-CSIC), Sevilla, Spain

Definition

CO_2 emissions are mainly produced by inadequate soil tillage combined with intensive cropping systems and climatic conditions.

Introduction

Losses of soil organic carbon (SOC) are associated with reductions in soil productivity and with increases in CO_2 emissions from soil to the atmosphere (Lal et al., 1989; Bauer et al., 2006; Ventera et al., 2006; Conant et al., 2007). Gas exchange between soils and the atmosphere may be an important contributing factor to global change due to release of greenhouse gases (Ball et al., 1999). Intensive agriculture frequently causes important losses of soil carbon. Conservation tillage (CT) agriculture (reduced tillage) has been promoted since approximately 1960 as a means to counteract all these constraints (Gajri et al., 2002). Moreover, CT improves soil quality and crop performance, especially under semiarid conditions (Moreno et al., 1997; Franzluebbers, 2004; Muñoz et al., 2007).

Tillage effects on carbon losses

Degradative effects of tillage on soil include rapid decline of soil organic carbon due to mineralization rate increase (Lal, 1993). This is particularly important under semiarid conditions using conventional tillage in which moldboard plowing with soil inversion is the main operation (López-Garrido et al., 2009). Moldboard plowing is one of the most important factors increasing CO_2 emissions by soil microbial activity stimulation due to greater soil aeration and breakdown of soil macroaggregates that conduces to a greater release of labile organic matter previously microbial protected. There are studies that suggest that the greenhouse gases contribution of agriculture, such as CO_2 , can be mitigated by widespread adoption of conservation tillage (Lal, 1997; Lal, 2000).

Conservation tillage (CT) is any tillage and planting system that maintains at least 30% of the soil surface covered by residue after planting to reduce soil erosion by water. Where soil erosion by wind is a primary concern, the system must maintain at least 1.1 Mg ha^{-1} flat small grain residue equivalent on the surface during the critical wind erosion period (Gajri et al., 2002). This system reduces the number of operations and trips across the field, and of course, avoids the soil inversion that buries most crop residues into the soil.

The effectiveness of CT in mitigating the greenhouse gas impact of individual agroecosystems could vary

substantially. Studies under different conditions are required to assess the broader of the greenhouse gas impacts of CT (Ventera et al., 2006). Tillage often increases short-term CO_2 flux from the soil due to a rapid physical release of CO_2 trapped in the soil air spaces (Bauer et al., 2006; Álvaro-Fuentes et al., 2008; Reicosky and Archer, 2007; López-Garrido et al., 2009). This rapid flux of CO_2 is influenced by the tillage system and the amount of soil disturbance (Reicosky and Archer, 2007).

Root and microbial activity together constitute soil respiration. Root and rhizosphere respiration can account for as little as 10% to greater than 90% of total “in situ” soil respiration depending on vegetation type and season of the year (Hanson et al., 2000). Nevertheless, only soil organic matter (SOM)-derived CO_2 contributes to changes in atmospheric CO_2 concentration. Long residence time of soil organic matter (SOM) results in very slow turnover rates relative to other less-recalcitrant respiratory substrates. This implies that SOM is the only C pool that can be a real, long-term sink for C in soils. Despite long residence times in steady state, if decomposition exceeds humification, the pool of C in SOM becomes a very large potential source of CO_2 (Kuzyakov, 2006).

Long-term adoption of conservation tillage (reduced and no tillage) in Mediterranean Spanish areas has proven to be an effective way to increase soil organic matter and, especially, to improve biochemical quality at the soil surface (Madejón et al., 2009). However, as the climatic conditions of the semiarid areas are an important limiting factor for the accumulation of organic carbon in the top soil layers, the simple determination of total organic carbon (TOC) is not always the best indicator of the improvement caused by conservation tillage. Under these conditions, it may be more interesting to study the stratification ratio of TOC calculated by the division of TOC content at surface between TOC content at deeper layers (Franzluebbers, 2002). This approach could also be applied to other variables related to soil biology, such as MBC (microbial biomass carbon) and enzymatic activities (Madejón et al., 2009), which are normally significantly correlated with TOC. Changes in soil biochemical properties with conservation tillage and in their stratification ratios should provide practical tools to complement physical and chemical test and, thus, evaluate the effect of conservation tillage in dryland conditions. Despite some studies have reported similar or even greater TOC accumulation in the total profile (1 m and more) under conventional tillage than under CT (Baker et al., 2007), the improvements made by CT surface are very important for the soil functions.

These processes are very influenced by the local conditions and management. Franzluebbers (2004) reported that low benefit of no tillage on TOC storage could be expected in dry, cold regions, in which low precipitation would limit C fixation by plants and decomposition, even when crop residues are mixed with soil by tillage.

However, for most soils, the potential of carbon (C) sequestration upon conversion of plow tillage to no-tillage farming with the use of crop residue mulch and other recommended practices is 0.6–1.2 Pg C year⁻¹ (Lal, 2004). The important ecological and agronomic benefits that can derive from these practices could be limited not only by plowing but also by using crop residues for other purposes. Numerous competing uses of crop residues under arid and semiarid conditions (Bationo et al., 2007) can be a constraint for CT establishment (e.g., grazing and feed livestock). Biofuel production may be another destination (Lal and Pimentel, 2007). There is at present an imperious necessity of using cellulosic biomass instead of crop grain for producing biofuel (mainly ethanol) and, currently, few sources are supposed to be available in sufficient quantity and quality to support development of an economically sized processing facility, except crop residues (Wilhelm et al., 2004).

Despite the suitability of CT to avoid C losses, this system may also have some drawbacks, such as the greater dependence of herbicides, higher level of residue management than conventional tillage, and it could not be adequate to all soils, climates, or crops. Moreover, the no-till system may lead to soil compaction. All these issues require experimentation in each particular scenario. However as a rule, CT does not cause yield losses when adequately established. Particularly, under arid and semiarid conditions in dry years, yields may be greater than under traditional tillage due to water savings resulting from conservation tillage.

Conclusions

Several studies have shown that the potential reduction for CO₂ emission from the adoption of conservation tillage under dryland conditions could be substantial. However, further investigation should be necessary to validate, under different scenarios, the potential effect of soil to sequester carbon in these conditions.

In any case, the adoption of conservation tillage, if adequately established, has a potential effect to increase organic carbon, and thus, soil quality especially at soil surface, essential for the soil functions.

CEREALS, EVALUATION OF UTILITY VALUES

Dariusz Dziki, Janusz Laskowski
 Department of Equipment Operation and Maintenance in the Food Industry, University of Life Sciences, Lublin, Poland

Definition

Utility values of cereals – feature or features of grains that characterize the properties of kernels in the aspect of

specific utilization. In the most cases, the utility value of cereals concerns using of grains to food production.

Introduction

The assessment of cereal utility value is made from the beginning of the food processing. The utility value of cereal grain depends mainly on species and cultivar properties, climatic conditions, and agricultural treatments. Moreover, the storage conditions of the cereals, the preparing conditions for processing, and the manufacturing process, all have an influence on the utility values of cereals.

The utility values of cereal is widely more significant than the technological value. The cereal utility value does not indicate only the utility of cereal grain to foodstuff production, but also takes into consideration other uses of cereals (e.g., seed production, and utilization in pharmaceutical or chemical industry) However, the technological value of the cereal grains for food production is the most often determined.

Methods of evaluation of cereal grains utility values

The methods of evaluation of the utility values of cereals can be divided into two groups: indirect and direct methods. The most commonly used indirect methods are selected physical and chemical properties of grain, specialist technological indices (such as falling number or sedimentation value), and rheological properties of dough. The results obtained from these tests indirectly provide information about the utility value of cereal grains.

Direct methods, on the other hand, are more suitable for examining the full characteristic of utility values of cereals; however, they are often time consuming and require more expensive equipment. These methods depend on processing grain or flour and imitated industry conditions. Subsequently, the quality of the product is evaluated. Examples of the direct methods are laboratory milling tests and laboratory baking tests.

Indirect methods

The basic assessment of the cereal grain includes such properties as appearance, smell, color, amount and the kind of impurities, the broken grains, and the presence of pests. A more detailed assessment includes the following *physical properties of grains*: density, test weight, 1,000 kernel weight, shape and size of grain, vitreousness (especially for wheat, rice, barley, and corn), mechanical properties (hardness, shear strength, rapture force and rapture energy, crushing strength, etc.) The research conducted on the endosperm structure (electron microscopy and X-ray methods) can also be used for the evaluation of the quality of cereals. Test weight (grain weight in a given volume) is the oldest and the most commonly used quality index of cereal grain. As a general rule, the higher the test weight, the better grain quality. Test weight is influenced by various factors, including fungal infection,

insect damage, kernel shape and density, foreign materials, broken and shriveled kernels, agronomic practice, and the climatic and weather conditions (Czarnecki and Evans, 1986). Tkachuk et al. (1990) have shown a positive correlation between wheat test weight and wheat flour yield and bread-baking usefulness. The test weight shows positive correlation with the grain density. The research of wheat grain density has revealed that the type of grain significantly affects the mean density; healthy kernels averaged $1,280 \text{ kg m}^{-3}$, sprout-damaged kernels averaged $1,190 \text{ kg m}^{-3}$, and scab-damaged kernels averaged $1,080 \text{ kg m}^{-3}$ (Martin et al., 1998).

Thousand kernel weight (TKW) is used by wheat breeders and flour millers as a complement to test weight to better describe cereal kernel composition and potential flour extraction. Generally, grain with a higher TKW can be expected to have a greater potential flour yield.

The parameter that is commonly used for the evaluation of utility values of wheat, barley, rice, and corn is vitreousness. Vitreousness indicates natural kernel translucence, which is a means of description of kernel appearance. Vitreous kernels have a translucent, glassy appearance, as opposed to mealy kernels, which have a light, opaque appearance. Vitreous grains are usually harder and denser, and have higher protein content than mealy grains. Vitreousness is usually described by a visual assessment of grain cross section. This parameter has a significant influence on the milling process (grain cleaning and tempering, passage and total flour extraction, and semolina yield).

The size and shape of grains are often useful parameters to evaluate the cereal utility value. The larger and more spherical grains are characterized by higher yield and endosperm. Small grain screenings are often separated to form sound grains and can be used as a feed component. Also, small grains have a higher level of microbiological contamination. Gaines et al. (1997) evaluated the influence of kernel size on soft wheat quality. It was found that besides kernel size, kernel shriveling should also be taken into consideration. Shriveling greatly reduced the test weight and decreased the amount of flour produced during milling. Compared to sound kernels, shriveled kernels had greater flour protein content, and increased flour ash and kernel softness. Small, non-shriveled kernels had slightly better baking quality than large non-shriveled kernels. In addition to the above mentioned parameters, the kernel size uniformity is very important to the wheat milling industry, especially in such processing as cleaning, conditioning, debranning, or grinding. Kernel size and shape can be precisely described using *Digital Image Analysis* (DIA). This method can be used for the evaluation of milling properties of cereals (flour or semolina yield) (Berman et al., 1996; Novaro et al., 2001).

The mechanical properties of cereals play a significant role in the evaluation of quality of cereals, especially the grain hardness, which is often evaluated. This parameter is one of the most important indices in the evaluation of

the utility value of wheat. The hardest wheat varieties are commonly used for semolina, cuscus, or bulgur production. Varieties having medium hardness are used as a main source for bread flour production, while soft wheat varieties are the good raw material for cookies or cakes flour production (Seibel, 1996).

Grain hardness has the greatest influence on the milling process. Particularly for wheat, this parameter should be taken into consideration both during wheat cleaning and conditioning and during flour milling. The denser structure of hard wheat endosperm does not allow tempering water to be absorbed by hard wheat at a rate faster than that for soft wheat, and therefore, the time of tempering is longer for hard wheat. In general, hard wheat cultivars are tempered to about 16–16.5% moisture whereas soft wheat cultivars are tempered to 15–15.5% (wet basis) (Fang and Campbell, 2003).

The endosperm of hard wheat during grinding tends to grind down to the coarser particles referred to as semolina whereas soft varieties give more flour particles directly. The bran layer of hard wheat is usually more susceptible to grinding than the bran layer of soft wheat. It is found that hard wheat kernels grind better during the reduction stage than soft kernels, and bran includes little endosperm (Gaśiorowski et al., 1999).

The flour particle size distribution also depends on the wheat grain hardness. Testing of the total percentage of flour with particle size of less than $50 \mu\text{m}$ shows considerable differences between soft wheat and hard wheat. Approximately 50% of total flour produced from soft wheat is smaller than $50 \mu\text{m}$ whereas it is only 25% in hard wheat. In fact, hard wheat cultivars display single-mode particle size distribution whereas soft wheat cultivars have bimodal distribution with the first mode at about $25 \mu\text{m}$ (Haddad et al., 1999). Moreover, the flour obtained from hard wheat is easy to sieve whereas soft wheat flour particles tend to stick to other surfaces and to other flour particles, causing sifting problems.

Several tests are available for the determination of cereal grain hardness. These methods often rely on the classic method commonly used for constructional materials (e.g., the Vickers or Brinnel hardness test). However, the most practical application for the evaluation of the utility value of cereals includes tests that indirectly express grain hardness. Especially for wheat, several methods of grain hardness determination have been proposed, such as wheat hardness index (WHI), particle size index (PSI), pearling resistance index (PRI), and a modern method called single kernel characterization system (SKCS). This system is especially useful for a rapid analysis of cereal grain physical properties (Grundas, 2004). The SKCS instrument analyzes 300 kernels individually and determines kernel weight by load cell, kernel diameter and moisture content by electrical current, and kernel hardness (HI) by pressure force. A number of researchers have shown the usefulness of SKCS for the evaluation of wheat utility value, especially milling value. This instrument can be used to evaluate the time of tempering wheat

grain before milling. The SKCS instrument can also be used to determine the physical properties of other cereal species.

Grain hardness is also related to important baking properties of flour. The flour obtained from hard wheat is characterized by higher content on starch damaged. As a result, this flour has higher water absorption and higher gas generation ability and thus bread yield is usually increased.

The chemical properties of cereal grain are also commonly used for the evaluation of cereal utility value. For example, the wheat protein content is one of the most important parameters taken into consideration for wheat grain technological value assessment.

Several tests are available for characterizing the utility value of cereals. For example, the sedimentation test is the basis parameter used for evaluating the baking value of ground wheat or flour sample. The sedimentation test provides information on the protein quantity and the quality. This test is conducted by holding the ground wheat or flour sample in an acid solution. During the sedimentation test, gluten proteins swell and precipitate as a sediment. The sedimentation values can be in the range of 7 for low-protein wheat with weak gluten to as high as 75 or more for high-protein wheat with strong gluten. Positive correlation is observed between sedimentation volume and gluten strength or loaf volume attributes. The sedimentation value depends, among other things, on the flour extraction during milling and the wheat variety (Kruger and Hatcher, 1995).

Another very important parameter is the falling number. This test informs about the enzyme activity (mainly α -amylase) of ground wheat or flour sample. The falling number instrument analyzes the viscosity of flour-and-water paste by measuring the time of mixing and falling stirrer. If the falling number is too high, enzymes can be added to the flour in various ways to compensate. However, on the other hand, if the falling number is too low, enzymes cannot be removed from the flour or wheat, which results in a serious problem that often makes the flour unusable for baking. High α -amylase activity could be caused by immature grain or low resistance to sprouting (Abdel-Aal et al., 1997).

Some methods characterize the cereal utility value on the basis of dough rheological properties. Apparatuses such as alevograph, farinograph, extensigraph, mixograph, and rapid visco analyzer are the most commonly used in the industry practice. Parameters obtained on the basis of these methods are very useful for evaluating the baking value of flour.

Direct methods

The two direct methods most often used to evaluate the cereal utility value are the laboratory flour milling tests and the laboratory baking tests. These methods indicate the milling and baking properties of small cereals and flour samples.

The laboratory flour milling test is used to evaluate the milling performance of wheat and other cereals and to produce flour for other laboratory tests. Various kinds of laboratory automated or semi-automated mills are used to determine the cereal milling value. The most common laboratory mills are the Brabender Quadramat Flour Mills, the Buhler Laboratory Flour Mill, and the Chopin CD1 and CD2 mills. Information obtained on the basis of laboratory flour milling is useful to adjust the mill settings of commercial mills.

The laboratory flour mill results are expressed as flour extraction and flour ash content. Also, parameters such as bran and shorts yield are determined (Posner, 1991). For example, the effectiveness of wheat flour milling can be expressed by the following equation, called Brabender index:

$$W_B = \frac{0.5w}{82z} \quad (1)$$

where, w represents flour extraction (%); z , is the flour ash content (%); 0.5, is the average ash content in wheat endosperm, and 82 represents the average endosperm content in wheat. The higher the value of this index, the better is the cereal utility value (Jurga, 2006).

The laboratory baking test is the best method to evaluate the baking value of cereals and flour. The baking tests can be divided as standard and optimum. The standard baking tests depend on the constant conditions of dough kneading and baking parameters, whereas the optimum methods recommend adjusting the baking recipe and baking parameters to the properties of the flour. Thus, this method allows for the optimum use of flour.

The laboratory baking tests can be realized in two ways:

- By the direct method (the dough is produced from all the ingredients)
- By the indirect method (at the beginning the leaven is prepared and after fermentation dough is produced)

It should be noted that on the basis of the baking tests the sensory assessment of bread is made. Also, the *bread's physical and chemical properties* are determined. The parameters of texture are commonly evaluated.

Summary

The methods of evaluation of cereal utility value are consequently improved for many years and allow to quickly evaluate the quality of grain. The full characteristics of cereal includes evaluation of many parameters, which decide about utility. The described physical properties of grain are the basis in cereal utility evaluation. However, the fully characteristic of cereal must include other parameters.

Definition

Chemical imaging in agriculture is a discipline at the intersection of statistics and biophysical chemistry (chemometrics), applied in agriculture, food science, and in agrobiotechnology. It is a discipline whose analytical capability consists in creating visual images (spectral images) of the composition, structure or dynamics of chemical samples (qualitative or quantitative – mapping) from simultaneous measurement of spatial and valid time-dependent spectroscopy variables, and quantitative interpretation of the images also provides answers to the questions “when”, “where”, “what” and “how much”.

Chemical imaging methods (without dyeing) can be used for gaining information about agriculture systems of all sizes, from the single molecule to the cellular level and to the ecosystem in agriculture. Diverse instrumentation, ultra-sensitive and selective techniques of interaction radiation with the sample are employed for making observations on such widely different systems. However, what is the most important in the discipline is the fact that several different physical phenomena and types of signal acquisition can be used in similar, but highly advanced chemometrics algorithms, and that created huge data sets will be processed by one software and computer, permitting multiple potentialities of field application for diagnosis.

Introduction

Many applications of chemical imaging touch our daily lives, for example in subjective (sensory) tests, in the human recognition of nutrient and pigment content in foods; it works as a non-invasive method of diagnosing, understanding and control of plant growth, harvest and post-harvest or simple preservation processes. In such aspects of human perception, the imaging is limited to the life experience, the power of human brain, and simple eye detectors of red, green and blue light data, and that set of human attributes combined permits the recognition of a sample as the chemical fingerprint method (Francis, 1995). In such applications, the present wide range of bio-spectroscopy techniques permits more quantitative analysis of bioactive ingredients, but it will not provide full and complete information on the spatial distribution of chemical components.

The idea that drives the analytical power of chemical imaging is that data scanning draws information from such a large portion of the spectrum of absorption, emission, mass, energy, power etc. that any given object should have a unique spectral signature – a “fingerprint” in at least a few of the many bands that can be scanned and exactly statistically processed.

Image processing

In a standard mapping experiment, i.e., univariate data analysis, an image of the sample will be made based on single value variation as is from data values (intensity at

point, signal to baseline, signal to axis), from the parameters of a curve model fitted to the data (peak area, position, width, intensity), or others (Chi-squared, percent Gaussian). For example, an anthocyanins map could be made from a strawberry sample, in which one band of anthocyanins absorbance is used for the intensity greyscale of the image. Dark areas in the image would indicate non-anthocyanins-bearing compounds. This mapping could potentially give misleading results with more interactive surroundings or color reactant.

By spectral mapping almost the entire spectrum at each mapping point is acquired, and a quantitative analysis can be performed by computer post-processing of the data. The main and increasingly important role of chemometrics is the analysis of multivariate data for many different application areas. Multivariate methods can analyze the whole data set simultaneously and directly related to chemical properties. It allows the potential qualification and quantification of very complex systems such as biological materials.

Packages of software designed for the visualization and analysis of large 3 or 4-dimensional hyperspectral image cubes offer extensive spectral and spatial pre-processing capabilities and support statistical pattern recognition, multivariate classification and quantitative analysis algorithms as well as standard image analysis. Software developed for laboratory imaging and mapping experiments identifies materials using reference spectra (direct classical least squares (DCLS) and partial least squares (PLS), principal component regression (PCAR), multilinear regression) or identifies materials even when no reference data is available (principal component analysis (PCA), multivariate curves resolution (MCR-ALS) or factor analysis). The standard image analysis and visualization post-processing tools, such as particle size and distribution analysis, transform qualitative information contained within an image into quantitative metrics that deliver objective answers.

Multivariate algorithms are constantly being developed, like a life experience, so there is a continuous supply of new and improved methods. The order follows a typical workflow consisting of loading or importing a data set, visualizing and pre-processing the data, analyzing to obtain qualitative or quantitative results, and finally visualizing. The true value of all data registration techniques of chemical imaging are exploited only with access to very advanced statistics and image analysis capabilities.

Techniques of chemical imaging

Many imaging techniques are used, and often used simultaneously in combination for exacting applications. They are significantly differing in their ability to capture lateral dimensions, ranges of penetration depths, or time scales. The bio-spectroscopy techniques, this umbrella term integrates both – are divided into the three main groups (Jackson et al., 2006).

1. Optical imaging and magnetic resonance

The techniques interact with samples using resonance of low-energy (electronic, vibrational, or nuclear). They are non-destructive and can be performed in the body (*in vivo*). Examples include:

- Vibrational imaging – identifies specific molecules by their chemical bonds and use vibrational spectrum like a “fingerprint” of matter (Himmelsbach et al., 2001; Thygesen et al., 2003; Gierlinger and Schwanninger, 2007).
- Fluorescence techniques – rely on fluorescent proteins that are genetically expressed in biological systems or can bind to targets as spectroscopic markers (Xiao et al., 1999; Roos, 2000; Lai et al., 2007).
- Ultrafast spectroscopy – uses ultrafast pulsed light sources that provide peak power needed to measure excited states useful in dynamics reaction (Lichtenthaler and Babani, 2000).
- Nuclear Magnetic Resonance and Magnetic Resonance – technologies that use magnetic fields to provide spatial information on molecules (Glidewell, 2006; Lambert et al., 2006).

2. Electron, x-ray, ion and neutron spectroscopy

The techniques interact with samples using high-energy radiation which provides high-resolution chemical and structural information below surfaces of materials. Examples include:

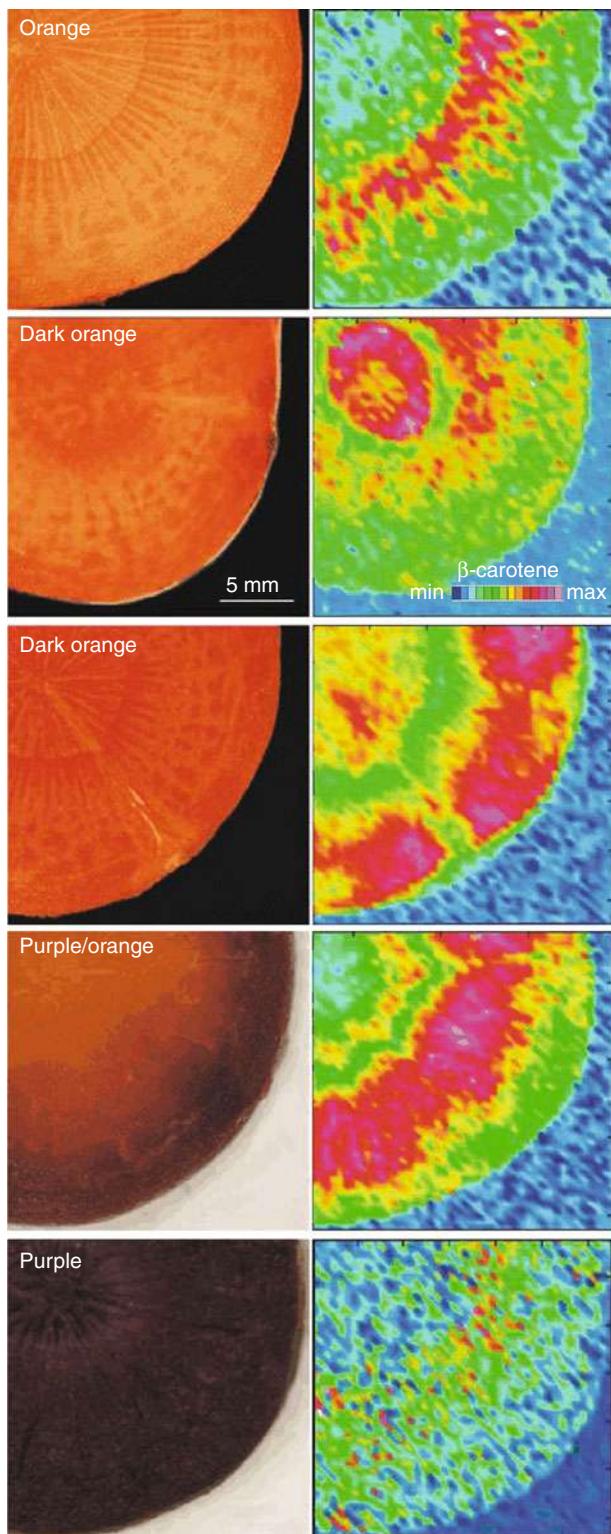

- Electron microscopy – takes advantage of the fact that an electron provides a much higher-resolution of probing than optical and can penetrate deep below the surfaces of materials.
- X-ray spectroscopy – uses high-energy photons to penetrate more deeply than electrons.
- Mass spectrometry – moving a point of ionization over a sample surface and is used for mapping biological samples (Mangabeira et al., 2006; Burrell et al., 2007; Sangwon Cha et al., 2008).

3. Proximal probe

The techniques use small probes very close to the sample. There is a wide variety of tips used in tunneling, force and near-field optical microscopes. For the purposes of recording images, that is an optical-fibre, a semiconducting, or a metallic probe positioned in close proximity to a sample. These methods are especially useful for understanding the chemistry of surfaces (Ding et al., 2008).

The challenge in agriculture

Chemical imaging in agriculture includes the biochemistry which is important in the processing effects on postharvest products, on the composition and safety of foods, feeds, beverages, and other products from agriculture, including wood, fiber and bio-based materials, by-products, and wastes. It covers the chemistry of pesticides, herbicides (Hake et al., 2007; Perkins et al., 2008), veterinary drugs, plant growth regulators, phytonutrients, flavours and aromas, fertilizers, together

Chemical Imaging in Agriculture, Figure 1 Classification of carrot roots by visual images of transversely cut roots and their Raman maps colored according to the band intensity related to β -carotene content. (Modified figure of Baranska et al., 2006.)

with their metabolism, toxicology, and environmental monitoring and remediation. These spectral analyses in agriculture emphasize the relationships between plants, animals and bacteria, and their environment and must be considered within the context of the soil, water, air – within the agro-ecosystem in which living and nonliving components interact in complicated cycles that are critical to a wide variety of organisms.

Chemical imaging in Agriculture can perform qualitative and quantitative analysis of the ingredient distribution (Figure 1), use the science of sampling, set error limits, validate and verify results through calibration and standardization, create new ways to make measurements based on differential spectroscopy properties, and interpret data in proper context and communicate results (Salzer et al., 2000). Finally, the goal for chemical imaging in agro-environment is to recognize and understand chemical structures and processes, and to use that knowledge to control, classify, or eventually create biological structures on demand. Our ability to domesticate crops and eliminate the need for hunting and gathering that allowed for the establishment of permanent settlements and the development of technologically advanced societies has led to a greater overall availability of food, both animal and plant.

Chemical imaging together with biotechnology (Schmidt et al., 2009) is a source of great promise for innovations ranging from improving the diagnosis and treatment of hereditary diseases, to safer drugs, to more environmentally friendly herbicides and pesticides to microbial processes to clean up the environment (Gowen et al., 2007). Making these promises a reality requires rethinking some fundamental assumptions.

Conclusions

In general, all chemical imaging in Agriculture could benefit from the development of higher data acquisition speeds, better data storage and management, new chemical probes and markers, ultrafast optical detectors, possibility of measuring multiple dimensions in parallel and further miniaturisation of instrumentation. As chemical imaging involves the use of a relatively new analytical technique and high cost of instrumentation, the full potential of chemical imaging in Agriculture cannot yet be fully realized, and that potential, should such analytical techniques be implemented on a large scale for the control of intensive agricultural and food production, may bring enormous benefits for health and prophylactic interventions.

CHEMICAL TIME BOMB, RELATION TO SOIL PHYSICAL CONDITIONS

Halina Smal

Institute of Soil Science and Environment Management,
University of Life Sciences, Lublin, Poland

Definition

Chemical time bomb (CTB), originally formulated by Stigliani in the late 1980s is defined as

an unforeseen chain of events resulting in the delayed and sudden occurrence of harmful effects due to the mobilization or chemical transformation of chemicals stored in soils and sediments in response to saturation or alteration in certain environmental conditions. (Stigliani, 2002, 99)

The CTB concept refers to the following: (1) soil/sediment ability to store and immobilize toxic chemicals (e.g., heavy metals such as Cd, Cu, Pb, and Ni; persistent organic compounds such as PCBs - polychlorinated biphenyls widely used in the past in many products mainly in electrical equipment, and some pesticides like DDT- dichloro-diphenyl-trichloroethane) in “chemical sinks” having limited capacity, (2) that harmful effects of pollution may not be observed directly but long after (e.g., decades) loading of the chemical to the environment (hence, CTB term). CTB may emerge when a retained, inert chemical is mobilized and released because the capacity of the sink is either exceeded by an excess of the chemical input, or diminished due to changes in “capacity-controlling properties” (CCPs), that determine the sink storage capacity. In the long term, CCPs are not constant and vary as affected by environmental changes (e.g., in land use and climate, hydrology). When any of CCPs passes a threshold, the system may reverse the role from a sink into a source of the chemical, for example, in

crops and vegetation, ground and surface waters. Such a reversal is usually unpredictable, unexpected and sudden (the “explosion”) – on a timescale that is relatively short in comparison with the time between the initial accumulation and the manifestation of detrimental effects.

With respect to heavy metals, particularly important soil CCPs are the following: cation exchange capacity (CEC), pH, redox potential (Eh), organic matter content, salinity, and microbial activity. They are interdependent and directly or indirectly related to the soil physical conditions; in case of CEC and Eh to the following:

CEC – soils with a low value have low capacities to retain heavy metals by sorption. It depends on clay minerals and organic matter content (decreasing reduces CEC) and is reflected in *soil texture* (clay fraction content).

Eh – decreasing (more reducing conditions) dissolves iron and manganese oxides, which mobilizes oxide-sorbed toxic chemicals. Its increasing (more oxidizing conditions) mobilizes heavy metals by dissolving insoluble metal sulfides. Eh is directly influenced by *soil moisture* and may be changed by flooding (Eh decreasing) or drainage (Eh increasing) of lands.

In CTB phenomena, also important are soil physical properties influencing leaching and transport of chemicals – *water retention* and *water flow, erosion*.

Water flow – depends on soil *hydraulic properties*. Among them, a *hydraulic conductivity*, which is a measure of the ability of a soil to transmit water and dissolved solutes and is strongly related to *soil texture, structure, and water content*.

Soil erodibility – erosion increases the risk of runoff and concentrations of toxic substances at locations where transported material is deposited. It reflects among other properties, *soil texture, structure, moisture*, and organic matter content. It is related to farming activities that influence these properties and to changes in land use (e.g., it increases with deforestation).

CTBs example – draining of wetlands in a coastal area of Sweden in the 1900s and in the 1940s, resulting in oxidation of sulfides to H_2SO_4 and strong acidification of nearby lakes; the Minamata (Japan) catastrophe (for details and more examples see Stigliani, 2002).

CLAY MINERALS AND ORGANO-MINERAL ASSOCIATES

Tatiana Victorovna Alekseeva

Laboratory Geochemistry and Soil Mineralogy, Institute of Physicochemical and Biological Problems of Soil Science, Russian Academy of Sciences, Pushchino, Moscow region, Russia

Synonyms

Phyllosilicates

Definition

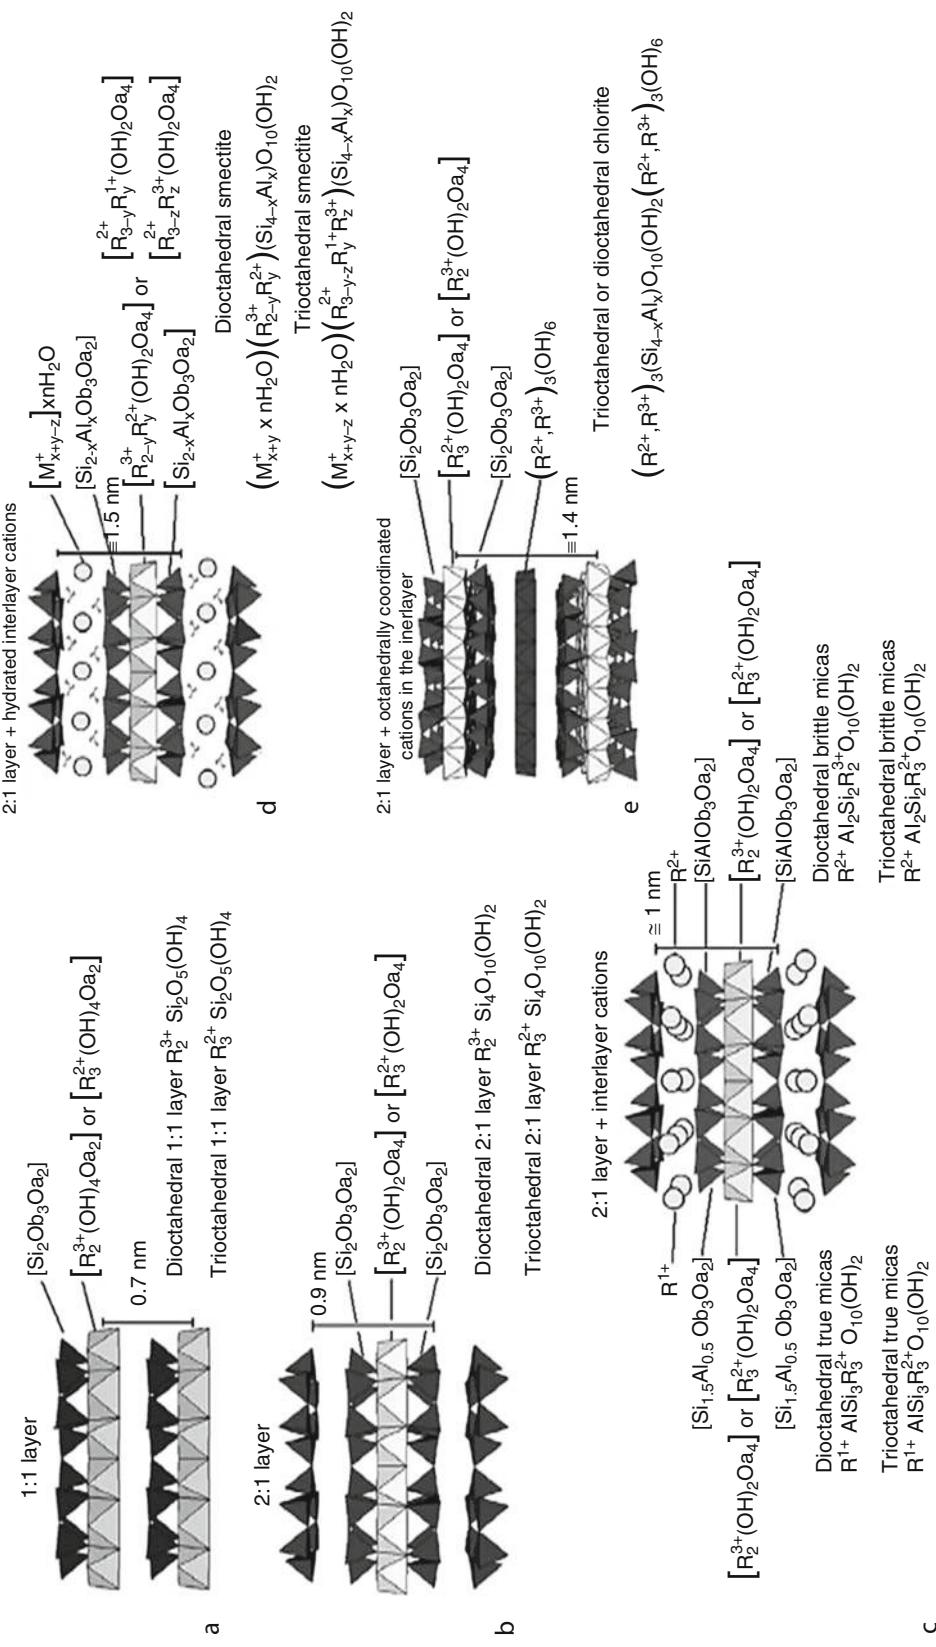

Clay minerals belong to the family of hydrous aluminum phyllosilicates. They make up the fine-grained fraction of rocks, sediments, and soils.

Introduction

Clay minerals are the most important constituents of so-called clay-size fraction (particles are less than 2 micrometers [μm] in equivalent spherical diameter) of soils. Commonly referred to as “fine-grained,” “submicron,” or “ultrafine” particles, recently the term “soil nanoparticles” is coming into usage. The clay size fraction in soils is seldom composed of a single mineral. Typically, it includes mixtures of phyllosilicates, oxides, and hydroxides of Fe, Al, and Mn, occasionally quartz and feldspars and organic materials – humic substances, enzymes, viruses, etc. (Theng and Yuan, 2008) (see *Nanomaterials in Soil and Food Analysis*). Soils’ clay fractions are typically enriched in organic C and P, total N, S, and P, inorganic P, Al, Fe, Ca, Mg; they have higher cation exchange capacity (CEC) in a comparison with bulk soils and coarser fractions. Many soils’ basic physical and chemical characteristics: *buffer capacity, bulk density, cracking and creeping, flocculation and dispersion phenomena, hydrophobicity, infiltration, shrinkage and swelling phenomena, soil aggregation* (see *Soil Aggregates, Structure, and Stability*), *soil structure and compaction limits*, and surface properties (see *Adsorption Energy and Surface Heterogeneity in Soils, Specific Surface Area of Soils and Plants*) (see, e.g., Alekseeva et al., 1999) are influenced by molecular-scale differences in soil clay minerals and/or their concentrations.

Phyllosilicate minerals in soils

The structures of phyllosilicates basically consist of sheets of SiO_4 tetrahedra and sheets of Al or Mg octahedra (as in gibbsite and brucite). Common tetrahedral cations are Si^{4+} , Al^{3+} , and Fe^{3+} . Octahedral cations are usually Al^{3+} , Fe^{3+} ,

Clay Minerals and Organo-Mineral Associates. **Figure 1** Different layer structures: (a) 1:1 layer (i.e., kaolinite- and serpentine-like layer), (b) 2:1 layer with anhydrous interlayer cations (i.e., the mica-like layer), (c) 2:1 layer with hydrated interlayer cations (i.e., smectite- and vermiculite-like layer), (d) 2:1 layer with octahedrally coordinated interlayer cations (i.e., chlorite-like layer). (After Brigatti et al., 2006. With permission from Elsevier.)

Mg^{2+} , and Fe^{2+} . Octahedra show two different topologies related to OH-groups position, i.e., the cis- and the trans-orientation. The 1:1 layer structure consists of the repetition of one tetrahedral and one octahedral sheet, and examples would be kaolinite and serpentine (Figure 1).

A 2:1 layer structure consists of an octahedral sheet sandwiched between two tetrahedral sheets, and examples are micas, smectites, vermiculites, and chlorites. In the 1:1 layer structure, the unit cell includes six octahedral sites (i.e., four cis- and two trans-oriented octahedral) and four tetrahedral sites. Six octahedral sites and eight tetrahedral sites characterize the 2:1 layer unit cell. Structures with all the six octahedral sites occupied are known as trioctahedral. If only four of the six octahedra are occupied, the structure is referred to as dioctahedral. Depending on the composition of the tetrahedral and octahedral sheets, the layer will have no charge or will have a net negative charge. If the layers are charged, this charge is balanced by interlayer cations (Na^+ , K^+ , or others). In each case, the interlayer can also contain water. The crystal structure is formed from a stack of layers interspersed with the interlayers. The periodicity along the c-axis varies from 0.91 to 0.95 nm in talc and pyrophyllite to 1.40–1.45 nm in chlorite. In talc, the interlayer space is empty, whereas in mica and illite it is occupied by anhydrous alkaline and alkaline-earth cations (layer periodicity about 1 nm). The interlayer space of smectite and vermiculite contains alkaline or alkaline-earth cations together with water molecules (layer periodicity is about 1.2 nm when the interlayer position is occupied by cations with low-field strength and water molecules, about 1.5 nm when the interlayer is occupied by high-field strength cations and water molecules, and more than 1.5 nm when water molecules are exchanged by different polar molecules) (Brigatti et al., 2006, p. 21). Table 1 gives the classification scheme for phyllosilicates with typical layer

structures and some basic properties (for detail reading see also Dixon and Weed, 1989).

Additionally to these main groups, chain minerals – palygorskite (attapulgite) and sepiolite are considered 2:1 phyllosilicates and these are important constituents in soils of arid and semiarid climates. They contain a continuous two-dimensional tetrahedral sheet; however, they differ from other layer silicates in that they lack continuous octahedral sheets. Thus, the structures consist of ribbons of 2:1 sheets 4 or 6 SiO_4 tetrahedra (in palygorskite and sepiolite, respectively) wide connected in a “net” structure with holes, which contain a variable amount of zeolitic water. Sepiolite is trioctahedral, whereas palygorskite is intermediate between di- and trioctahedral. Chain phyllosilicates have a fibrous habit with channels running parallel to the fiber length. Fiber sizes vary widely but generally range from about 10 to about 30 nm in width, and from about 5 to about 10 nm in thickness. The CEC of these minerals is low – 3–20 meq 100 g^{-1} . At the same time, anion exchange capacity exceeds 70 meq 100 g^{-1} which together with large external surface (up to $200\text{ m}^2\text{ g}^{-1}$) and even larger internal pore surface (up to $600\text{ m}^2\text{ g}^{-1}$) provides high adsorption capacity for cations, anions, and neutral molecules, and good suspending or gelling characteristics (Mackenzie, 1975; Raussell-Colom and Serratosa, 1987; Brigatti et al., 2006).

Besides monomineralic clay samples and mixtures of discreet clay minerals, one more type of mixtures exists – interstratified or mixed layer minerals or structures. Mixed layers are usually built up by layers of two mineral types but may be the combination of more different components. Interstratified clay minerals can have ordered or regular mixed-layer structures if different layers alternate along the c-direction in a periodic pattern (e.g., the stacking of A and type B layers can be ABABAB or AABAAB etc.) or disordered (irregular) mixed-layer structures, if the

Clay Minerals and Organo-Mineral Associates, Table 1 Classification scheme for phyllosilicates with typical layer structures and their major properties. (Modified after Thorez, 1976.)

Layer type	Interlayer	Net layer charge per formula unit (x)	CEC (meq 100 g^{-1})	SSA ($\text{m}^2\text{ g}^{-1}$)	Group names	Subgroups names (octahedral layer)

stacking along the c-direction of type A and B layers is random (e.g., ABBABAA or AAABABAAAAABABA etc.). Regular sequences are identified by special names. For example, the name “rectorite” is attributed to a regular interstratification of dioctahedral mica and dioctahedral smectite; “tosudite” is a regular interstratification of dioctahedral chlorite and dioctahedral smectite. Interstratified minerals have been mostly recognized in soils but also in sediments and as the hydrothermal and weathering products (MacEwan and Ruiz-Amil, 1975; Thorez, 1976; Brigatti et al., 2006, p. 25).

Three models of origin of soil clay minerals are: (1) inheritance directly from parent materials, (2) transformation when the original structure is usually retained but the interlayer region is visibly altered, and (3) neoformation by the synthesis from the dissolved and amorphous products of weathering; here, the structures may have no relationship to those of the parent material. The soil clay mineral predominance is correlated with climate factors (temperature and water availability in the soil), because these factors strongly affect the chemical weathering in the soil profile. The correlation of soil clay mineralogy with climate conditions has been reviewed extensively. It was suggested that clay mineralogy follows a weathering pattern, from hot and humid to cool and dry, in the order kaolinite→smectite→vermiculite→chlorite and mixed-layer phyllosilicates→Illite and mica (for details see Dixon and Weed, 1989; Wilson, 1999).

Previously neoformation of clays regarded mostly as abiotic processes. Recent findings show that different clay minerals can be synthesized with the participation of microorganisms (Tazaki, 2006). Konhauser and Urrutia (1999) concluded that bacterial clay authigenesis is a common biogeochemical process. Like a biomineratization process, biochemical weathering of clays also meets more interest (Robert and Berthelin, 1986).

Clay minerals are ultrafine particles and their characterization requires special analytical techniques. Standard set includes x-ray diffraction, various spectroscopic methods such as Mossbauer spectroscopy, infrared spectroscopy, NMR spectroscopy, thermal analysis, and electron microscopy (for detail reading see Thorez, 1976; Bergaya et al., 2006).

Organomineral associates in soils

In temperate cultivated soils 50–75% of soil organic matter (OM) exists within clay-sized organo-mineral particles (Kleber et al., 2007). The interactions of clay minerals and OM play the important role in the formation and stabilization of soil aggregates and the behavior of nutrients and pollutants (Six et al., 2002; Alekseeva et al., 2006; Besse-Hoggan et al., 2009).

The ability of minerals to preserve OM results from the combined influence of reactive surface sites and a large specific surface area (SSA). These properties result from heterogeneity and imperfection of the natural mineral

surfaces and small size of clays and soil oxides (Kogel-Knabner et al., 2008).

The interactions of humic substances with soil clay minerals may have a variety of mechanisms which mainly depends upon the nature and properties of the organic species, the properties of the clay mineral and the kind of exchangeable cation at the clay surface, the water content of the system, and the pH of the surrounding medium. The type of clay becomes increasingly important when the soil OM content is low (Cornejo and Harmosin, 1996).

The interactions of OM with mineral surfaces (phyllosilicates and Fe-, Al-, Mn-oxides) and metal ions is one of the mechanisms of OM stabilization. Evidence comes from the fact that soil OM in fine silt and clay fractions is older or has a longer turnover time than OM in other soil OM fractions. Adsorption of OM to mineral surfaces effects the OM decomposition mechanisms and rates. Main chemical mechanisms of interactions are: (1) ligand exchange, (2) polyvalent cation bridges, (3) weak interactions such as hydrophobic interactions, van der Waals forces, and H-bonding (Mineral Organic Microbial Interactions) (Luetzow et al., 2006).

OM bound to minerals mainly by ligand exchange is more resistant against mineralization than OM held by van der Waals forces. Ca-bridges enhanced the stability of sorbed OM but less than by the binding via ligand exchange (Kogel-Knabner et al., 2008).

For each mechanism, only certain amount of OM can be protected and each soil has its own protective capacity. The mineralogy of soil particles controls the protection of OM via the effect of the type and density of active sites capable of adsorbing organic materials. The presence of Fe-Al oxides – hydroxides increases the surface charge density which increases the reactivity of mineral surfaces. Kleber et al. (2007) showed that singly coordinated, reactive OH groups on Fe and Al oxides and at edge sites of phyllosilicates, which are able to form strong bonds by ligand exchange, are a measure of the amount of OM stabilized in soils in organo-mineral associations.

Preferential binding at reactive sorption sites favors typically discontinuous surface accumulation of OM rather than in a continuous coating. Thus, OM is not distributed over the available mineral surfaces but clustered ([Clusters in Soils](#)) in small patches with some vertical extension (Kaiser and Guggenberger, 2003; Kleber et al., 2007). Recently, Kleber et al. (2007) came to the conclusion that adsorbed OM creates the zonal organo-mineral architecture with regular features: contact zone, hydrophobic zone, and kinetic zone. The molecules of the inner zone are the most stable, and molecules of the outer zone have the faster exchange with soil solution. It is suggested that proteins (*N*-containing materials) play a prominent role in the formation of organo-mineral complexes due to both the relatively high abundances of these compounds in soils and the ability of these materials to adsorb irreversibly to mineral surfaces. Proteins can bind particularly strongly and create a basal layer with further opportunities for more numerous interactions. The affinity of proteins

for all types of interfaces found in soils originates in the flexibility of the polypeptide chain and in the diversity of the 2-amino acids that can be classified as positively, neutrally, or negatively charged and on a hydrophobic scale from polar (hydrophilic) to non-polar (Quiquampoix and Burns, 2007).

Additionally to chemical stabilization of OM in soils, its physical protection in soil microaggregates influences OM accumulation ([Physical Protection of Organic Carbon in Soil Aggregates](#)).

Summary

Interactions of clay minerals with OM (soil natural organic polymers) modify properties of both partners and have the large-scale effect on the physical, chemical, and biological properties of soils. Fractionation of soil organic substances due to the properties of a mineral matrix is the other aspect of these interactions. Up to now limited information is available on the relationships between mineralogy and the chemistry of bound OM. Solid state NMR spectroscopy (^{13}C , ^{15}N , ^{31}P , ^1H , etc.) is a promising tool for solving this problem. Kogel-Knabner et al. (2008) showed that mineral-bound OM is depleted in lignin and phenolic components. Clay fractions generally show a higher content alkyl-C groups than whole soils and higher proportions of carboxyl-C than plant residues, indicative of the more oxidized stage of the stabilized OM. Laird et al. (2001) postulated that existing relationships between clay mineralogy and the chemical nature of the associated humic substances indicate that either soil clay mineralogy strongly influences the humification process or that humic substances with different properties are selectively adsorbed on different clay mineral species. Further investigations of the OM associated with different clay minerals are needed before the role of clay–organic interactions on OM constitution, stabilization and turnover times, diagenetic transformations, and other aspects will be clear.

CLAYPAN AND ITS ENVIRONMENTAL EFFECTS

Definition

Claypan refers to a subsoil layer, having a much higher clay content than the surface horizons. This layer is slowly permeable and is separated by a sharply defined boundary from overlying horizons. Claypans are dense and hard when dry but plastic and sticky when wet. (Soil Science Society of America, 2008). These soils often have a perched water table present above the claypan during a portion of the year.

Pan. A pan can be genetic or induced. A genetic pan is a natural subsurface soil layer with low or very low hydraulic conductivity. The layer differs in physical and chemical properties from the soil layers immediately above and below the pan. Some genetic pans include claypans, fragipans, and hardpans. An induced pan is a subsurface layer having a higher bulk density and lower total porosity than the soil layers immediately above and below the pan and is a result of pressure that has been applied by normal tillage operations or other artificial means. Synonyms for these induced pans include plowpans, plowsoles, pressure pans, or traffic pans (Soil Science Society of America, 2008).

Introduction

Soils with claypans include significant areas throughout the world. In the Midwestern USA, these soils are included in Major Land Resource Area (MLRA) 113 Central Claypan Area (2.9 million hectares), with most soils classified as Aqualfs and some Udalfs. The United Nations FAO system classifies these soils as Eutric Planosols (Food and Agriculture Organization of the United Nations, 2001). Eutric Planosols have a global extent of 47.53 million hectares. Planosols include 130 million hectares and are extensive in southern Brazil, northern Argentina, Paraguay, eastern Africa, South Africa, eastern Australia, eastern United States, and in southeast Asia from Bangladesh to Thailand (Food and Agriculture Organization of the United Nations, 2001).

The US Soil Classification System of 1938 used the name Planosols for claypan soils. The subsequent US classification system, USDA Soil Taxonomy, includes Planosols in the Great Groups Albaqualfs, Albaquults, and Arialbolls. Claypan soils are in the Great Group Albaqualfs.

Claypan soils include a significant amount of area within the Midwestern USA (Blanco-Canqui et al., 2002). Soils in this area are characterized by a subsoil horizon with an abrupt and significant increase in clay content within a short vertical distance in the soil profile (Soil Science Society of America, 2008). The Midwestern US claypan region and similar soils encompass an area of about 4 million hectares within Missouri, Illinois, and Kansas (Anderson et al., 1990). The depth to the claypan varies from 0.10 to 0.50 m with clay content ranging from 350 to 600 g/kg (35–60%; Blanco-Canqui et al., 2002). Dominant clay minerals include smectites with high shrink swell potential.

Throughout the year, these clays swell during the winter and spring periods and often shrink during the late summer and early autumn periods. When the clays are swollen, their low saturated hydraulic conductivity impedes infiltration and perches water above the claypan, causing a high probability of runoff (Blanco-Canqui et al., 2002). When the clays shrink, preferential flow through these cracks is significant (Baer and Anderson, 1997).

Most claypan soils are classified in high runoff hydrologic groups (Lerch et al., 2008). Soils primarily on hillslopes in dissected till have a slow infiltration rate and moderate runoff potential due to argillic horizons or paleosols that impede downward movement of water. Soils occurring at summit landscape positions have a very slow infiltration rate and high runoff potential due to claypans.

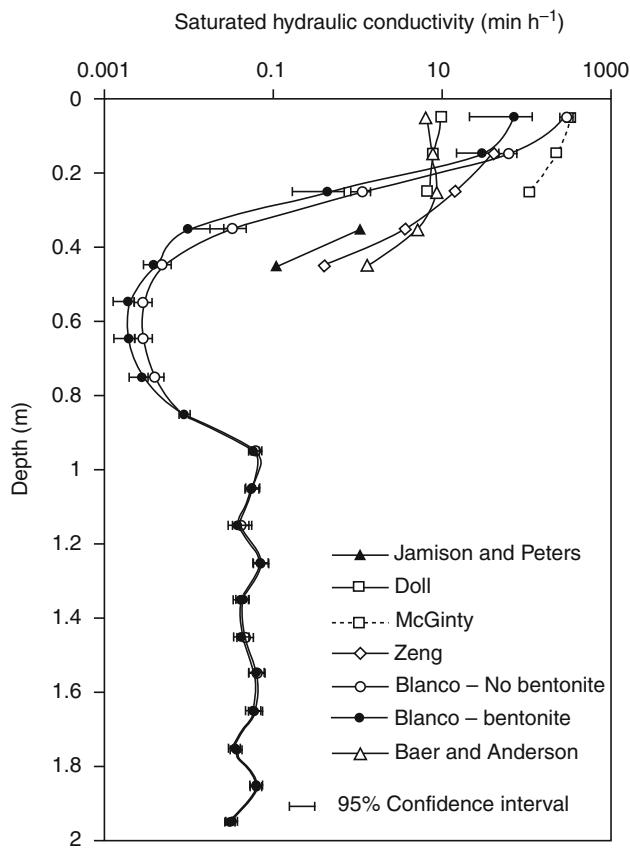

Hydrology

Soil texture and structure have strong effects on saturated hydraulic conductivity, K_{sat} (Blanco-Canqui et al., 2002). Clay-textured soils typically have low to very low K_{sat} values. Due to their low subsoil permeability, claypan soils perch water and create lateral flow and surface runoff. Field work on claypan hydrology suggests that runoff rates may be equal to rainfall under saturated conditions (Saxton and Whitaker, 1970). Long-term studies of runoff and rainfall with the McCredie rainfall-erosion plots at Kingdom City, Missouri, USA indicate that lateral flow known as interflow is a significant component of the total runoff during springtime when precipitation is usually the most intense and erosion rates are highest (Minshall and Jamison, 1965; Ghidley and Alberts, 1998). Claypan soils have enhanced runoff during winter and spring periods due to very low infiltration rates.

In situ lateral K_{sat} has been estimated for claypan soils in monoliths 0.25-m wide by 0.50-m long by 0.23-m deep (Blanco-Canqui et al., 2002). Field measurements of lateral K_{sat} provided a value of 72 mm h^{-1} . This value corresponds well to soil core (76-mm diameter by 76-mm

length) estimates of 71 mm h^{-1} through the silt loam surface horizon (Figure 1). The field estimate of K_{sat} for the claypan was $0.9 \mu\text{m h}^{-1}$. The lowest K_{sat} of the profile measured with soil cores was $2 \mu\text{m h}^{-1}$, which occurred within the 0.50–0.75-m depth (Figure 1), just below the claypan (depth of maximum clay concentration; Blanco-Canqui et al., 2002). The physical nature of this layer was weakly developed, compact, with a firm structure.

A high probability of interflow occurs within these soils (Jamison et al., 1968; Wilkinson and Blevins, 1999). Information on in situ lateral K_{sat} through the horizons above the claypan is important for determining their ability to conduct water laterally and assessing runoff and erosion. Because of their hydrologic attributes, claypan soils have quite different effective K_{sat} values with depth from other Alfisols. Information on K_{sat} depth distribution is valuable in explaining claypan hydrology and for the characterization of variability in horizons of low and high permeability required for accurate flow studies (Blanco-Canqui et al., 2002).

Claypan and its Environmental Effects, Figure 1 Comparison of saturated hydraulic conductivity (K_{sat}) data for claypan soils (Blanco-Canqui et al., 2002). Error bars represent 95% confidence intervals of mean K_{sat} values ($n = 9$). Data obtained with bentonite (Blanco-Bentonite) to plug visible pores represent K_{sat} data for claypan soils. (Reprinted with permission from the Soil Science Society of America.)

Claypan soils under native vegetation have significantly different hydraulic properties compared to soils under long-term grain crop management (Udawatta et al., 2008). Differences can be attributed to better structure as well as preserved pore networks. Soils under native vegetation have enhanced macropore flow, permanent roots, and higher organic matter content. Native permanent vegetation prevents water erosion, which increases the thickness of surface horizons; eroded soils have about 0.25 m thinner silt loam surface horizons than soils with native vegetation. Thicker surface horizons with coarser soil textures have higher hydraulic conductivity values. Under long-term grain crop management, soil hydraulic properties for claypan soils can significantly change due to a reduction in surface layer thickness above the clay layer through erosion as well as from the traffic by agricultural equipment. Improvements in these properties have been observed when using permanent vegetative buffers such as cool season grass buffers and agroforestry tree buffers (Seobi et al., 2005). Although the claypan horizon dominates the surface hydrology for these soils, buffers often provide benefits by slightly reducing runoff from soils under row crop management.

Conservation Reserve Program (CRP) and hay management systems increased field-measured infiltration rates in a summit landscape position compared to grain crop systems (Jung et al., 2007). Hydraulic conductivity measured in a backslope position for CRP and hay cropping systems was 16 and 10 times higher, respectively, than for a mulch-tilled grain cropping system (Jiang et al., 2007a). This was attributed in part to perennial grasses improving aggregate stability and soil organic carbon. Backslope landscape positions are more vulnerable to soil degradation with grain cropping systems compared to other landscape positions.

Soil erosion and agrichemical runoff

Due to enhanced runoff on claypan soils, soil erosion and sediment transport can be a concern. Minimum tillage as well as no-till systems are recommended to reduce this problem. Some studies have shown that no-till management can slightly enhance runoff on claypan soils relative to conventional tillage systems (Ghidley and Alberts, 1998; Ghidley et al., 2005); however, other studies have shown no differences in runoff among tillage systems (Lerch et al., 2008). No-till systems with corn (*Zea mays*) and soybean (*Glycine max*) cropping systems have significantly reduced sediment transport. Most annual soil loss (80% of annual loss) occurs during the rough fallow and seedbed preparation periods, with soil loss under no-till management five to seven times lower compared to other tillage systems (Ghidley and Alberts, 1998).

Vegetative filter strips have been used on claypan soils to mitigate surface runoff, sediment, and nutrient losses (Blanco-Canqui et al., 2004). Narrow, 1-m-long native switchgrass (*Panicum virgatum*) barriers in combination with 8-m-long fescue (*Festuca arundinacea*) filter strips

significantly reduced sediment transport as well as organic N, nitrate, ammonium, particulate P, and phosphate runoff compared to traditional fescue filter strips.

These vegetative filter systems have also been shown to reduce dissolved and sediment-bound herbicide losses in runoff (Lerch et al., 2008). Studies evaluated the transport of glyphosate [*N*-(phosphonomethyl)glycine], atrazine [6-chloro-*N*²-ethyl-*N*⁴-isopropyl-1,3,5-triazine-2,4-diamine], and metolachlor [2-chloro-*N*-(6-ethyl-*o*-tolyl)-*N*-(1*R,S*)-2-methoxy-1-methylethyl]acetamide]. Four meters of native vegetation buffers (mostly eastern gamagrass [*Tripsacum dactyloides*] and switchgrass) reduced herbicides about 75–80% in runoff. Four meters of native species resulted in greater reductions in herbicide transport compared to 8 m of fescue. Buffers enhance plant transpiration which enhances infiltration to reduce surface runoff in these high runoff potential claypan soils. As a general pattern, herbicide concentration or mass loss was greatest for the first runoff event and decreased rapidly as the season progressed.

Contour buffer strips have been demonstrated to reduce runoff, sediment, and nutrient losses in cropped watersheds (Udwatta et al., 2002). Paired watersheds were used to make an assessment of the degree of benefit from these contour buffers. Agroforestry buffers (trees and grasses) and contour grass buffers were found to reduce runoff (1% and 10%), sediment (0% and 19%), total phosphorus (17% and 8%), and nitrate (37% and 24%) losses. Most runoff reductions occurred during the second and third years after treatment establishment.

Management of runoff and associated effects on surface sediment, nutrient, and herbicide transport is an important challenge when using claypan soils for grain crop production. No-till management has been shown to enhance herbicide runoff relative to conventional tillage systems due to lack of herbicide incorporation and slightly increased runoff with no-till systems (Ghidey et al., 2005).

Agrichemical leaching

The claypan soils of the Midwestern USA contain silt loam surface textures and silty clay subsoils (Blanco-Canqui et al., 2002). The subsoil contains a high proportion of montmorillonitic clay, which results in a relatively impermeable soil horizon when wet. Since the claypan is highly impermeable, the assumption is often made that water and solutes cannot move through the claypan to reach groundwater. However, cracks often occur in these soils when they are cropped and their water content is low (Baer and Anderson, 1997). These cracks can allow preferential flow of water and chemicals. In addition, soils have natural features such as interpedal planar voids and biologically induced, highly conductive macropores, which may act as channels for water and chemical transport. In one study, claypans were hypothesized to restrict the movement of agrichemicals to groundwater; however, N fertilizer moved rapidly through preferential flow paths in the soil into the underlying glacial till aquifer (Blevins

et al., 1996; Wilkinson and Blevins, 1999). About one third of the N fertilizer migrated to the groundwater, while another one third was lost due to denitrification which can be a challenge for these soils since they have high soil water content in the spring.

Although enhanced annual runoff occurs from claypan soils, vertical transport can occur after periods of infrequent precipitation. Kazemi et al. (2008) found enhanced herbicide leaching in soils which had antecedent water content near the permanent wilting point (dry treatment). Atrazine, alachlor [2-chloro-2',6'-diethyl-*N*-methoxymethylacetanilide], and the bromide tracer were detected significantly deeper (0.15–0.30 m) when applied to a dry treatment compared to the wet treatment (water content near field capacity). Herbicide retardation coefficients estimated using soil properties were substantially higher compared to estimates from herbicide and bromide profile concentrations, suggesting evidence of nonequilibrium adsorption of atrazine and alachlor probably due to less surface area available for adsorption when transport occurs in shrinkage cracks. Preferential flow of atrazine and alachlor herbicides was found when applications occurred on initially dry claypan soils. The deeper movement of herbicides in initially dry plots was attributed to the presence of shrinkage cracks resulting from low soil water content.

Herbicide degradation has been found to decrease with dry soil water conditions (Kazemi et al., 2008). Degradation was found to be lower for initially dry conditions compared to initially wet conditions. This was attributed to better microbial growth in soils under initially moist conditions. Thus, dry claypan soils enhance preferential transport of herbicides and also decrease their rate of degradation.

Plant productivity

Variable claypan properties across the landscape affect grain yield due to soil property effects on root growth (Myers et al., 2007). Soybean roots were inhibited in E horizons above the claypan; however, roots were stimulated 20–40 cm below the initial claypan depth. Depth to claypan can be used to predict soybean root distributions in claypan landscapes. The depth to the claypan can be rapidly assessed using the apparent bulk electrical conductivity measured using electromagnetic induction (Kitchen et al., 1999). The topsoil thickness above the claypan layer is highly related to the plant available water capacity (Jiang et al., 2007b) and the crop yield (Kitchen et al., 1999). Apparent bulk electrical conductivity from these sensors can be correlated with crop yield due to the effect of the depth to the high charge claypan layer affecting the sensor signal (Kitchen et al., 1999).

Summary

Crop productivity is highly sensitive to topsoil thickness in claypan soils. Prevention of soil erosion is critical in maintaining grain production as well as enhancing water

infiltration in these soils. Conservation best management practices (BMPs) are important to reduce and prevent soil erosion. In some cases, selection of a BMP for one desired outcome may be opposite to another desired outcome (e.g., no-till may be good for erosion control but can increase herbicide loss). When this is the case, priorities will need to be established in order to select the appropriate BMP (Lerch et al., 2008).

CLIMATE CHANGE: ENVIRONMENTAL EFFECTS

Miroslav Kutílek
 Prague, Czech Republic

Synonyms

Global warming

Definition

Climate is defined as the statistical evaluation of meteorological data. They are air temperature, humidity, rainfall, wind, and eventually other observed elements in a given region over a long time period; the World Meteorological Organisation recommends 30 years, but longer periods may be used depending upon the purpose. The obtained results are applied in climate classification; the oldest and well known is the Köppen classification. Several other classifications are used, too, again according to the purpose. Climate should not be confused with weather, which is the set of meteorological data valid at time of observation, usually on scale of days.

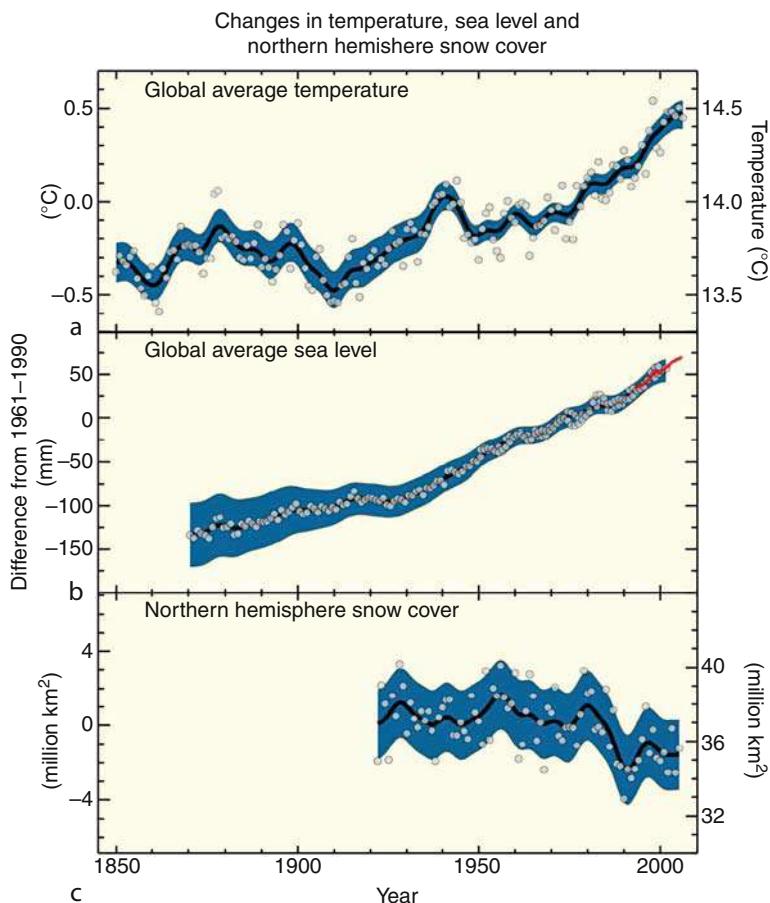

Recent climate change

Introduction

The recent climate change started about 1850. Actually the estimation of the year is a matter of general agreement and it is not strictly equal to local or regional observations.

The climate change is usually characterized by the global temperature in recent studies; other climate characteristics are only sometimes mentioned, too. The temperature increase in the twentieth century was estimated as 0.74°C and the rate of its rise is increasing. Eleven of the last 12 years (1995–2006) rank among the 12 warmest years in the instrumental record of global surface temperature (since 1850). The warmest years in the instrumental record of global surface temperatures are 1998 and 2005 (Trenberth et al., 2007), with 1998 frequently considered as the first one in the rank. Measured temperature of the global ocean has increased to depths of at least 3,000 m in the last 40 years. The energy balance shows that the ocean absorbs more than 80% of the heat added to the climate system. The global warming caused the rate of rise of seawater level by $1.8 \pm 0.3 \text{ mm/year}$ in the second half of the twentieth century (White et al., 2005) (Figure 1).

The reported rise of the global temperature by 0.74°C does not mean that the temperature rose uniformly over the Earth. This same value would not have been obtained

Climate Change: Environmental Effects, Figure 1 Change of the surface global average temperature for the time period 1850–2007 (top); change of the global seawater level elevation (center); change of the northern hemisphere snow covered area in March–April (bottom). Smoothed curves represent decadal averaged values, while circles show yearly values. (According to Fig. SPM-3, IPCC, 2007; Summary for Policymakers.)

everywhere that the temperature was measured locally during the past 100 years. The observed warming has been greater over land than that over the oceans, owing to the smaller thermal capacity of the land. Since the continents occupy larger area on the northern hemisphere, there was a tendency for a higher temperature rise in the northern than in the southern hemisphere (Trenberth et al., 2007). Values of average temperature rise also differ according to differences in climate of various regions. The rise is very small in the equatorial regions and increases with the latitudes, both north and south. The latitude dependence is only one of the many factors that play a role and the local average temperature rise depends upon its particular geographical position on a continent. Values differ for inland climates compared with lands close to the ocean. In Central Europe, the average temperature increased between 1.1°C and 1.3°C in 100 years (Czech Meteorological Institution, 2007), while in Northern Ireland at Armagh Observatory the increase was only 1.2°C in 200 years, that is, from 1796 to 2002. Within the Arctic Circle at latitudes between 70° and 90°, the average temperature rise was 2.1°C in the period 1880–2004 (Trenberth et al., 2007, Figure 3.7). During the first 60 years of that 124-year period, the average temperature increased, then decreased for the next 20 years, and again increased for the following 44 years. In that 124-year period, the average temperature rises were there higher in the period 1920–1940 than they are today.

Warming is strongest over the continental interiors of Asia and northwestern North America and over some mid-latitude ocean regions of the southern hemisphere as well as southeastern Brazil. In the recent period, some regions have warmed substantially while a few have cooled slightly on an annual basis. (Trenberth et al., 2007, p. 250)

These few examples enable us to imagine how difficult it is to estimate the global temperature and its rise merely from the data obtained from any number or all meteorological stations. “No single location follows the global average, and the only way to monitor the globe with any confidence is to include observations from as many diverse places as possible (Trenberth et al., 2007, p. 250).” The estimation of the global temperature from the surface meteorological stations was therefore a difficult task. During the last 28 years, the instrumentation in satellites was applied to measure the Earth’s global surface temperature. These methods of measurement are considered by meteorologists to be the most objective proof of global warming. It was just by these methods that the temperature was found as no more rising in the last decade (Solomon et al., 2007; Easterling and Wehner, 2009).

Measuring methods

In 1653, organized measurements of air temperature began in northern Italy with the first meteorological network initiated in Tuscany, however, without standardized thermometers. In 1714, the mercury thermometer was

provided with a reliable, physically based scale named after its German inventor Gabriel Daniel Fahrenheit (1686–1736). In 1742, another scale established by the Swedish astronomer and physicist Anders Celsius (1701–1744) was proposed and gradually accepted as the standard in meteorology. Then the international meteorological network could start and first networks were realized in the second half of the eighteenth century. Even now with the dense internationally interconnected observation nets, the estimation of the global temperature requires application of sophisticated statistical methods and the results obtained by various institutions and authors may differ. Starting in 1978, the use of satellites to measure the temperature in the troposphere simplified the assessment of the global temperature. The measurements are not performed by classical thermometers. Values of temperature, derived from an analysis of the wavelengths of radiation data, are evaluated and checked by two independent procedures. The most frequently, but not universally used procedures are the remote sensing system, RSS, and that developed by the University of Alabama, Huntsville, UAH. The UAH procedure indicates a slightly smaller global warming than RSS. Because directly measured temperatures during the last 2 and eventually 3 centuries cover very short period, other methods must be used when we study ancient climates. The temperature is ascertained from other measured data, and since temperature is indirectly and approximately estimated, we use the word *proxy* from the Latin *propis, proprius, proximus* – near, nearer, nearest, or very similar. Following proxies are applied: (1) The analysis of concentration changes of isotopes of oxygen and hydrogen in glacier deep core drilling provides estimates of temperature. (2) The concentration change of the isotope beryllium 10 (^{10}Be) in either sediments or ice indicates temperature as well as solar activity. (3) Pollen analysis (palynology) offers information on the dominant plants, which infer past climatic conditions. (4) Tree-ring width and density records (dendrochronology) estimate temperature change and age. (5) Isotopic ratios and chemical composition of corals estimate surface sea temperature. (6) Change found in annual lake sediments called varves provides information on temperature and age. (7) Change in growth of stalagmites in karst caverns and isotopic ratios indicate climatic change. (8) The size of lichens offers information on age and climate. (9) The pedogenesis of fossil and buried soils reflects the climate at the time of their origin.

Factors influencing climate change

Climate change is caused by the action of several factors, which may mutually influence each other. Their forcing varies with geologic time, too, and generally their variability is one of the greatest problems in modeling their role upon the climate change. Another important problem in estimation of the influence of the factors upon the studied meteorological element – the temperature – is the nonlinearity of the relationships.

Astronomic factors: Milankovich cycles

The change of the solar radiation reaching the planet Earth is due to the regular periodic repetition of the change of the Earth's orbital geometry. There are three orbital parameters that change in cycles named Milankovich cycles (Milankovitch, 1920, 1941):

1. The eccentricity of the Earth's orbit around the Sun changes from nearly circular (eccentricity of 0.005) to elliptical (eccentricity 0.058). One complete cycle lasts almost exactly 100,000 years. The combined gravitational field of Jupiter and Saturn is the primary cause of eccentricity change. Earth's orbital eccentricity is now close to its minimal value indicative of a nearly circular path.
2. Axial tilt (obliquity) is the inclination of the Earth's axis in relation to its plane of orbit around the Sun. Oscillations of Earth's axial tilt ranging from 21.5° to 24.5° occurs during a periodicity of 41,000 years. At present, the axial tilt is roughly in the middle of its range.
3. Precession is the Earth's slow wobble as it spins on its axis. It has a periodicity of 21,000 years, while some authors assume it to be closer to 23,000 years. It is primarily caused by the gravitational forces of the Sun and the moon with Saturn and Jupiter also secondarily involved. These cycles and variations of incoming solar radiation are important because the Earth has an asymmetric distribution of continents. They are mainly located in the northern hemisphere. When northern hemisphere summers are coolest since they are farthest from the Sun (aphelion position) due to precession and greater orbital eccentricity and when winters are relatively mild with minimum tilt, snow does not melt in summer and accumulates. In thousands of years, it is transformed into ice and glaciation occurs. A high albedo (reflection of solar radiation) of snow and ice contributes to the cooling during glacial period.

Astronomic factors: solar activity

Solar activity is not constant; it manifests cycles of various lengths and fluctuates periodically around a value of $1,365 \text{ W/m}^2$ (Eichler et al., 2009). Solar activity is accompanied by the existence of the sunspots. When sunspots are abundant during the cycle, it is called the solar maximum and when there are only a few sunspots, it is considered to be the solar minimum. Solar activity is more or less correlated to climatic oscillations with higher solar activity being accompanied by globally warm climate (Lane et al., 1994). The high solar activity and a strong solar wind including the rise of the Sun's magnetic field cause a weakening of the galactic cosmic ray flux – commonly referred to as the shadowing of cosmic rays. The stronger the galactic cosmic ray flux, the greater is the ionized part of the atmosphere having a greater density of nuclei on which water vapor will condense, forming clouds primarily in the lower part of the troposphere (Svensmark, 1998; Marsh and Svensmark, 2000). The clouds reduce the solar

radiation penetrating to the Earth surface and thus cause a relative cooling of the Earth. A 2% decrease in low cloud cover during the solar activity cycle is equivalent to the Earth accepting radiation increased by 1.2 W m^{-2} (Svensmark, 2007). The solar activity had a peak in the time interval 1985–1987 and now it is slightly decreasing, but it is still high above the average of the last 150 years.

Continental drift

Continental drift is a shift of plate carrying the continents and bottom of oceans as a result of plate tectonics. The plates slide very slowly with a speed of 1 to about 15 cm/year on the asthenosphere that is visco-elastic solid. They are associated with geological events such as earthquake, volcanoes, uplift of mountains, mid-ocean rift, and oceanic trench. Where the oceanic plates are moving away from each other, the magma from the asthenosphere fills in the gap and a new oceanic crust is formed (the sea-floor spreading). When two continental plates collide, mountain ranges are created as the colliding crust is compressed and pushed upward. Such collisions may be accompanied with the rise of magma to form volcanoes. Due to the collisions, new supercontinents were formed several times in the geologic history (Rodinia, Pangea, Gondwana). When a thin oceanic plate collides with a thick continental plate and is forced under the continental plate, this process is called subduction. It is responsible for transporting mainly sedimentary rocks rich in CaCO_3 . Hence, great amounts of carbon are conserved below the lithosphere. This gigantic dynamic process influences the entire topography and climate of the “floating” continents. At the same time, continents are shifted from the polar to the equatorial regions and vice versa. An additional consequence of this relocation and of the disruption and fusion of continents is the change of the sea streams and of the direction and strength of blowing winds. All these continually contributed to substantial climate changes during the geologic history of the Earth. Continental drift was discovered by Alfred Wegener (1912, 1920), who related it to climate changes, too.

Greenhouse gases

Radiation from the sun is the source of energy that warms planet Earth. The solar radiation has a value of about $1,366 \text{ watts per square meter (W/m}^2)$ on the outer surface of the Earth's atmosphere (solar constant). It oscillates by about 6.9%, owing to Earth's elliptical path around the Sun. Because the Earth rotates daily, only one-half of our planet receives solar radiation at any one moment. And, taking into account the varying angles at which the radiation is received by the spherical surface of the planet, the average incoming solar irradiance on the Earth's surface is about 342 W/m^2 – approximately four times less than the value of the solar constant. The seasonal and latitudinal distribution and intensity of solar radiation received at the Earth's surface varies substantially. For example, at latitudes of 65° the change in solar energy between summer and

winter can vary by more than 25%. The ratio of incoming and reflected electromagnetic radiation is called albedo. The range of possible values is from 0 (complete absorption and no radiation reflected) to 1 (no absorption at all, the entire incoming radiation is reflected without change). The average albedo is 0.37; therefore, 63% of incoming solar energy contributes not only to the warmth of our planet but also is used in many processes as, for example, the production of green matter, in climatologic processes, etc. The heated surface emanates long-wave infrared radiation (IR). The Earth's atmospheric envelope contains gases that absorb IR from the heated Earth's surface. They are called greenhouse gases. Water vapor, methane (CH_4), carbon dioxide (CO_2), nitrous oxide (N_2O) and ozone (O_3) are the primary greenhouse gases. Without the atmosphere and greenhouse effect, the Earth temperature would be -18°C . Some man-made gases belong to greenhouse gases, too, like fire fighting materials, aerosol spray propellants or solvents, some of the other greenhouse gases are human made, like chlorofluorocarbons (CFC) known under the trade name freon, hydrofluorocarbons (HFC), hydrochlorofluorocarbons (HCFC), sulfur hexafluoride (SF_6), but their use is restricted or they are prohibited due to their very strong greenhouse effect. Earth temperature due to the greenhouse effect is mainly caused by water vapor in the atmosphere; it is 80–90% of the total greenhouse effect. It means that without water vapor the Earth would be cooler by about $29\text{--}30^\circ\text{C}$. The cooling effect of clouds is roughly equivalent to 30 W/m^2 , while the greenhouse effect of CO_2 is about 1.5 W/m^2 , contributing to warming. The concentration of CO_2 in the atmosphere has been fluctuating in ranges from 180 to 300 ppm (parts per million) during the last 2 million years. Only in the industrial era during the last 150 years has there been an increase from 280 ppm to today's CO_2 concentration of about 387 ppm. The authors of Assessments of the Intergovernmental Panel on Climate Change (IPCC) assume that this increase of atmospheric CO_2 concentration is mainly responsible for the recent global warming. Considering Earth's climate system as a balance between incoming short-wave (solar) radiation and outgoing long-wave (thermal infrared) radiation and the increasing greenhouse effect, they made the prognosis on the temperature rise by $3 \pm 1.5^\circ\text{C}$ as the range of uncertainties provided that the CO_2 is doubled to 560 ppm. However, Schwartz (2007) used a detailed balance model to estimate climate sensitivity and obtained the increase of temperature by $1.1 \pm 0.3^\circ\text{C}$ for 560 ppm CO_2 concentration. In addition, he derived a much shorter time constant characterizing the climate response to the atmospheric change of CO_2 when compared to some predictions on the extension of global warming by decades or centuries after CO_2 concentration is lowered. Predictive procedures are not fully acceptable with the simplified assumptions on the sole or dominant greenhouse effect as acting agent in the climate change and if the feedbacks are not fully appreciated in the models.

Thermohaline circulation

Oceanic waters are great regulators of Earth temperature. The heat capacity of water is 4.18 J/g-K , of air it is 1 J/g-K , and of soil and rocks around 0.8 J/g-K . The heat uptake of the world ocean constitutes 84% of the total heat uptake by the climate system. Other major components are heating of continental landmasses, 5%; melting of continental glaciers, 5%, and heating of the atmosphere, 4% (Levitus et al., 2005). When ocean waters flow, they transport huge amounts of energy from the equatorial to the polar regions. With this, transport of energy influencing not only the weather but also the climate, oceanic streams are one of the important factors influencing the climate. There are two main causes of oceanic streams – temperature gradients and differences in seawater density. Due to the temperature gradient, the water flows from the equator to cool poles, as a stream at the ocean surface with the depth about 8001,200 m, and the width of the current is 80–150 km. The discharge is between 20 and 150 Sv (Sverdrups, $1 \text{ Sv} = 10^6 \text{ m}^3/\text{s}$). Just for comparing, the Amazon River has an annual average discharge of 0.2 Sv. When the salt waters of the ocean stream reach the cool regions of high latitudes, they cool also and mix with fresh water of melting ice. Their density increases and the oceanic surface water flows downward. The surface stream changes to the deep ocean stream and flows in opposite direction to the equator. Due to the Earth rotation, the ocean streams direction is deviated by the Coriolis force from the straight path (normal to equator) and the surface and deep streams have not identical paths. For the inhabitants of the northern hemisphere, the Gulf Stream is the best-known ocean current. It is a connected part of all other ocean streams. The whole Earth is encircled by them and since the main cause of their existence is the differences in temperature and in salt content, the term thermohaline circulation is used. Its existence depends upon the configuration of continents. Generally speaking, the form of one supercontinent is less favorable for the thermohaline circulation and the more continents mutually separated exist the better conditions for circulation. It was an important factor of climate change in the geologic past due to the continental drift.

Aerosols volcanoes, asteroids

The term aerosol denotes generally a suspension of fine solid particles or small liquid droplets in a gas. Although their dimensions range from 0.01 to $10 \mu\text{m}$, their maximum occurrence is from 0.6 to $1 \mu\text{m}$. Particles greater than $0.2 \mu\text{m}$ can be detected with an ordinary optical microscope. Particles with diameters less than $0.05 \mu\text{m}$ disappear quickly because they are caught by other particles and lost by aggregation. Particles greater than $15 \mu\text{m}$ are relatively quickly deposited by gravitation. Particles between 0.1 and $2 \mu\text{m}$ remain suspended from 1 to 2 weeks or even more, depending on the winds, keeping them in the atmosphere. Although aerosols can be transported for thousands of kilometers, occurrences of their global

transport is extraordinary, for example, by eruption of large volcanoes. Water vapor condenses on the surface solid particles, which are called condensation nuclei and clouds are formed. The majority of solid aerosol particles occur naturally, originating from volcanoes, dust storms, forest fires, living vegetation, and sea, where water evaporates from droplets leaving salt particles suspended in the air. Human activities, such as burning of fossil fuels and alteration of natural vegetation, also generate aerosols but it accounts for only about 10% of all solid particles. Aerosol particles act mainly as an obstacle to the solar irradiation of the Earth. Their reflection of solar radiation depends primarily upon their size distribution. Incoming solar radiation with the maximum energy at wavelengths between 0.4 and 1 mm is reflected to the outer space by particles in the size range of 0.1–2 μm . The effect is increased if the solid particles are covered with a liquid water film. Since the Earth surface is deprived of its source of heating in this way, an increase of aerosol concentration causes cooling of the Earth, and the opposite, its decrease leads to relative warming. Aerosols greenhouse effect exists, too, but it has low importance in the heat balance. When we deal with the influence of aerosols upon the climate, we purposely measure the concentration (number of aerosol particles) and not the mass (weight) of particles in a volumetric unit of air. The radiometric measurement of solar radiation transmission through an aerosol layer is expressed as the aerosol optical thickness AOT. These types of data have only been available during the last 30 years. The quantitative evaluation of the aerosol influence on the energy balance of the Earth is one of the most difficult parts of climate modeling. For example, models and direct measurements indicate that the cooling effect caused by aerosol scattering could be two times larger than that modeled by IPCC – on the order of 1.5 W/m^2 . Generally, the aerosol effect belongs to the worst quantified parts of models. Regionally, it could even be much larger than the warming effects of greenhouse gases. An intensive increase of aerosol concentration occurred several times in the geological past of the Earth after the impact of an asteroid. The abrupt climate change led to the partial extinction of living organisms. The impact of volcanic eruptions had year's duration because the emitted ashes spread over the entire Earth in an atmospheric aerosol envelope layer. There are many examples on it in Holocene.

Vegetation cover

The incoming solar radiation is absorbed and partially reflected in different ways as the vegetation changes naturally or due to human action. Examples of albedo of various kinds of soil cover are shown in [Table 1](#). They indicate that the entire radiation balance is changing when the vegetation is changed. The most drastic change in the radiation balance occurs when the original forest is lumbered and the soil surface is left without vegetation. In addition to the heating effect due to radiation balance, there is a loss of soil water due to the evaporation. Since there is

Climate Change: Environmental Effects, Table 1 Albedo

Conifer forest	0.08–0.15
Deciduous forest	0.15–0.19
Bare soil	0.17
Grass	0.25
Sand of desert	0.40
Ice	0.6–0.7
Snow	0.8–0.9

a difference between simple evaporation and evapotranspiration from the soil covered by vegetation, the cooling effect differs, too. Deforestation causes changes in the carbon cycle. A forest together with the soil stores more carbon in organic compounds for a much longer time than does an arable soil cultivated for annual crop production. Deforestation results in an abrupt and rapid release of CO_2 from the soil into the atmosphere. Large forested areas differ in clouds regime from the agricultural soil. All these indirectly acting factors contribute to the change of the climate after deforestation of large regions.

Earth's magnetic field

Earth's magnetic field is generated by the so-called geodynamo. The iron in its outer core is a conductor and the geomagnetic field induces electric current in the slowly flowing material surrounding the solid inner core. The Earth rotation plays an important role in it. The feedback process is the generation of a magnetic field by the electrical current and convective flow. The reversal of magnetic poles occurred several times in the geologic history and it has a high probability when the field is very weak. Recent average values in Holocene remain high compared to earlier values. Its last reversal was some 780,000 years ago. Moreover, the magnetic pole position is also not constant – it moves up to 15 km/year. The geomagnetic intensity, measured in Tesla, varies from slightly less than 30,000 nanotesla (nT) to about 60,000 nT at the Earth's surface. Another unit of geomagnetic intensity is 1 Gauss equivalent to 100,000 nT. As the Earth's magnetic field changes, instabilities in the ozone layer occur in both vertical and horizontal directions. They lead to modified temperature gradients and atmospheric circulation. These changes influence the solar wind in the atmosphere and modulate cosmic ray particles. When the geomagnetic field changes its shape and intensity, distinct changes of the climate are expected ([Knudsen and Riisager, 2009](#)). The general increase in precipitation observed over the past 1,500 years correlates with the rapid decrease in dipole moment observed during this period.

Climate change in geologic history

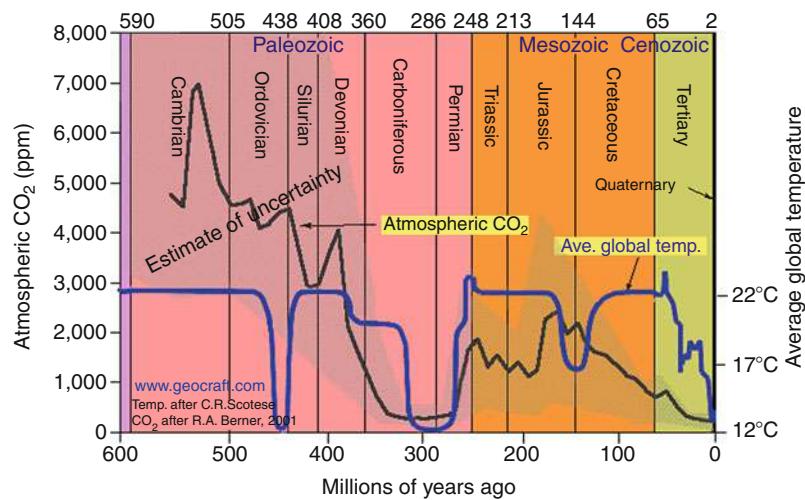

All imaginable forms of climate existed in the past: there were several glacial periods even with Earth existing as a huge snowball, there were also humid tropical periods on all continents without a trace of ice even on the poles, and there were periods when the majority of continents

were occupied by deserts (Kutílek, 2008). In the Precambrian period strong glaciation occurred (Snowball Earth). The supercontinent existed at that time shifted to the southern polar region, the great albedo of snow and ice reduced the absorption of the solar radiation, and the thermohaline circulation was very weak, if even existing. Due to plate tectonic, breaking of the supercontinent, and volcanic activities, greenhouse gases escaped into the atmosphere at the end of Neoproterozoic Era and increased the temperature. Then the climate of the Cambrian Period (540–488 million years before present [Myr BP]) is typically mild without polar ice caps and without substantial climate differences between individual climatic zones. The environmental conditions were completely favorable for the Cambrian life explosion in seawaters. At the end of the Cambrian, the first extinction of life organisms in the Paleozoic Era occurred probably due to the depletion of oxygen by excessive number of various organisms and due to their decay in seawaters. With this extinction, the Ordovician Period (488–445 Myr BP) started. The climate of the Ordovician up to its middle epoch was mild and conditions for life development were favorable. The abrupt cooling in the middle of the period cannot be caused by the change of atmospheric CO₂ concentration since it was 10–15 times higher than that occurring today. One important cause of the glaciation was the shift of a new supercontinent Gondwana to the South Pole. Additive influence had a combination of some not yet well-defined terrestrial, atmospheric, and astronomic factors. The Silurian period (445–410 Myr BP) started as a relative stable greenhouse climate following the Ordovician glaciation. The sea level rising and flooding large, flat, continental coastal belts was a significant impulse for further life evolution and adaptation of life outside of the waters. Climate was diversified according to latitude positions. During the second part of the Silurian period distinct climate oscillations existed. At the Devonian period (410–362 Myr BP), Gondwana shifted from its southern position to the north and the formation of Euramerica, another supercontinent, was completed. With the shifting of great continents, oceanic streams changed their patterns, and the circulation of air modified by strong volcanic activity and plate tectonics changed the distribution of rainfall. Arid regions of rain shadows started to exist while other regions received extremely large amounts of precipitation. Cooling started during the second part of the Devonian, and it was not caused by CO₂ since its atmospheric concentration had risen to about 4,000 ppm. Main factors contributing to cooling were the changes of ocean streams and prevailing major winds. The Carboniferous period (362–299 Myr BP) started with a warming of climate. Collision and subduction of the continents on a great scale led to the gradual, yet strong decrease in atmospheric CO₂ concentration. The second factor playing an important role for CO₂ consumption was a rich abundance of plant life, described frequently as an explosion of terrestrial life. The eastern part of Gondwana began to drift toward the South Pole during

the second half of the period and the development of southern polar ice cap started with subsequent icing of the part of the continent. The very low level of atmospheric CO₂ concentration of the Late Carboniferous continued together with relatively high O₂ concentration during the early Permian (299–251 Myr BP). The climate was influenced by Carboniferous glaciation at the start. Warming gradually followed and glaciers receded. As the majority of land in the large supercontinent was away from the sea and in the rain shadow, its interior was hot and dry. Volcanic activity together with the release of greenhouse gases during large lava eruptions contributed to general warming. In the late Permian and during the transition to the Triassic, a massive extinction dominated (P-Tr extinction), and with about 95% of all-marine taxa and 70% of terrestrial vertebrate disappearing, it was the most severe extinction in the whole geologic history of the Earth. Several mechanisms are discussed in the literature. It probably proceeded in several steps starting with a gradual change of the environment as the sea level changed, increased aridity, and ended owing to catastrophic events of one or multiple impacts of bolides events accompanied by an increased volcanism and the release of methane hydrate from the ocean floor. The first period in the next Mesozoic Era was the Triassic (251–200 Myr BP). Following the catastrophic events of the Permian, a hot and dry climate dominated the majority of the supercontinent Pangea with no evidence of glaciation at or near poles. The Triassic period ended with extinction being restricted primarily to sea life caused by huge volcanic activity accompanying the breaking of Pangea. Bolide impact also contributed to climate change, but with a substantially smaller force than that compared to the Carboniferous, and all changes caused strong climate oscillations. In the Jurassic period (200–146 Myr BP), the breaking up of the supercontinent continued. Today's Greenland was separated and North America divided from Europe and Africa to open the new Atlantic Ocean. India started separating from Antarctica. Before the separation process became intensive, a warm humid climate dominated even in those zones where a mild climate would have been expected, and strong ocean streams contributed to the distribution of warmth far to the high latitudes. Even the poles had mild climates without ice caps. The consequence was the rise of atmospheric CO₂ content up to 2,000 ppm. The climate changed to form distinct climatic zones, some of them with regularly changing wet and dry seasons. All of these conditions are assumed to be the key moment in the evolution of big dinosaurs. The last period of the Mesozoic era was the Cretaceous (146–65.5 Myr). The favorite conditions for a warm and balanced climate continued from the preceding period. The atmospheric CO₂ concentration decreased substantially probably due to the continuing subduction and plants extension while the temperature first remained constant and then even increased. On the boundary with the next time period, the Tertiary, the asteroid impact caused a catastrophic event (the K/T event). The climate change

due to multiple effects ending with aerosols over the entire Earth led to the extinction of dinosaurs. The Paleogene period started with the Paleocene epoch (65.5–55.8 Myr). New fauna together with the evolution of mammals started to develop after the extinction of dinosaurs. The climate was first renewed as it was before the K/T event with only a slight cooling. Even the high latitude kept a mild climate favorable for subtropical vegetation. Later on, close to the transition to the Eocene, the temperature suddenly rose to form the Paleocene/Eocene Thermal Maximum (PETM) lasting for about 100,000 years. The global average temperature rose by 5–8°C within about 10,000 years. It was hypothetically due to the greenhouse effect when closed methane hydrate clusters below the ocean floor were released after the first temperature pulse. Volcanic activity could contribute to it, too. The Eocene epoch (55.8–33.9 Myr BP) was characterized by mild warm climate on all continents – tropical and subtropical vegetation reached up to high latitudes. The warm regime was probably the consequence of the Paleocene/Eocene Thermal Maximum and the very active function of ocean currents carrying warmth from the equator to the Polar Regions. Mammals started to be dominant among the fauna. CO₂ values were distinctly decreasing without causing a decrease of temperature. The bolide impact at the end (“Grande Coupure”) caused the climate change and a limited extinction of some flora and fauna. Oligocene (33.9–23.1 Myr BP) was the end of the Paleogene period (Figure 2). The increased plate dynamics characterized by collision of India with Asia, the separation of Australia from Antarctica, and the increased volcanic activity changed the ocean currents, intensity of monsoons, and resulted in the climate cooling with the initiation of

Antarctic glaciation. The consequence of this climate was that the grassland occupied large areas, and that tropical forests receded from the mild zones of Europe and North America and was restricted to the equatorial belt. At the end of Oligocene, a mild warming caused Antarctic thawing without the influence of CO₂ change. Slight increases of temperature continued into the start of Neogene’s first epoch, the Miocene (23.1–5.3). The increase was monotonic up to the Miocene Climate Optimum (MCO). The continents reached their greatest separation from each other during the entire history of the Earth. This maximum separation brought intensive ocean streaming from the equatorial region to the poles, transporting energy from the warmed belt to originally cool regions. In this geologically most recent warming event, the temperature raised by 3–5°C higher than today, but with atmospheric CO₂ only about half or eventually equal to its present value. The forest cover was large and extended far toward the Polar Regions. At about 14 Myr BP, a strong change of the climate occurred – an initial rapid cooling started a long-time lasting cool climate with significant temperature oscillations. The cool climate brought fluctuating glacial conditions and the beginning of large, continuous continental ice sheets. The global albedo increased, allowing ice sheets to exist at higher CO₂ atmospheric concentrations than that required for glaciation. The start of the event was caused by complex relationships between orbital forcing, carbon burial in ocean and sediments, a major reorganization of ocean circulation patterns and the change in sun activity. The global cooling resulted in the increased aridity. One of the consequences of the decrease of atmospheric CO₂ concentration and of the aridity was the expansion of C4 plants and grassland

Climate Change: Environmental Effects, Figure 2 Throughout the past 600 million years, almost one-seventh of the age of the Earth, the mode of global surface temperatures was ~22°C, even when carbon dioxide concentration peaked at 7,000 ppmv, almost 20 times today's near-record low concentration. If so, then the instability inherent in the IPCC's high-end values for the principal temperature feedbacks has not occurred in reality, implying that the high-end estimates, and by implication, the central estimates, for the magnitude of individual temperature feedbacks may be substantial exaggerations. (Temperature reconstruction by C. R. Scotese; CO₂ reconstruction after R. A. Berner; see also IPCC, 2007; according to Monckton, 2008.)

ecosystems became gradually more important. The next epoch, the Pliocene (5.3–1.8 Myr BP), is the second and last one during Neogene period. The climate became cooler and drier with great zonal differences. Antarctica started to be covered with ice sheet and Arctic icing appeared as a constant ice cap from the mid-Pliocene. The cooling was caused primarily by continental drift. For example, the formation of the narrow strip of Panama completely changed the system of ocean currents in both the Atlantic and Pacific Oceans. The next Pleistocene epoch (1.8–0.0115 Myr BP) is characterized by the existence of long-lasting (about 100,000 years) glacials and short (12,000 years) interglacials. The principle change of climate in the Pleistocene was predominantly caused by Milankovitch cycles, while the relatively short-term warm episodes during glacials were influenced by other factors such as solar activity, thermohaline circulation, aerosols, and volcanoes, with possible role of the change of the Earth's magnetic field. The concentration of atmospheric CO₂ was changing as the consequence of glacials and interglacials. It rose by 80–100 ppm with the total value not exceeding 300 ppm. The change had a time delay up to 600 ± 300 years during the last four interglacials. A similar delay was in the decrease of CO₂ concentration after the start of the glacials. The maximum average temperature lasting for 1,000 years in the last four interglacials was by 2–4°C higher than the recent average. If the whole Pleistocene is characterized by large and intensive glaciations interrupted only by short interglacials, we have to assume that our recent epoch Holocene starting 11,500 years ago is also an interglacial. The warming of the last glacial started already about 16,000 BP but it was twice interrupted by Older and Younger Dryas. The rate of each next warming was roughly the same as the recent one. The retreat of glaciers was slow up to 9 kyr BP, then increasing for 3,000 years. Their melting caused the sea-water level to rise with the average rate about 1.2 m/100 years. It was seven times faster than the recent seawater level rise. During the Würm glaciation (115–11.5 kyr BP), the Sahara desert was larger than it is today and its southern boundary reached several hundred kilometers further south than at the early Holocene (Roberts, 2004). From about 10 kyr BP up to 6 or 5.5 kyr BP, it was basically transformed into a savanna since the whole region was under the influence of the pluvial with frequent and abundant strong rains. The time period between 9,000–5,500 years BP, denoted as the Global Thermal Optimum, is explained by the special position of the Earth axis in the Milankovitch cycle precession, causing a shift of the Intertropical Zone of Convergence (ITZC). The accompanying growth of vegetation changed the albedo resulting in general warming with increased humidity. ITZC moved several times to the north and back and brought differences in rains to the region known as climatic oscillations. A similar situation developed in Mesopotamia and in the Indian subcontinent. The climate in Holocene was never monotoneous. The first short but very intensive cooling arrived at 8,200 BP and lasted only about 400 years. The

main cause was the abrupt drainage of the North American large sea Agassiz, which originated due to melting of the continental glacier. The freshwater drained into the Atlantic Ocean and interrupted the thermohaline circulation. The proxies in Europe indicate a thermal maximum about 6 kyr BP with the temperature by roughly 2°C higher than we have now. Just after the Holocene Thermal Optimum, a global cooling occurred at about 5.5 kyr BP. The vegetation zones shifted to the south of Europe and their composition gradually changed. Global cooling was revealed by a rapid aridization and extension of vast deserts of the Sahara, Arabia, India, and Pakistan. Another strong climate change (about 4.3 to 4.2 kyr BP) accompanied by the reduction of precipitation and by aridity caused strong social and political crises, leading even to the decline of some civilization and cultural centers. Two further rapid climate changes occurred in the BC time period (Mayewski et al., 2004). The Roman Warm Period was detected in the time range between 200 BC and AD 300, where the end is locally shifted in some regions to about AD 100. After that, the Dark Ages Period had the minimum temperature around AD 600. Then the Medieval Warm Period started about AD 850, even though its start could be shifted to a later time in some regions. It lasted as a stable climate up to about AD 1200 with temperatures higher than the recent ones by 1–3°C. In some regions, it ended later about AD 1350. The stable climate of the Medieval Warm Period ended after AD 1350 and the era of unpredictable weather changes began. The first frosty attack came in the first third of the fifteenth century and between 1630 and 1730 the extreme frosty cycle of the Little Ice Period arrived. The main factor causing the oscillation named Little Ice Age was the solar minimum activity detected in three separated waves. The best known Maunder minimum is known, too, by minimal to zero number of sunspots (AD 1645–1715). The lowering of the thermal gradient was another acting factor causing the reduction of the thermohaline circulation. The negligibly small change of CO₂ concentration in the atmosphere, if any, could not have caused such Holocene climate oscillation.

Summarizing remarks

The atmospheric CO₂ concentration is only one of the many factors influencing climate change on the geologic time scale. In some instances it was the dominant agent of warming or cooling. However, there were other geologic periods when the climate changed, but CO₂ concentration remained either constant or the increase of temperature was accompanied by the decrease of CO₂ concentration. This conclusion is valid even for short time climate oscillations detected starting from the Miocene up to Pleistocene. In Holocene, the climate oscillations are typical with the existence of warm and cool periods even on the century scale in the second half of the epoch. The main factors of their occurrence are solar activity, thermohaline circulation, aerosol concentration, and volcanic activity with changes in vegetative cover being less

important. Changes of atmospheric CO₂ concentration were so small that their influence was negligible up to and including the Little Ice Age. Considering earlier interglacials and Holocene climate oscillations, the recent increase of CO₂ atmospheric concentration contributes only to the action of two factors, the solar activity and the change of vegetation cover. The quantification of the role of the acting factors and forces has not yet been estimated by testing the models on the oscillation events in Holocene. The prediction of global warming cannot be therefore based upon the results of models where the greenhouse effect plays a dominant role (IPCC Fourth Assessment, 2007). The environmental effect of the observed global warming can be deduced from the environmental change documented on proxies of the Medieval Warm Period (MWP). A lower intensity of recent warming compared to MWP has to be considered. The mountain glaciers are receding; the polar Arctic glacier shrinks, while the Antarctic glacier does not change substantially. The biota shows the tendency of shifting to the north in the northern hemisphere, but there are no notes of extinction of numerous taxa. Even the further warming will not cause global aridization, desertification, or extension of area of deserts and catastrophic events for the life on the planet (Kutílek, 2008 and the detailed literature quotations there). Quite opposite, the warming if it lasts enough long could bring stronger monsoon in Sahelian part of Africa (Zhang and Delworth, 2006). The increase of CO₂ concentration up to doubling the 1,850-year data does not have catastrophic consequences, the yields will have a rising tendency, and famine is not expected due to the climate change (Kirkham, 2007). On the other hand, the human disturbances may not produce a whole ecosystem breakdown as a single acting force. However, this type of weakening of the resistance of the whole ecosystem can have some not expected consequences, if another impact like global warming acts at the same time (Roberts, 2004).

CLOD

A compact, coherent mass of soil varying in size, usually produced by plowing, digging, etc., especially when these operations are performed on soils that are either too wet or too dry and usually formed by compression, or breaking off from a larger unit, as opposed to a building-up action as in aggregation

CLUSTERS IN SOILS

David L. Pinskiy

Institute of Physico-Chemical and Biological Problems in Soil Science, Laboratory of Physical-Chemistry of Soils, Moscow Region, Russia

Synonyms

Adsorptive cluster; Aggregation; Cluster structure; Fluctuating associations

Definition

Cluster is an association of a limited number of interacted uniform elements (atoms, molecules, ions, superdispersed particles), which generate a new property or a sum of properties.

Introduction

The term “cluster” is widely used in the modern science and technique, however, the precise time of its entry in the science is impossible to define, because it has an especially wide everyday use. Depending on the field of application it attaches different meanings. Kipnis (1981) considers that the term “cluster” for the first time appeared in the manuscript of G. E. Meyer on the statistical mechanics of nonideal gases in 1937. Booming development of studies on the cluster formation is timed to the second half of the twentieth century and is connected to the synthesis of artificial clusters widely applied in the industry. By

the 1980s, a new approach – cluster chemistry – arose as a cross-disciplinary science based on chemistry, physics, and material science. The processes of cluster formation in soils and agrosystems are practically unstudied. There are scarce publications, where the process of cluster formation is mentioned. Yet it is evident that in soils, these processes are important due to the presence of large number of components and heterogeneous phases interacted and permanent changes of the state under external factors.

Cluster formation is possible in different soil phases: solid, liquid, gaseous, and alive, and on the boundaries of their interfaces. Minimal number of cluster elements equals two (Cotton and Walton, 1993). Maximal number corresponds to a value when addition of the next one already does not change the properties of the cluster. Approximate estimates carried out by the chemists for molecular clusters are 10^3 elements (Kipnis, 1981).

Cluster groups form superstructure or supramolecular structures where clusters stand as individual elements.

Formation of cluster structure in soils

Apparently the first studies are that by Bleam and McBride (1985) and Bleam and Bridge (1986), where they describe cluster formation during adsorption of Cu(II) and Mn(II), Mn(II) and Mg(II) cations on titanium dioxides, boehmite, and goethite. The formation of adsorptive clusters $(H_3SiO)_3SiR$ ($R=OH, Cl$) is a simultaneous process at interactions of nucleophilic reagent on silica surface (Chuiko et al., 2007). Numerous studies indirectly confirm the formation of cluster structures at interactions of organic and mineral (mainly clay minerals) soil components. It was demonstrated that the distribution of organic material on mineral surfaces of soil particles has fragmentary (discrete) mode (Mayer and Xing, 2001; Kahle et al., 2002; Kurochkina and Pinskii, 2002; Kaiser and Guggenberger, 2003). Aluminum silicate sediments with low and moderate loadings of organic matter (<3 mg organic C m^{-2}) generally have less than 15% of their surface coated, with organic materials existing in discrete spots on the mineral surface (Arnanson and Keil, 2001). This indicates that the organic material must instead be clustered in small patches with some vertical extension (Kleber et al., 2007).

The formation of solid soil phases passes through the clustering step as well. In particular, it was shown that the formation of new phases from supersaturated water solutions of silica acids is accompanied by clustering of basic (starting, initial) elements (“fluctuating association”). Heterophase fluctuations of the material characterizing pre-transitional state of the system are also probable (Chuiko et al., 2007). On the whole, the formation of a new phase occurs within a common scheme: (1) nucleation, (2) clusterization, (3) formation of grain structure, and (4) formation of crystallites. Evidently, similar processes occur within the formation of other new phases in soil, including the formation of clay mineral during the weathering of *parent rocks*.

Application of new instrumental methods (EAXFS, HRAF) for studying of soils *in situ* made it possible to find out the phenomenon of surface precipitation with participation of heavy metal cations. One of the mechanisms of this phenomenon supposes a range of sequential stages distributed over the time: (1) adsorption, (2) nucleation, (3) precipitation, (4) nucleation, and (5) re-precipitation (Scheidegger et al., 1997; Borda and Sparks, 2007). Another mechanism of the formation of surface-precipitated structures may be connected with micro-heterogeneity of the pH in the vicinity of clay minerals or soil particles. In this case in the solution volume in the close vicinity to the protonated part of the surface, the increase of OH^- ion concentration takes place. It is resulted from H_2O dissociation and binding of H^+ during the surface protonation. The pH values within this part of solution become essentially higher compared to those of the whole solution volume. Therefore, in the close vicinity of the protonated surface the conditions for precipitation of hydroxides or metal carbonates arise, in contrast to the lack of such conditions in the whole volume (Pinsky and Kurochkina, 2006).

Cluster structures are formed in a result of partial hydration of the surface of non-hydrated sparingly soluble salts and minerals as well. The hydration process involves several steps: (1) adsorption and capillary condensation of water in the pore space, (2) dissolving of a part of sparingly soluble salt in the capillary moisture, (3) formation of hydrated structures in solution volume (through clustering of dissolved hydrated elements), and (4) formation of films of hydrated compounds on the surface of unhydrated salt (Kurochkina and Sokolov, 1997).

In general, the processes of cluster formation may be combined by terms of aggregation and disaggregation. In doing so, the mechanisms of their formation differ and are determined by the character of cluster elements, the formation conditions, and the environment. The processes of aggregation take place at the formation of cluster from single elements, distributed within the space or at the formation of larger clusters from the ones of less size. In soils, this group covers the compounds, which are formed in the soil air, during the solvation process and association of ions and molecules in soil solution, including clustering of the solvent – the water (Kipnis, 1981). The existence of such clusters does not result in the new phase formation. They exist in dynamic equilibrium with the environment and, hence, their composition is inconstant. An example of the formation of cluster structures due to disaggregation is generation of secondary minerals from the components of weathering of the parent rocks.

Life time, properties, and functions of clusters

One of the important properties of clusters is their lifetime. It is determined by the properties of the elements forming the cluster, the type of cluster compounds, and the environment, where the formation takes place. We should distinguish free and stabilized by certain factor clusters. Free

clusters more often occur in uncondensed phases – in the soil air, more seldom – in the condensed ones (associates in solutions). Their minimal lifetime evidently is close to the duration of the collision of particles in the gaseous phase – $10^{-12} - 10^{-13}$ s.

Stabilized clusters have more complex structure and composition. The “body” of cluster (the group of interacting elements of a certain type) and stabilizing elements (the ligand cover, central particle, around which the cluster is formed (Kipnis, 1981; Chenu and Plante, 2006), or the matrix may be discriminated. The lifetime of stabilized clusters is comparable with the duration of the existence of molecules or their compounds. For soil science and agrophysics, the most important are the clusters with a lifetime long enough to participate in various physical, chemical, and physicochemical soil processes. A typical example of stabilized clusters is adsorptive clusters and surface precipitates. The existence of matrix, which is parts of the surface of soil particle, is the most vigorous stabilizing factor.

The most important common features of clusters are the following: (1) limited number of interacting elements; (2) transitional (intermediate) form of organization of the matter with elevated (maximal) specific activity compared to that of the elements and providing the transition of the system from one state to another; (3) solid-bodied clusters, which are somewhat intermediate state of the material – in between amorphous and crystalline, when the material exists neither as atoms and molecules, nor in the crystalline frame (Kipnis, 1981).

The formation of clusters requires the overcoming of a certain activation barrier by cluster-forming particles (Suzdalev and Suzdalev, 2001).

Cluster organization of soil matrixes

Soil matrix is an active part of surface layer of solid particles, which induces certain properties of the surface, composition of cations, thickness of water film, organic humus and organo-mineral matrixes, and by that creates relatively constant properties of soils (Zubkova and Karpachevskii, 2001). The basis for soil matrix is the mineral matrix, which comprise mainly clay minerals, amorphous compounds, metal oxides, and talus. In contrast to cluster, the matrix has no limitations by maximal size.

The terms “matrix” and “cluster” are tightly bound. The matrix is one the strongest factors, which stabilizes cluster in soils, and a basement for generation of surface cluster structures. In the information transfer of structure from mineral base to interacting compounds, the key role belongs to active sites and electric heterogeneity of surface elements rather than the geometrical structure of the surface (Distler, 1972).

Studies of adsorption of organic matter on mineral soils, oxides, gibbsite, ferrihidrite, goethite, hematite, kaolin, and illite have demonstrated that the interaction occurs mainly with active (“reactive”) sites on the surface of solid particles (Kaiser and Guggenberger, 2003). The existence

of different types of surface of soil particles with different functional peculiarities was mentioned by Pinskii (1997) and Kleber et al. (2007). Carboxyl-containing organic molecules form firm organo-mineral compounds on positively charged sites of amorphous aluminum silicates via the mechanism of activated chemosorption (Kurochkina and Pinskii, 2002). The distribution of such sites has fragmentary insular character and includes not only tops of angles, edges, or defects of the crystal surface but also the mouths of micropores (Kaiser and Guggenberger, 2003). Uncompensated defects within the volume of the solid body also induce special groups of atoms on the planar crystal surface, which should be considered as peculiar surface clusters (Kipnis, 1981). Thereby, in soils cluster-matrix structures are formed, and they may be designated as active matrixes.

The formation of cluster-matrix structures on the surface of soil particles conditions its *heterogeneity* by composition and properties, affects *adsorption energy*, *structure and stability of aggregates*, soil *hydrophobic-hydrophilic* properties, *sorptivity*, *buffer capacity of soils*, and other *properties and functions*. In particular, the formation of organo-mineral compounds in soils makes *organic matter* much more persistent to biodegradation.

Methods of study of cluster-matrix structures in soils

Current progress in the experimental studies of cluster and matrix structures was provided by application of high-resolution transmission electron and atomic-force microscopy (HRTEM and HRAFM), extended X-ray absorption fine structure spectroscopy (EXAFS), and Fourier transfer infrared (FTIR) spectroscopy. EXAFS has provided the studies of bonding environments of adsorbed and structural species to ascertain the geometry of complexes at mineral surfaces as well as the structure of three-dimensional phases such as precipitates. The recent push to investigate reactivity of critical zone illustrates the need for scientists working in the Earth and environmental sciences to adopt techniques that allow them to gain insight about reactivity, and the changes in the reactivity, on very small scales.

Summary

The term of cluster is defined. The formation of clusters occurs during the adsorption of heavy metals by soils and their further transformation in layered double hydroxides and more persistent compounds. The adsorption of organic matter by the surface of soil mineral particles is accompanied by the formation of cluster compounds as well. As a result, the distribution of organo-mineral compounds within the surface of solid phases has fragmentary character. The processes of clusterizing are followed by the formation of solid phases from the products of parent rock weathering and are accompanied by the formation of hydrated films on the surface of non-hydrated salts

and minerals. Common properties of cluster structures are described. The cluster character of active soil matrixes and their role in the formation of soil properties is demonstrated.

Synonyms

Food color measurement

Definition

Color ordering system. A series of standardized color boards or cards used in colorimetric and photometric calibration.

Color space. A color system that consists of color components represents the image values of a color image as numbers.

Color temperature. A characteristic of a visible light that is determined by comparing the chromaticity of a light source with that of an ideal black-body radiator.

Segmentation. A process of partitioning a digital image into multiple segments in order to detect the region of interest.

Introduction

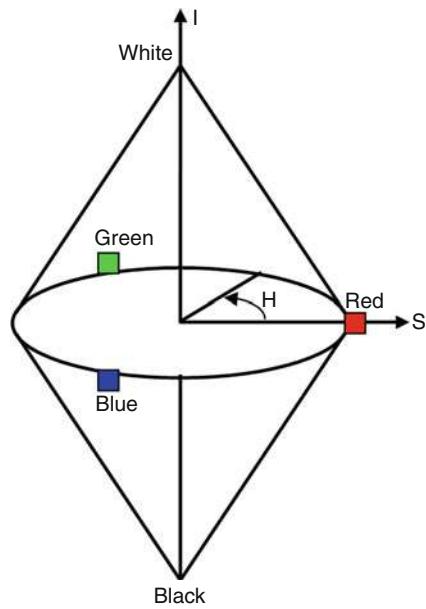

Color has been one of the important factors in food quality measurement. The quality of some food is estimated by its external or internal color. For example, ripeness of fruits could be judged by the external color. This kind of color evaluation could be performed by human visual perception. The color measurement by human perception could vary by persons and the environment-like lighting condition at the place. Thus, color measurement for food evaluation must be carried out by taking into account the color to be measured and the instruments used. There are two important points to consider for color measurement in food evaluation. First, the proper *color space* must be chosen for the specific purpose of the measurement. Second, the equipment setup is also important, because color measurement could be easily affected by any environment change such as lighting devices and color sensors.

Color spaces in food evaluation

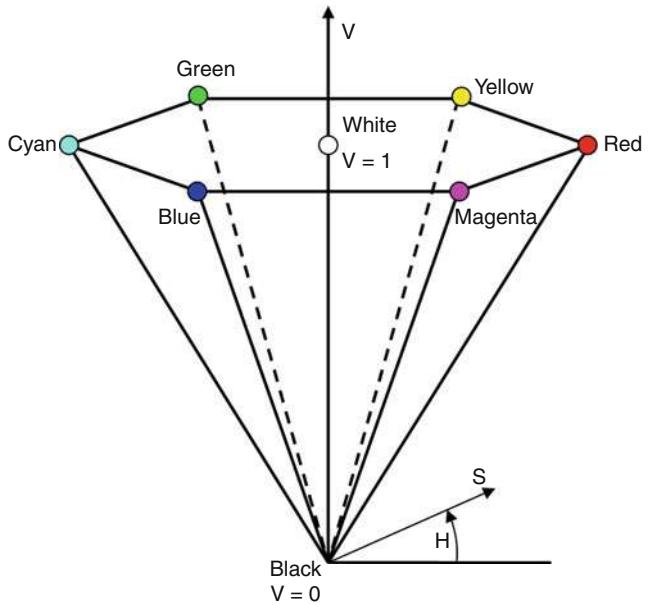

There are various color spaces for various purposes, and four of them are mainly used in food evaluation. The most common color space in digital image processing is RGB. The RGB color space is based on the international standardized wavelengths of the primary colors that are red, green, and blue. This color space is intended to provide description of the standardized primary colors, like long (red), middle (green), and short (blue) wavelengths of the visible light. Image data of CCD (Charge-Coupled Device) sensors of digital cameras are based on this RGB color space. It is easy to use for analysis without color conversion process. However, the wavelength range of each component of the RGB color space is not clearly separated from other components – the ranges overlap with one another. Thus, when a long-medium color (yellow or orange) is represented using the RGB color space, not only the red and green components are used but also the blue component is used because the green component overlaps with the blue. This property of the RGB makes difficult to reproduce real colors. It means that visible colors in real world cannot be equivalent to the combination of the wavelengths of the RGB color space. Many of the research projects in food analysis, like Gökmen et al. (2008), Kılıç et al. (2007), Sun and Brosnan (2003), and so on, employed RGB color space for food color analysis.

HSV (hue, saturation, and value) and HSI (hue, saturation, and intensity) color spaces are used in many food research papers in Du and Sun (2005) and Riquelme et al. (2008). Both color spaces are based on human color perception and generally used in the fields of computer vision and computer graphics (Koschan and Abidi, 2008). These color spaces are based on the RGB color space. In the HSI color space, the three color components are used as coordinate axes as shown Figure 1. The hue H describes the color itself as a value between 0° (at the centre) and 360° (at the edge). The saturation S is a measurement of color purity that represents how much the color is affected by white color. The range of the saturation component is between 0 (black) and 1 (white). The intensity I represents the brightness, having a value between 0 and 1. Thus, all of the three components are calculated from the RGB color components. In the HSV color space, the hue H has a value between 0° and 360° , but the plane represented by H is like a hexagon with different color at each vertex as shown in Figure 2. The value V represents the brightness of the color. V is 0 at the apex in Figure 2.

The common color space in food research has been $L^*a^*b^*$ (CIELab). The CIELab color space is the international standard color space, recommended by the Commission Internationale d'Eclairage (CIE) in 1979 (León et al., 2006). CIELab is a uniform color space that same-size changes in the color coordinates correspond to the changes in the visible space (Koschan and Abidi, 2008). Thus, the color measurement using CIELab could be

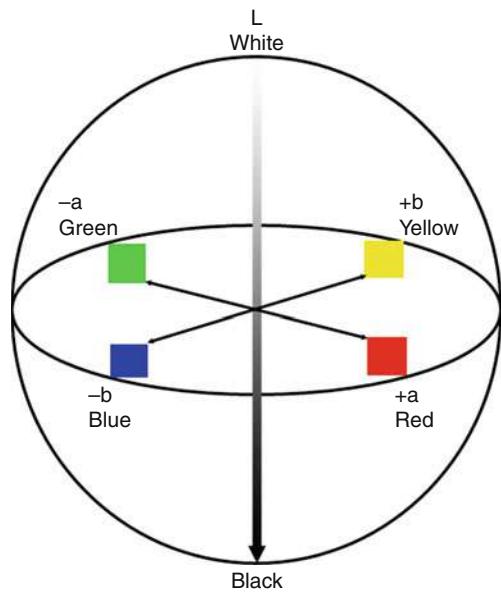

Color in Food Evaluation, Figure 1 Representation of the HSI color space.

Color in Food Evaluation, Figure 2 Representation of the HSV color space.

absolute measurement that detects the color changes and differences between objects. The CIELab space could be expressed as shown in Figure 3.

- L^* represents the lightness, having a value in the range of 0–100, where 0 is black and 100 is white.

Color in Food Evaluation, Figure 3 Representation of the CIELab color space.

- a^* represents variation from green to red in the range of -100 to $+100$.
- b^* represents variation from blue to yellow in the range of -100 to $+100$.

An example of using this uniform color space CIELab is in that the maturity of some fruit could be evaluated without destroying the fruit. If the color changes were modeled and the fruit color is changed as it ripens, the maturity of the food could be estimated. Jha et al. (2007) carried out such experiment and modeled the maturity of mango based on its external color. If the color of the fruit is changed from green to yellow as it ripens, the value of a^* will be changed from negative value to positive or nearly zero, and the value of b^* will be increased. In addition, the values of a^* and b^* components are not affected by the lightness on the curved surface of the objects as reported by Mendoza et al. (2006). Thus, the color changes could be plotted in two-dimensional (2D) plane (a^* vs. b^*). Then the trend of the color variation will be clearly shown on the plots. For such applications, *hue* and *chroma* could be useful, and these are computed from CIELab as below in Equation 1:

$$\text{Hue} = \tan^{-1} \left(\frac{b^*}{a^*} \right), \quad (1)$$

$$\text{Chroma} = \sqrt{a^{*2} + b^{*2}}.$$

There is an example of this kind of experiment using mango carried out by Kang et al. (2008). The green surface color of a fresh mango gradually changed to yellow as it ripened by in a certain storage condition. Then the hue of the green region is gradually decreased as the color

turns into yellow. There is another example using this property of the CIELab color space. Kang and Sabarez (2009) developed a very simple color *segmentation* that obtains a polynomial equation from plots of a^* and b^* on 2D plane and found points close to the equation. Thus, the property of the CIELab color space as a uniform color space could be useful if the food to be examined is affected by the lighting, and the color on the surface must be measured regardless of illumination effect.

The hue components of the HSI and the HSV color spaces are also not affected by lightness of curved surfaces, and other components are reliable only if the object is flat. All the components of the RGB color space are affected by lightness on curved surfaces. The results are presented in Mendoza et al. (2006). If the external surface of the food is not flat, the color values at different height but same color would have different color values. Thus, these color spaces are nonuniform color spaces. The changes of the color components do not correspond to the changes of the visible color. If the color measurement system is based on computer vision system (CVS) and the area to be measured is not flat, the result could not be accurate.

Color values in other color spaces like RGB, HSI, and HSV can be converted into CIELab, and the procedures were explained in Mendoza et al. (2006), Kang et al. (2008), and Koschan and Abidi (2008). Other color conversions are explained in Koschan and Abidi (2008).

Vision system setup in color measurement

In color measurement, the consistency of the measurement is extremely important. If any condition like sensor setting or lighting condition is changed since the previous measurement, the new color measurement cannot be compared with the previous one. Thus, the conditions of the measurement setup such as illumination and sensor calibration must be consistent.

The most common illumination is D65 (i.e., known as “daylight,” corresponding to the *color temperature* at 6,500 K). There is another standard illumination called as illuminant C used as “daylight” likewise 6,500 K. However, the property of the illuminant C is lack of UV radiation if compared to the real daylight, thus D65 is commonly used at present (Koschan and Abidi, 2008). In food evaluation, using the illuminant C can cause wrong color measurement result if the used material has the property affected by UV radiation. On the other hand, D65 has a disadvantage in that it is difficult to manufacture. Thus, fluorescence tube lamps (TL-D Delux, 18 W/965, 6,500 K, Philips) are used as the D65 standard lighting source by Mendoza et al. (2006) and Kang et al. (2008).

Moreover, the color measurement sensors must be selected with consideration of the purpose of the measurement. Colorimeters and digital cameras are generally used as the color measurement sensors. Both sensors could be used to measure absolute colors of food. The advantage

of the colorimeter is easy to use and reliable, but this device has a disadvantage that the sensing area is very small. This device only gives the average value of the small area. Thus, the demand of CVS using digital cameras is rising because of the wide sensing area upto 10° observation angle. However, digital camera-based systems are not simple to use like colorimeters. The digital camera-based systems require analysis software and color calibration under the circumstance to be measured. The digital camera calibration process is explained in Mendoza et al. (2006) and Kang et al. (2008). The brief process is as follows: First, the color measurement system must be decided. Then, images of a set of *color ordering system* must be taken. The actual color values of the color ordering system must be known. The color values in the images should be compared and repeated until the closest camera setting, such as aperture, shutter speed, ISO, and so on, to the color ordering system is found.

Summary

Color spaces and equipment used in food evaluation have been discussed. There are various color spaces, and the right color space must be chosen for the purpose of the evaluation. The CIELab color space has widely been used for color measurement and analysis in food engineering because this is a uniform color space. On the other hand, two color measurement sensors (i.e., colorimeter and CVS) have been discussed. The demand of CVS has been increasing because of wide sensing area. However, when using CVS, the vision system must be designed by taking into consideration about the consistency while the measurement is carried out.

COLOR INDICES, RELATIONSHIP WITH SOIL CHARACTERISTICS

Manuel Sánchez-Marañón
 Departamento de Edafología y Química Agrícola,
 Universidad de Granada, Granada, Spain

Synonyms

Color indicators, descriptors or parameters

Definition

Soil. Unconsolidated material at the earth surface that serves as a medium for plant growth (see *Agrophysical Objects (Soils, Plants, Agricultural Products, and Foods)*).

Color. Perceptive attributes of a light emitted by a source of visible radiation and diffused by an object such as the soil.

Index. Something that reveals or indicates; a sign; a number used to characterize a set of data.

Soil-color index. Quantitative expression of soil color and indirect indicator of characteristics for the soil.

Introduction

Color has hardly any direct influence on the soil behavior, except for the albedo and the amount of heat absorbed (see *Adsorption Energy and Surface Heterogeneity in Soils*). Most soil processes, however, have color consequences, which can be used as traces of the quality and soil conditions. Early soil scientists such as Dokuchaiev, Sibirtsev, and Hilgard considered the soil color to be a straight-line function of the amount of humus and ferric oxides, and they discussed the significance of black, red, and white colors to soil productivity, age, and drainage (Bigham and Ciolkosz, 1993). Since the 1940s, the visual color

determination by standard Munsell soil-color charts has been widely employed worldwide for soil description. Some workers in the 1960s used the Munsell notation as index for several soil characteristics, but it was chiefly after 1980 when the color indices were supported by instrumental measurements and quantification in uniform color-space models. The present article focuses on the merit of color indices as sources of soil information. It describes (1) the soil-coloring process, (2) the numerical expression of soil color, and (3) the relationship of soil color with soil characteristics. For simplicity, no index of remote sensing is described here (see *Remote Sensing of Soils and Plants Imagery*).

Soil-coloring process

The soil has multiple solid particles surrounded by water and/or air. When light strikes a soil, some light is always directly reflected as if from a mirror (specular reflection). Light may be also partly transmitted through the particles, undergoing refraction, being partly absorbed as heat, and ultimately scattered. Scattering means that light is reemitted traveling in many different directions (Berns, 2000). Most soil particles are opaque or translucent and cause enough scattering so that light is diffusely reflected by them. The color of soil depends on the diffuse reflection of light after interacting with all particles in its way. The final soil color is an additive function of the color of particles weighted in accordance with their proportions (Sánchez-Marañón et al., 2004). A yellowish soil, for example, is due to a majority presence of yellowish particles; they selectively absorb more amount of blue (380–480 nm) and green (480–560 nm) light, while diffusely reflect the remainder light spectrum (yellow, 560–590 nm; orange, 590–630 nm; and red, 630–780 nm).

Silicates, carbonates, sulfates, and other salts are gray, white, or colorless. Soil pigmentation comes from Fe (hydr)oxides such as goethite (α -FeOOH), hematite (α -Fe₂O₃), maghemite (γ -Fe₂O₃), ferrihydrite (Fe₅HO₈·4H₂O), and lepidocrocite (γ -FeOOH). Their yellowish, brown, or reddish colors result from selective absorptions by electronic transitions in the metal, between the metal and ligands, or between adjacent metal ions in different oxidation states. Organic matter is also a usual colorant, causing strong absorption in all wavelengths of the visible range and darkening the soil. Less common are the Fe (II, III) hydroxy salts such as jarosite (KFe₃(SO₄)₂(OH)₆) and vivianite (Fe₃(PO₄)₂·8H₂O) having yellow, green, or blue tints of limited saturation, and black monosulfides, pyrite, and Mn oxides (Bigham and Ciolkosz, 1993). Particle size and arrangement as well as water content also influence soil color. The smaller soil particles (clay fraction) often exert greater influence because they (1) exhibit more surface area for altering the light, (2) contain the majority of pigmenting compounds, and (3) favor physicochemical interactions with colorants due to their charge and surface area. In addition,

scattering decreases as the soil particles become coarser. On the other hand, aggregation involves (1) particle arrangement and the consequent anisotropic distribution of compounds, occluding some and exposing others to the light; (2) increased size of soil units; and (3) generation of pores, trapping light. Finally, upon wetting, the refractive index of pores filled with water increases and a large amount of light is absorbed (Sánchez-Marañón et al., 2007).

Quantifying the soil color

Color can be measured with our own visual system, spectrometers, and colorimeters, following numerical specifications in a color system. The visual determination needs standard soil-color charts made with artificially colored papers and organized in the Munsell system. An observer seeks the closest match between a soil sample and one of the standard colors, for which the notation is: hue H , value V , and chroma C . Spectrometers record the amount of light reflected (R_{λ}) by the soil with respect to that of a perfectly reflecting diffuser (reference white) about each wavelength (λ). Color specification also requires the spectral distribution of a standard illuminant (S_{λ}) and three standard spectral curves ($\bar{x}_{\lambda}\bar{y}_{\lambda}\bar{z}_{\lambda}$) created by the Commission Internationale de l'Éclairage such as the Standard Observer for converting a reflectance spectrum to three perceptive stimuli (Berns, 2000). Tristimulus values represent the amount of red (X), green (Y), and blue (Z) of any color and are given by the following equations:

$$X = \frac{\int_{380}^{780} S_{\lambda} R_{\lambda} \bar{x}_{\lambda} d\lambda}{\int_{380}^{780} S_{\lambda} \bar{y}_{\lambda} d\lambda} \quad Y = \frac{\int_{380}^{780} S_{\lambda} R_{\lambda} \bar{y}_{\lambda} d\lambda}{\int_{380}^{780} S_{\lambda} \bar{y}_{\lambda} d\lambda} \quad Z = \frac{\int_{380}^{780} S_{\lambda} R_{\lambda} \bar{z}_{\lambda} d\lambda}{\int_{380}^{780} S_{\lambda} \bar{y}_{\lambda} d\lambda}$$

Colorimeters directly measure tristimulus values using filtered detectors combined to have responsive matching as closely as possible to $\bar{x}_{\lambda}\bar{y}_{\lambda}\bar{z}_{\lambda}$. Several color-space models have been derived from tristimulus values, with the aim of more closely correlating color parameters with the visual perception and having more uniform steps and spacing. The CIE and CIELAB systems are two outstanding examples. CIE system uses chromaticity coordinates x , y , and tristimulus Y , drawing a horseshoe-shaped spectrum locus by connecting the chromaticity points of the spectrum colors, which define the dominant wavelength (λ_d) and excitation purity (P_c) of the Helmholtz coordinates. CIELAB system considers a three-dimensional space defined by rectangular coordinates a^* b^* L^* or cylindrical polar coordinates L^* C_{ab}^* h_{ab} . Munsell HVC , by far the most familiar to soil scientists, may also be inferred from tristimulus values. Calculations and conversions CIE \leftrightarrow CIELAB \leftrightarrow Munsell are available in the modern measurement equipment and their formulation has been summarized by Viscarra Rossel et al. (2006).

Munsell H has long been used as soil-redness index. Because redness increases as the hue goes from

Y (yellow) to YR (brown) and R (red) and the range of Y and YR decreases from 10 to 0 (e.g., 3.7Y, 0.9Y, 9YR, 5YR, 2.5YR, 10R), it is usual to assign a single number to each hue (e.g., 23.7, 20.9, 19, 15, 12.5, 10). The CIELAB coordinates a^* and b^* , respectively, scalar quantities of red and yellow, are increasingly common in soil studies. CIELAB hue angle h_{ab} , an angular expression of the value of b^* respect to a^* , more accurately indicates the redness degree, which intensifies toward the lower values (usually in soils from 90° to 40°). In the CIE chromaticity diagram, the relative increase of x with respect to y signifies redder λ_d . Munsell V (0–10), CIELAB L^* (0–100), and CIE Y (luminance) provide accurate lightness values serving as soil-darkness indices; the lower the values are, the darker is the soil. Finally, Munsell C or the degree of departure (0–8) of the color from a gray of the same lightness, as well as CIELAB C^*_{ab} and Helmholtz P_c , both measured as the length of the line from the neutral point to the sample point, are used as soil-chromaticity indices. Besides these general indices, many other specific ones have been designed by researchers to incorporate various data into one value (Table 1).

Quantitative relationships between color indices and soil characteristics

Redness indices correlate with free Fe forms. There is a progressive increase of soil redness with an increased amount of free Fe (Figure 1a). The correlation, positive or negative, depending on each index, usually has a significant coefficient r not exceeding 0.7 ($P < 0.05$). The relationship is complicated not only by the combined presence of different pedogenic Fe minerals overlapping colors or by the size, arrangement, isomorphous substitutions, and crystallinity of these minerals, causing variation in their colors, but also by organic matter and Mn oxides,

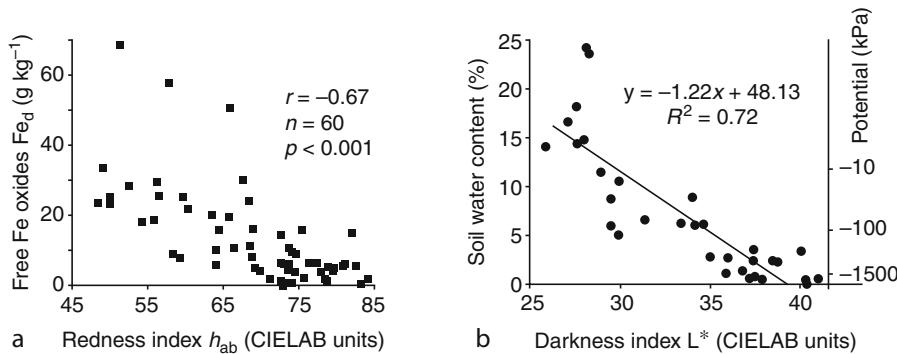

Color Indices, Relationship with Soil Characteristics, Table 1
Some specific color indices for assessing soil characteristics

Index	System	Characteristic	Author
$H \cdot C$	Munsell	Development	Buntley and Westin (1965)
$10(\Delta H + \Delta C)_{\text{dry}} + 10(\Delta H + \Delta C)_{\text{moist}}$	Munsell	Development	Harden (1982)
$\frac{(10 - H)^3 C 10^3}{V^6}$	Munsell	Hematite	Barrón and Torrent (1986)
$\frac{(x - 0.34)^2 10^4}{(y - 0.34) Y^2}$	CIE	Hematite	Barrón and Torrent (1986)
$\frac{a^*(a^{*2} - b^{*2})^{\frac{1}{2}} 10^{10}}{b^* L^{*6}}$	CIELAB	Hematite	Barrón and Torrent (1986)
$\sum \frac{A \text{ thickness}}{(V \cdot C) + 1}$	Munsell	Organic C	Thompson and Bell (1996)
Redox depletions	Munsell	Water saturation	He et al. (2003)

which mask the color of Fe-oxides. Redness indices specifically devised for predicting hematite content (Table 1) consider that dry ground soil samples gain redness as well as chromaticity and darkening with increasing hematite until reaching 15%, the threshold for color saturation. The regression equations fit linear models reaching R^2 coefficients 0.9, especially for the index designed from CIELAB parameters. The regression, however, varies for different sets of soils and is consistent only for soils with very low amounts of organic matter and amorphous Fe forms. Other specific indices related with hematite and goethite are based on the height of selected peaks in the second derivative of the reflectance spectrum, and coefficient K_λ (absorption) and S_λ (scattering) of the Kubelka–Munk theory, but they have been rarely used.

Aerobic weathering generates oxidized (often hydrated) free Fe forms for the soil; as a result, the soil development also correlates with soil redness. Redder hues signify increased weathering and development, which also explains the relation between redness indices, the content in clay and neoformed kaolinite, and soil age. To avoid the influence of the geological substrate on the redness indices, some authors (e.g., Harden, Table 1) subtract the color of parent material from that of the soil horizon. The redness-development relationships are usually fitted to curvilinear models because redness progresses slowly in the first steps of soil development and faster when Fe forms become matured by dehydration and recrystallization. High soil temperatures and dry seasons favor the maturity of Fe forms, and therefore redness indices are also related to climatic factors. Even under the same climatic conditions, somewhat warmer and drier soils are redder because the first weathering product (poorly crystalline Fe hydroxides) rapidly changes to hematite, while appears goethite in colder and damper soils (Singer et al., 1998). Other soil characteristics influenced by the type and amount of Fe oxides such as aggregate stability, porosity, drainage, and phosphate sorption are also connected to the redness indices. The *Soil Physical Quality* (qv) often improves with soil redness, while the yellowness component b^* was found to be positively related to P sorption (Scheinost and Schwertmann, 1995).

Although all color parameters can change depending on organic matter and soil wetness, stepwise multiple-regression analyses usually select Munsell V or CIELAB L^* as more informative (greater explained variability) of both soil characteristics (negative relationship). Strong relations, however, depend on a homogeneous soil landscape if soil textures and parent materials do not vary widely. This guarantees that the quality of organic matter, the way of epitaxial covering, and the lithogenic color baseline do not confuse the relationships. Soils with high organic C content consisting of aliphatic humus can display a similar darkness index as those having comparatively low amounts of organic matter but high aromaticity. Fine particles are better supports for humic pigments, encouraged by their superficial activity, and

Color Indices, Relationship with Soil Characteristics, Figure 1 Relation between redness index h_{ab} and dithionite-soluble iron Fe_d (a), and between darkness index L^* and water content (b) using samples from Mediterranean soils (Sánchez-Marañón et al., 2004, 2007).

the same soil color can be achieved with different organic C contents if the geological substrate also varies. Curvilinear relationships could point to variations in some of these factors in the datasets. The decrease of L^* with increased soil-water content and potential is also similar for soils with the same forming factors and characteristics. The calibration curve in a soil is frequently stepped (ladder shaped) with changes pronounced at certain potentials (-100 and -10 kPa in Figure 1b). There is weak correlation at intermediate potentials, and above -10 kPa, the water effect on L^* is hardly noted or the relation becomes positive. Therefore, a regression model applied to soils with the same color and origin predicts from L^* if the soils are dry, contain plant-available water, or move closer to **Field Water Capacity** (qv). Many other soil-fertility characteristics that depend on organic matter and soil wetness may be related to darkness indices, and some specific index combining thickness of A-horizons and Munsell VC (Table 1) was proved useful to differentiate soil conditions in Mollisols.

Soils in which water saturation occurs in normal years are said to have aquic conditions, and chroma indices usually describe their significance, duration, and water-table fluctuation. Soil-water saturation causes oxygen depletion and chemical reduction of polyvalent metallic elements. This process, called gleization, implies the presence of redoximorphic color features, including bluish- to greenish-gray matrix colors and colored mottles (sometimes, nodules and concretions). The $Fe(II)$ is removed during the reduction time, causing low chromaticity to the soil (Munsell $C \leq 2$), while $Fe(III)$ re-precipitates as hydroxides (often lepidocrocite) in mottles of higher chroma when the saturation event disappears. Low chroma indicates soil areas with redox depletion, while high chromas are redox concentrations. Low chroma colors increase in abundance, the longer a soil is saturated and chemically reduced. Authors that work in this field usually combine the chroma values and abundance of redox depletions into one index.

Conclusions

Soil color can be described by scalar quantities, called color indices, that are related to soil components and, by extension, properties depending on them or conditions for their formation. Accordingly, such color indices provide an integrative way of comparing soils, including evolution, pedoclimate, and fertility. Several circumstances involved in the color of soil materials and their interaction, however, alter the quantitative relationships. For predictive purposes, the relationships should be calibrated in a homogeneous soilscape, using the index and sample type best adapted to the soils and characteristics under study.

CONDITIONERS, EFFECT ON SOIL PHYSICAL PROPERTIES

Ryszard Dębicki
Department of Soil Science, Maria Curie-Skłodowska University, Lublin, Poland

Definition and introduction

The search for new effective means of improving the physical, physical-chemical, and chemical properties of soils, which enhance soil fertility, used to and still does arouse interest in many regions of the world for a number of reasons:

1. Classic methods of improving soil fertility require prolonged periods of use and are work-, cost-, and energy-intensive.
2. In contemporary agriculture, there is a lack of sufficient amounts of organic fertilizers, which could eliminate the deficit of humic compounds and prevent the physical degradation of soils.
3. Discovered synthetic structure-forming agents can also be used for such a utilization of some industrial and agricultural waste materials, so that they can be more effectively used for soil fertility enhancement.

Improving the physical properties of soils is directly related to the soil structure (see *Soil Aggregates, Structure, and Stability*). Thus, investigating the phenomena that accompany the creation and sustaining of the soil crumbs allowed to formulate the following hypothesis: The activity of natural binding agents occurring in the soil can be strengthened by introducing synthetic substances, which are more effective and more resistant to microbiological decomposition, and which, during their transition from the soluble into the non-soluble state, will create durable soil aggregates. It has been stated that, beside the mineral colloids (clay minerals, among others), the high molecular organic substances of the linear polymer character, lignin, proteins, nucleic acids, and other substances play a primary role in such processes in soils. Together, these substances create the compounds that are not water-soluble in the soil. All these compounds contain a sufficient number of polar groups to ensure their adsorption on the colloidal soil particles. The cross-bindings and van der Waals' forces between the chains ensure good cohesion of the soil particles (Dechnik and Dębicki, 1977).

Research on the utilization of synthetic, structure-forming agents began as early as in the 1950s (Martin, 1953; Wallace and Terry, 1998). However, despite the investigation of numerous compounds of various chemical characters and of different origin, to date, no agent has been found whose use would be economically justified in broad agricultural practice and environmental protection. Based on extensive studies, it has been concluded that effective structure-forming agents should have good binding properties, be easy to use, durable in the soil environment, nontoxic, and inexpensive. Although an agent that would satisfy all of the above conditions has not yet been found, some of the investigated compounds have been widely used in several measures. For instance, they have been used in the moderate climates; in plant cultivation – to improve the sprouting conditions and germination of industrial or highly marketable plants (Dechnik and Dębicki, 1977); in amelioration – to combat water and wind erosion on terrains susceptible to such phenomena (Fullen et al., 1993; Bjornberg and Aase, 2000) (see *Water Erosion: Environmental and Economic Hazard*); in engineering – to secure road shoulders and road edges, canals and rivers; in the dry climate – to prevent the soil from water evaporating from the bared surfaces or to prepare the ground for tree and bush cultivation in sandy terrain (De Boodt, 1972). Moreover, many of synthetic soil conditioners (e.g., polyelectrolytes) are used for transforming some waste products from various branches of economy (agriculture, forestry, food processing industry, wastewater treatment plants, etc.) or for manufacturing of polymer-coated urea in order to control the release of nitrogen, e.g., polyurethane (Golden et al., 2009). Today, according to Sojka et al. (2005), all synthetic and natural agents, including fertilizers in all stages of modification or unmodified, which are introduced into the soil for the purpose of improving its natural, agronomic, technological, preventive, and other properties, are considered among soil conditioners. In this paper, special consideration is given to the synthetic agents of soil enhancement and to natural wastes transformed through addition of synthetic agents.

Classification, characteristics, and the influence mechanism of synthetic agents used to enhance the physical properties of soils

Numerous patented synthetic and natural soil improvement agents exist. Known are several of their classifications in which the main criterion is either the chemical composition or mode of action, technology, method and area of use, their origin, etc. One characteristic feature of all the soil improvement agents is their ability to create or stabilize the aggregates or the ability to alter other physical and chemical soil properties (such as the size and durability of the soil aggregates, ability to retain water and mineral nutrients, wettability and sorptivity, rate of filtration, cation exchange capacity, and others). The dominant and most widely investigated groups are the organic, water-soluble,

high molecular linear polymers (polyelectrolytes). They were the first synthetic, structure-forming agents introduced in the market by the Monsanto Chemical Co. (USA) under the commercial name "Krilium" (Martin, 1953).

To date, the described synthetic agents are classified by researchers in a variety of ways. Schamp (1976) distinguished between the following groups: polyelectrolytes; emulsions of homopolymers and copolymers of polyvinyl and polybutadien esters; cellulose derivatives; crude oil derivatives; resin substances of various origin; substances derived from fermentation and processing of various wastes (saw dust, industrial plants, municipal wastes, paper wastes, agricultural wastes, etc.).

De Boodt (1972) classified the synthetic agents of soil improvement according to the mode of influence on various soil properties: agents stimulating the hydrophilic phenomena (polyelectrolytes); agents causing hydrophobization of the soil (selected bituminous emulsions); agents increasing the surface horizon temperature of the soil (some bituminous emulsions); agents sustaining only the arable soil structure which loosens the soil and does not impede the development of the plant root system; agents aimed at increasing the cation exchange capacity of the soil (e.g., emulsions of strong acidic character, Al and Mg silica solutions, ion exchange resins, etc.).

Kullman (1972) divided the synthetic agents of soil enhancement into three groups: (1) agents of indirect influence on soil enhancement, i.e., substances, which when introduced in the soil, sustain its looser structure, improve its structural state, increase its resistance to thermal and mechanical factors, but do not directly impact the water and air content in the soil (e.g., flocculants, surface-active substances, some detergents, fat alcohols); (2) direct influence agents, whose introduction in the soil is directly related to the improvement of the water-air relations due to their specific composition (synthetic substances which can fix and store water and nutrients, have the ability to transfer them to plants, create a nonuniform mixture with the soil, improve the structural character of the soils, loosen the soils, and simultaneously increase their water capacity) (Styromull, Hygromull, Pianizol, among others); and (3) agents of indirect and direct influence (all bituminous emulsions, nonorganic gels, ion exchange resins, and others). Using emulsions enables the surface stabilization of the soil, increases the temperature, decreases evaporation, and thus increases the water content in the soil.

The impact of synthetic agents on the physical properties of soils

The wide interest in the possibility of using synthetic and waste-related agents to enhance the soil properties resulted in the fact that today the literature on this topic is extensive. The majority of the research was concerned with investigating the direct impact of the synthetic agents on the soil structure (its aggregation and durability, both in water and

mechanical) (Kullman, 1972; Dechnik and Dębicki, 1977; Wallace and Terry, 1998; Sojka et al., 2005).

Among the presented groups of enhancing agents, the most recognized is the influence of polyelectrolytes and polymer emulsions. Research points to a clear improvement of both the aggregation and the water resistance of various soils with the use of these agents in amounts as small as 0.05–0.1% of the soil mass. Observed is also a significant change in the distribution of the size of the aggregates. Along with the increased content of higher diameter crumbs, the soil loosens, which is indicated by the results of porosity, strength, and micromorphology tests. The scale of these changes depends on the kind and dose of the substance, means of use, state of soil matrix and texture, and level of the soil moisture during the procedure. Optimum structure-forming results were obtained at the level of soil moisture of 60% FWC (field water capacity).

Using the agents with different chemical composition also results in changes of other soil features, for example, the conductivity abilities, which occur not only due to the loosening of the soil, but also because of the changes in its wettability. The presence of the hydrophilic and hydrophobic substances leads to the change in the contact angle between soil particles and the soil solution. This results in the increase or decrease in the rate of water filtration in the soil, its retention, and the rate of evaporation (De Boodt and Dębicki, 1988). Lately again, polyacrylamide was used to reduce saturated water hydraulic conductivity in sandy soils (Young et al., 2009). Research showed that water-soluble polymers had hydrophilic characteristics, while polymer and bituminous emulsions had hydrophobic features. Still others, for example, the foamy substances of the Hygromull, Pianizol, and Polystyrene type, were neutral. They did, however, significantly increase the sorptive capacity of the soil in relation to water and nutrients. Included in this group are urea-formaldehyde resins, zeoliths, and others.

Discovery of the properties of a specific agent and the mechanisms of its influence in the soil allowed steering the physical processes in the soil. It has been shown that due to the use of hydrophobic substances, one could limit the evaporation-related water loss by 40–90%, depending on the procedure used (for instance, mulch or inserting the agent up to the depth of 10 cm or at a specified depth in the soil profile). The use of surface mulch from the hydrophobic substance increases the reserve of plant-available water within the season of germination and sprouting by 5 days.

Introducing the structure-forming agents into the soil results also in significant changes in the physical-chemical and chemical properties of the environment. The use of polyelectrolytes or polymer emulsions leads to the changes in the sorptive capacities of the soil. The kinetics of the ion sorption, the size and energy of the sorption, and the exchange capacity of the soil also change. The agents also influence the soil reaction, mobilization, and the uptake of nutrients, which is related to the biological life of the soil.

Summary

Literature data indicate that the doses of the investigated synthetic agents had a wide range from 0.001% to 1% in relation to the soil mass, depending on the type of the agent, purpose, and the procedure used. These amounts are significant, which led to the idea of using the most effective synthetic agents for such preparation of selected organic and mineral wastes from the industry and agriculture, that they can be further used in the process of improving the soil fertility on a much wider scale than has been used to date. Literature points to the great importance of such research not only in the aspect of reclaiming the soil fertility, but also for the purposes of environmental protection. During the utilization of the wastes with the use of synthetic, structure-forming agents, the doses of these agents substantially decrease and the created substances can be used as means of increasing the fertility of the soil. From the agricultural and economic point of view, it is desirable that synthetic, structure-forming agents and the agents derived from waste processing are characterized by high resistance to microbiological decomposition in the soils. However, from the environmental protection point of view, it is essential that these agents are biodegradable and the products of their decomposition are not toxic to the soil flora and fauna. Therefore, the knowledge of the speed of decomposition of these products and their impact on the microbiological processes in the soils is critical for the wider utilization of these agents in agriculture and environmental protection. The literature on biodegradation of the synthetic, structure-forming agents is scarce. However, research has shown that both the high molecular linear polymers and other agents (used in doses up to 0.1% of the soil mass) have not negatively influenced the biological activity of the soil and were not toxic to the soil microflora.

Definition

Contact area. Surface of the soil which is closely connected with the wheels or tracks of the agricultural engine.

Introduction

The main dangers threatening agricultural land in the industrialized world in recent decades are erosion, loss of organic material, and compaction (Jones, 2002). Field driving and field tilling with heavy machines contribute to soil compaction and soil shearing and reduce the storage, and hence availability of oxygen, water nutrients, and heat to the soil with a resulting crop yield decrease (Coehlo et al., 2000; Heinonen et al., 2002; Gregory et al., 2007). This affects the environment by increasing N₂O, CH₄ and CO₂ emission from soils (Horn et al., 1995). It is therefore essential to estimate the contact area *A* of agricultural tyres, since this parameter appears in: (1) the calculation of surface pressures (Keller, 2005; SchjØnning et al., 2008), (2) the models of strain stress propagation in soil (Söhne, 1953; Smith, 1985; Bastgen and Diserens, 2009), and (3) the prediction of severe risks of compaction (van den Akker, 1998; O'Sullivan et al., 1999; Defossez and Richard, 2002; Diserens et al., 2010). Moreover, on farmland or on the road, *A* is also related to the forces acting on the wheel (traction force, rolling resistance, braking force), determining vehicle grip, wear on tread, and road safety (Eichhorn, 1999). As *A* increases due to the use of broad tyre or twin tyre and the correct setting of the inflation pressure, not just the soil loading but also the rolling resistance is reduced, and this saves fuel consumption too (Döll, 1999). The contact area

also depends on the rolling resistance. Rempfer (1998) differentiated between internal and external rolling resistance. The internal resistance relates here to the dissipated energy within the tyre that is mainly dependant on the hysteresis of the material used and therefore the tyre deformation. The external rolling resistance, however, results on the one hand from the soil compaction caused by the tyre and on the other from the so-called "bulldozing effect." Here, it should be said that the internal rolling resistance of trailer is lower than that of traction tyres. Due to the stronger carcass, in particular at the flanks, the implement can be operated at higher inflation pressures to carry higher loads. The higher net-to-gross of the implement tyre tread pattern is designed for a free-rolling application.

The most common relationships between tyre size TS (width $W \times$ outer diameter D), wheel load F , inflation pressure P_i , and contact area A of traction and trailer tyres will be presented here. Influences of loading and of soil resistance on contact area A will be also discussed.

Measurement of the contact area A of tyres

The measurement of A is carried out using the photometry method (two-dimensional projection of the actual static surface area when the tyre is stationary). On meadow, the plant cover is first cut using a mower, followed if necessary by a second cut with a grass mowing machine. The print circumference of the tyre on the ground is first sprinkled with calcium oxide powder. For reference, a rule is placed on the edge of the print area once the load has been removed (Figure 1a and b). The contours are photographed with a digital camera. Print area or contact area A is analyzed by photometry (Diserens and Steinmann, 2002).

Coefficients of variation lower than 5% were found by examining the repeatability of the measurements by the sprinkling method.

To consider also the soil hardness on the surface, the penetration resistance of topsoil is measured with the aid of a Pesol penetrometer (20 daN or 33 MPa, a screwdriver head, bar width $6 \cdot 10^{-3}$ m, bar thickness $1 \cdot 10^{-3}$ m, stem

length $20 \cdot 10^{-2}$ m, stem diameter $4 \cdot 10^{-3}$ m) (Diserens, 2009).

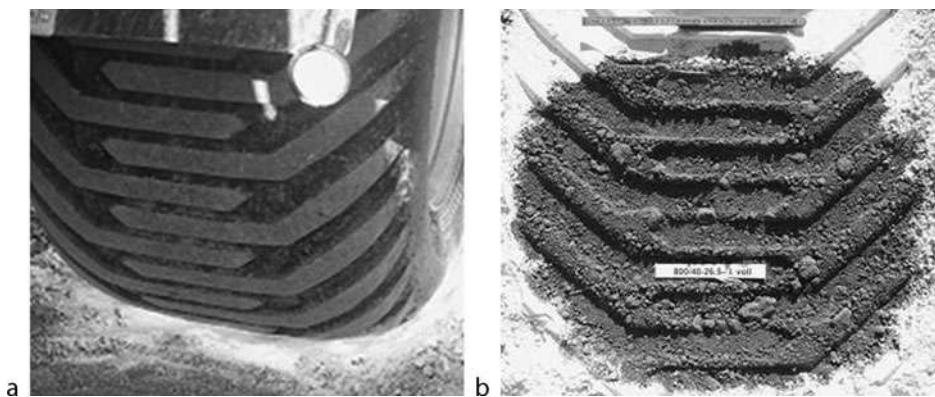

Contact area for traction tyres

There are numerous algorithms for estimating A of traction tyres on agricultural ground. Previous studies have described A strictly on the basis of the measured contact dimensions and the unladen tyre radius (Schwieger, 1996), or the depth of the rut (Bolling, 1987).

The equations developed for a wide range of tyres are characterized by the small number of variables. For high and low bearing capacity, simple formulae are used that take into account the diameter (D) and the width (W) of the tyre (McKyes, 1985). These equations are used to compare different tyre sizes. Similar formulae on soft soils considering the ratio q between tyre height and section width for normal profile ($q \geq 0.8$) and for low size profile ($0.8 < q < 0.6$) are also given (Diserens, 2002).

For hard surface, Steiner (1979) developed two algorithms for cross ply and radial tyres, both for normal profile with inflation pressure ranging between 80 and 220 kPa and wheel load between 5 and 25 kN, taking into account the wheel load, tyre diameter, and inflation pressure. In their Compsoil model, O'Sullivan et al. (1999) used the same independent variables (overall width and diameter of tyre, static wheel load and inflation pressure). In addition, they introduced a proportionality factor according to the soil hardness, which requires information on the soil bulk density of the soil surface. Comparing the shape of A to an ellipse, Grecenko (1995) suggested multiplying the product of the length and the section width of A by a coefficient c varying between 0.8 and 0.9 (1 for a rectangle). From measurements of rather soft ground, Keller (2005) considered A as a super ellipse described by the width of the tyre and the length of the ellipse. The length is correlated with the diameter of the tyre and the pressure ratio (measured tyre pressure divided by recommended pressure for a given load and speed).

The most common relationships given A for traction tyres on soft and hard soils are reported in the Appendix.

Contact Area of Agricultural Tyres, Estimation, Figure 1 Trailer tyre 800/40-26.5. (a) Marking on the field by means of a bellow, (b) Digital recording with reference rule for picture analysis.

Based on field measurements on soft and semi-firm arable soils (penetration resistance $PR < 13$ MPa) for a wide range of radial traction tyres (15 tyre types, rim diameter 24–42), relationships between contact area A (m^2) and easily accessible variables such as tyre size TS (in m^2), wheel load F (kN), and inflation pressure P_i (kPa) are given by means of regression analyses after selecting the tyres in three classes:

For small traction tyres ($TS < 0.6 \text{ m}^2$, $F \leq 25 \text{ kN}$) on soft soils (Equation 1):

$$A = 0.247[TS] + 5.821 \cdot 10^{-3}[F] - 1.933 \cdot 10^{-4}[P_i] \quad R^2 = 0.949 \quad (1)$$

For medium tyres ($0.6 \text{ m}^2 \leq TS < 1.2 \text{ m}^2$, $F \leq 65 \text{ kN}$) on soft soils (Equation 2):

$$A = 0.327[TS] + 3.333 \cdot 10^{-3}[F] - 5.386 \cdot 10^{-4}[P_i] \quad R^2 = 0.970 \quad (2)$$

For large tyres ($TS \geq 1.2 \text{ m}^2$, $F \geq 35 \text{ kN}$) on soft soils (Equation 3):

$$A = 0.230[TS] + 6.014 \cdot 10^{-3}[F] - 11.604 \cdot 10^{-4}[P_i] \quad R^2 = 0.985 \quad (3)$$

Reliable results can be obtained on soft soils after setting also the limit of the wheel load within each class (Equations 1–3). For traction tyres, the dynamic contact area can be deduced by taking into account, respectively, the dynamic load.

Contact area for trailer tyres

Because of the various functions of the farming trailer tyre, taking into account raised load-bearing, adherence

at high speed, lateral stability on wet roads, increased contact area, self-cleaning profile with respect to the traction tyre with raised traction force, raised working speed, the farming trailer tyre has a different composition. Its carcass (heavier cable) on the side transmitting the braking forces and change of direction forces of the wheel on the ground is reinforced. A belt with thicker textile layers and steel layers on the tread exerts a further stabilizing effect when the tyre is subject to heavy loads.

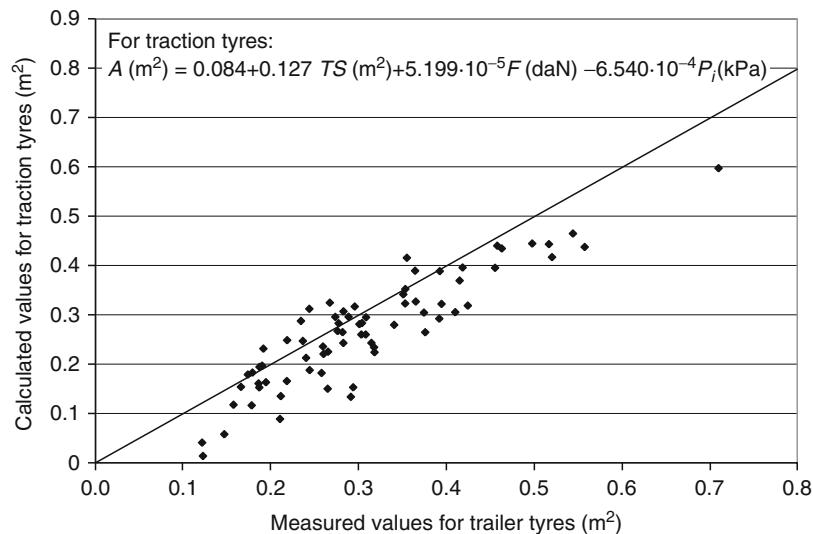

Figure 2 gives a comparison of A values, measured on the ground for farming trailer tyres with the corresponding values calculated from an equation derived from a data sheet of traction tyres with the same soil condition ($PR > 8$ MPa). Most of the points are below the line 1:1 (Figure 2). At similar loading, the diameters are generally smaller and the maximal loads lower (comparing the full loads from self-propelled harvester), thus the values for the trailer tyres will be underestimated after introducing the data in the equation calibrated for traction tyres with higher loads (Figure 2).

Based on field measurements on semi-firm and firm soils, representative conditions in fodder farming ($PR > 8$ MPa) for a wide range of trailer tyres (24 tyre types, rim diameter 15.3–30.5), relationships between A (m^2), tyre size TS (in m^2), wheel load F (kN), and inflation pressure P_i (kPa) are presented by means of regression analyses after representing the tyres by four classes (Diserens, 2009):

For cross-ply trailer tyres ($W < 0.5 \text{ m}$, $F \leq 25 \text{ kN}$) on hard soils (Equation 4):

$$A = 0.208[TS] + 3.176 \cdot 10^{-3}[F] - 0.679 \cdot 10^{-4}[P_i] \quad R^2 = 0.988 \quad (4)$$

For cross-ply trailer tyres ($W \geq 0.5 \text{ m}$, $F \leq 90 \text{ kN}$) on hard soils (Equation 5):

Contact Area of Agricultural Tyres, Estimation, Figure 2 Calculated values for contact area A of traction tyres and measured values for contact area of trailer tyres with a line 1:1 on comparable soil conditions according to Diserens (2009).

$$A = 0.132[TS] + 7.034 \cdot 10^{-3}[F] - 3.725 \cdot 10^{-4}[P_i] \quad R^2 = 0.985 \quad (5)$$

For radial low size ($0.8 < q < 0.6$) trailer tyres ($F \leq 70$ kN) on hard soils (Equation 6):

$$A = 0.069[TS] + 3.140 \cdot 10^{-3}[F] - 1.935 \cdot 10^{-4}[P_i] + 0.092 \quad R^2 = 0.859 \quad (6)$$

For radial terra ($q \leq 0.6$) trailer tyres ($F \leq 70$ kN) on hard soils (Equation 7):

$$A = 0.178[TS] + 4.169 \cdot 10^{-3}[F] - 4.240 \cdot 10^{-4}[P_i] + 0.063 \quad R^2 = 0.830 \quad (7)$$

Reliable results can be obtained on semi-firm and firm soils after setting also the limit of the tyre width W and the wheel load within cross-ply classes (Equations 4 and 5), respectively, within each class (Equations 4–7).

Influences of the loading and the inflation pressure on the contact area A

Several authors note an increase in A when inflation pressure falls for traction tyres (Steiner, 1979; O'Sullivan et al., 1999; Keller, 2005). However, a variation in inflation pressure alone is in fact not always enough to determine whether A increases or decreases (Diserens, 2009). Tyre loading could also play an important role (Table 1). When the tyre is under a light load, the volume of the tyre subject to increased inflation pressure increases (balloon effect) or, in a other way, when the distortion of the tyre decreases after increasing the inflation pressure, the contact pressure increases causing additional deformation of the soil. A could increase in both cases. Above a particular load threshold, the inflation pressure is insufficient to counter the load, so the tyre distorts under the weight and A increases.

Contact Area of Agricultural Tyres, Estimation,
Table 1 Influence of loading on farming trailer contact area assessment. Two examples

Loading [%]	Wheel load [kN]	Inflation pressure [kPa]	Contact area [m ²]
28L-26			
22	9.8	150	0.179
22	9.8	180	0.194
72	32.4	150	0.308
72	32.4	180	0.277
100	45.1	190	—
340/65R18			
31	6.9	450	0.060
31	6.9	500	0.067
98	22.1	460	0.102
98	22.1	510	0.098
100	22.6	540	—

The influence of the load on the inflation pressure depends on the initial inflation pressure and on the volume of the tyre too. The greater the tyre volume and initial inflation pressure, the smaller the inflation pressure variation for loads will be. In comparison with the variations of A or of the mean contact pressure, the variation of the inflation pressure following the loads remains negligible (Diserens, 2009).

Influence of the soil resistance on the contact area A

Several authors note an increase in A when PR of the top-soil decreases (Söhne, 1953; Mc Kyes, 1985; O'Sullivan et al., 1999). However, the opposite can occur (Diserens, 2009). At the same loads and inflation pressures, A values of the farming trailer tyres and traction tyres were measured for two different soils: one on natural grassland ($PR = 15.5$ MPa) and one on winter barley stubble ($PR = 11.7$ MPa) (Figure 3).

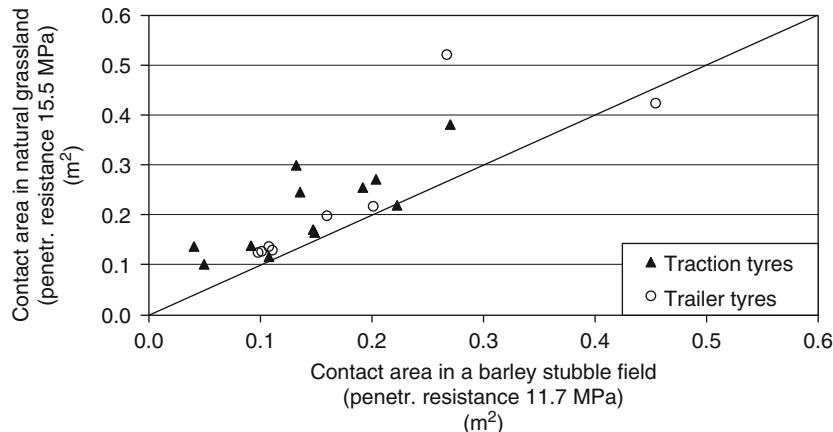

On harder, natural grassland, higher A values were measured. Comparing distortion of the internal contour of a traction tyre 520/70R34 on concrete and on a sandy silt soil, using a laser device placed inside the tyre, Schlotter and Kutzbach (2001) note greater flattening of the tyre on concrete; on a flexible soil, tyre distortion is less marked. On a hard soil, A mainly depends on tyre stiffness, while in the open field, the plasticity and elasticity of the soil combine with that of the tyre, and as the two elements adapt to each other, the distortion of the tyre is reduced. Results on the field and in laboratory show that there is no necessarily linear relationship between soil hardness and contact area.

Summary

- All the measurements for the contact area A occurred are carried out for stationary tyres. For an estimation of the dynamic contact area, it is recommended that the dynamic load for traction tyres be taken into account.
- The connection between the wheel load and the tyre size of a traction tyre and of a trailer tyre is not similar. Consequently it is necessary to develop and use distinct relationships to evaluate A of farming tyres.
- By low loading, A can increase with an increase of inflation pressure. For reliable estimations, loading values above 50% of the maximum permissible load are recommended.
- By estimating A , the aim is henceforth to provide a parameterization of soil hardness while also considering tyre stiffness.

CONTINUITY EQUATION

A statement, in mathematical form, that for a conserved substance (i.e., one, such as water, that is neither created nor destroyed in the soil), the time rate of change of content must equal the negative rate of the change of flux with distance (i.e., the amount per unit time entering minus the amount exiting a volume element of soil).

CONTROLLED TRAFFIC FARMING

Thomas Anken, Martin Holpp
 Federal Department of Economic Affairs, Agroscope Reckenholz-Tänikon Research Station ART, Ettenhausen, Switzerland

Definition

Controlled traffic farming (CTF) is a farming system where all field traffic is restricted to permanent, distinct parallel traffic lanes (Figure 1). These traffic lanes are normally untilled and not planted to optimize traction and traffic ability. Soil in the intervening beds is managed to provide the most favorable conditions for crop performance uncompromised by traffic and associated compaction (Tullberg, 2001).

Controlled Traffic Farming, Figure 1 In contrast to random traffic system where the working widths are not adjusted, all the machines are running on the same tracks with a controlled traffic farming system.

Controlled Traffic Farming, Figure 2 In 1983, the first trials have been started with a widespan Gantry vehicle at the Silsoe Research Institute in the UK.

History

The first CTF research projects started with a widespan Gantry in 1983 at the Silsoe Research Institute in the United Kingdom (Chamen et al., 1992). This vehicle had a 12-m-wide track. In the field, the drive wheels were positioned

at right angles to the lateral axis of the frame. On the road, the wheels were positioned parallel to the frame (Figure 2). Compared to the tracked surfaces, Chamen et al. (1992) already observed in these first experiments increased yields and an important decrease in fuel consumption for the

tillage operation and an improvement of the soil structure on the untrafficked area. In spite of good results, the gantry system did not make the breakthrough. This changed in the 1990s in Australia, where CTF was applied with conventional machinery. The increased working widths of the machines and satellite guidance systems made it possible to practice CTF without wide-span vehicles. Yule (2000) estimated for Australia in 1995 a surface of 3,000 ha and already 300,000 ha in year 2000. In 2009, about 3 million hectares were estimated in Australia (Tullberg, 2009). This shows that Australia is by far the leading nation. First initiatives in Europe have been started by Great Britain, Denmark, the Netherlands, Switzerland, Germany, Czech Republic, and Slovak Republic. In contrast to the overseas countries where track width of 3 m are very common, the European countries are practicing CTF mostly with smaller track width. This is due to road regulations which are not allowing vehicles wider than 2.55 m to run on the roads.

Advantages of CTF

- Better soil structure which leads to less fuel consumption for tillage operations. As less power is needed, it is possible to decrease the tractor sizes.
- Increased yields due to the improved soil conditions.
- Better water infiltration and decreased soil erosion due to undestroyed open soil pores (earthworm burrows, cracks).
- Better traffic ability on the consolidated tracks what widens the possibilities for plant protection interventions under wet soil conditions.
- Better nutrient availability due to the better soil structure and improved gas exchange. First results are showing that also the emission of nitrous oxide (Ball et al., 1999) might be reduced.

Inconveniences of CTF

- Field operations can only be executed with adapted equipment.
- Once a track system has been chosen, this system has to be applied during the following years. All the machines have to fit into this system.
- In case of a damaged machine, the exchange with another machine may cause a problem as the replaced machine has to fit into the chosen working and track width.
- Auto steering systems are causing extra costs.
- As traffic over the field is only possible on the defined tracks, the transportation of harvested crops is more time consuming (no shortcuts across the field are possible anymore).
- Sugar beet and potato harvester are not easy to fit into a CTF pattern as their working widths are small and the weights are extremely high. Machineries like the multiphase system for the sugar beet harvest have to be adapted.

The frictional resistance toward a tangential stress tending to slide one surface against another is proportional to the normal stress pressing the bodies together.

COUPLED HEAT AND WATER TRANSFER IN SOIL

Joshua L. Heitman¹, Robert Horton²

¹Soil Science Department, North Carolina State University, Raleigh, NC, USA

²Agronomy Department, Iowa State University, Ames, IA, USA

Synonyms

Coupled heat and water transfer in soil is sometimes referred to more generically as coupled heat and mass transfer or coupled energy and mass transfer.

Definition

Coupled heat and water transfer in soil refers to the connected processes of heat and water flow in and through the three-phase (i.e., solid, liquid, and gas) soil system, where heat may be latent and/or sensible and water may be liquid and/or vapor. The processes are coupled because water moving through the soil system always carries with it heat, i.e., convective heat transfer, and temperature differences in the soil system, which also drive heat transfer and water flow. Furthermore, soil water content influences soil thermal properties (e.g., heat capacity, thermal conductivity, and thermal diffusivity), and even the extent to which the soil surface absorbs radiant energy (i.e., albedo) for radiative heat transfer. The soil thermal environment, in turn, influences the extent to which water partitions between liquid and vapor phases.

Coupled heat and water transfer in soil

Background and applications

Coupled heat and water transfer is commonplace in nature and has long been recognized (e.g., Bouyoucos, 1915). When it rains both water and heat enter the soil. As the sun rises and warms the soil surface, the resultant water vapor pressure deficit drives water vapor movement in the soil. This water vapor carries with it both sensible and latent heats, which are transferred through the soil to the atmosphere. As the sun begins to set, the soil surface cools and water vapor from the atmosphere condenses on the soil, losing latent heat through phase change. This liquid water is adsorbed on surfaces due to affinity between solid and liquid or liquid and liquid, and the water may move deeper into the soil profile. In either case, the water carries heat into the soil system by replacing soil air with lower enthalpy per unit volume. This diurnal cycle is present to greater and lesser extents in terrestrial environments worldwide. Annual seasonal cycles occur as well.

Temperature gradients exist in soil due to periodicity of insolation, geothermal temperature distributions, functioning of buried cables, heating and cooling pipes, etc. Existence of temperature gradients causes fluxes of heat and water in soil. All soil biological, chemical, and physical processes are influenced by the fluctuations of soil water content and soil temperature that result from coupled heat and water transfer processes. Coupled heat and water processes occurring in shallow surface soil also exert critical influences on land–atmosphere exchange and drive climate dynamics. Yet, because surface soil is the most dynamic portion of the geosphere, full understanding of these processes remains elusive. Early field experiments provided the first opportunity to observe temporal patterns in near-surface soil moisture and temperature (e.g., Jackson, 1978). Since then, soil-coupled heat and water processes have been parameterized in large-scale models, often with limited appreciation for ubiquitous order-of-magnitude variations in hydrologic and thermal properties within the surface few centimeters of

soil. Routine measurements are also unable to capture rapidly shifting near-surface soil heat and water processes. Still, soil remains so central to understanding life that the 2007 Phoenix Mars Mission included devices specifically designed to measure soil temperature, thermal properties, and water content (Cobos et al., 2006).

Improved insight into coupled heat and water transfer is needed as a basis for more complete understanding of soil water and temperature conditions, soil water evaporation, crop and weed seed germination, nutrient cycling, pesticide volatilization, surface fluxes of carbon dioxide, and trace gas emissions from soil. Improved understanding of coupled heat and water transfer is also fundamental to understanding of the interaction between climate and the near-surface soil environment, as well as the implications of climate change.

Transfer mechanisms

Three principal mechanisms, radiation, convection, and conduction, are responsible, simultaneously, for the transfer of heat in soil. Radiative energy transfer includes incoming direct and diffuse solar (shortwave) radiation as well as longwave sky radiation to the soil surface and longwave radiation emitted outward from the soil surface. Radiative transfer is a significant component of heat transfer at the soil surface, but its significance decreases below the soil surface. Convective heat transfer in soil is associated with a net flux of fluids (liquid and gas). Convection may be responsible for a major portion of the soil heat transfer during periods of large water flux (e.g., during rainfall or irrigation). Convection is also important via vapor fluxes in shallow unsaturated soil layers when large thermal gradients occur. Conduction heat transfer involves the transfer of heat at a molecular scale from positions of large kinetic energy (high temperature) to positions of small kinetic energy (low temperature). Generally, radiative heat transfer primarily occurs at the surface. Convection and conduction occur within soil. In soil, conduction and convection often occur together.

For isothermal water transfer, we typically consider two driving forces: the chemio-potential gradient of soil water and gravity. Refer to [Water Flow](#) for further description. For non-isothermal water transfer, temperature gradients also act as a driving force. Soil moisture transfer induced by a temperature gradient is called thermal moisture transfer (TMT). The flow resulting due to interaction of TMT with moisture flow induced by factors other than temperature gradient is called *non-isothermal moisture transfer* (NIMT) (Globus, 1983). TMT can be vapor, liquid, and combined (series-parallel). For unsaturated conditions, where we have both liquid and vapor components of water, this leads to two additional components of flow, thermal vapor transfer and thermal liquid transfer.

Thermal vapor transfer results mainly from the dependence of water vapor pressure (or concentration) on temperature. As temperature increases, water vapor pressure increases. Thus, a temperature gradient leads to a water

vapor gradient. Treated as diffusion, this temperature gradient drives thermal vapor transfer toward cooler temperature. Like diffusion, thermal vapor transfer depends on the diffusion path and therefore liquid-free porosity and tortuosity, which are in turn related to soil texture, structure, and bulk density.

Liquid TMT can occur by several mechanisms: (1) Expansion and contraction of entrapped air due to temperature change pushes liquid back and forth in nearly saturated soil, for example, in the capillary fringe and near the groundwater table. This is called the *thermomeric effect*, and it is transient. (2) Due to temperature dependence of surface tension at a liquid–air interface, a temperature gradient induces a gradient of surface tension and a respective gradient of capillary pressure of menisci. This can induce hydrodynamic flow just the same as under the influence of a pressure difference of any other origin. This is called the *thermo-capillary meniscous* flow. (3) When a thermal gradient exists along the liquid–air interface of a liquid film covering solid particle(s), the induced surface tension gradient produces *thermocapillary film* flow. The velocity profile of this flow (as a function of distance to solid phase) differs from that of hydraulic flow, since the moving force is applied only to the interface. Both thermocapillary flows are directed toward lower temperature. (4) When enthalpy of pore liquid differs from that of bulk liquid, and, particularly, when there exists some distribution of enthalpy as a function of distance to the solid phase, *thermoosmotic* flow can occur. Thermoosmotic flow directs toward higher temperature. (5) In unsaturated soil, there exists a special *vapor–liquid series-parallel* (or *combined*) TMT, consisting of thermal vapor micro-diffusion inside air space of a pore, combined with liquid flow in capillary and film elements of soil matrix. Because of its dual nature, this flow bears features appropriate both to vapor diffusion as well to liquid flow. For example, it depends upon ambient gas pressure P as vapor diffusion (diminishing with rise of P) and on wettability of a medium (liquid flow diminishes in hydrophobic media).

One particular case of moisture migration in soil under the influence of a temperature gradient is the movement of moisture in soils induced by freezing. This process is often described as TMT, where the driving force is formally represented by the temperature gradient. However, actual water flow in this case is caused by the gradient of chemical potential of water, which arises due to locally reduced liquid water content at and behind the freezing front after soil water freezes. Differences in unfrozen water content create differences in matric potentials. So in this case, it would be proper to substitute temperature gradient by hydrostatic pressure gradient.

Transfer theory

Much of the current theory for describing coupled soil heat and water transfer is rooted in the diffusion-based formulation of Philip and de Vries from the 1950s and 1960s

(Philip and de Vries, 1957; de Vries, 1958), which treats gradients in soil water content and temperature (as well as gravity) as the drivers for liquid flow. This theory has since been modified by others to include the chemopotential gradient in water as a driver for water flow (in place of the water content gradient) (Sohocleous, 1979; Milly, 1982). Alternate theory rooted in irreversible thermodynamics has also been developed (Cary, 1963; Taylor and Cary, 1964) but has mostly been applied treating soil water as a single-component fluid.

Here, we present a mechanistic framework following Philip and de Vries (1957), Milly (1982), and Nassar et al. (1992). The following theory assumes (1) the soil is rigid and inert; (2) hysteresis of water retention curves and transport coefficients can be neglected; (3) transfer of mass and energy occurs only in the vertical direction; (4) the driving forces for water are temperature and matric pressure head gradients and gravity; (5) osmotic potential is negligible; (6) there is local thermodynamic equilibrium within the soil; and (7) heat transfer occurs by conduction and by convection of latent heat and sensible heat.

Water flow

The total flux of water in the soil is the sum of liquid and vapor components

$$q_w = q_l + q_v, \quad (1)$$

where q_w , q_l , and q_v ($\text{kg m}^{-2} \text{s}^{-1}$) are the mass flux of water (total), liquid, and vapor, respectively. In saturated soil, q_v becomes negligible, whereas in relatively dry systems, q_v may be the dominant flux.

The liquid water flux q_l can be described as

$$q_l/\rho_l = -K \frac{\partial \psi}{\partial z} - K \mathbf{k} - D_{Tl} \frac{\partial T}{\partial z}, \quad (2)$$

where ρ_l (kg m^{-3}) is the liquid water density, K (m s^{-1}) is hydraulic conductivity, ψ (m) is the matric potential, z (m) is the vertical space coordinate, \mathbf{k} is a unit vector positive downward, D_{Tl} ($\text{m}^2 \text{s}^{-1} \text{K}^{-1}$) is the thermal liquid diffusivity, and T (K) is temperature. The first two terms on the right represent the classical Darcy–Buckingham flow, driven by the matric potential and elevation (viz. gravity) gradients. See Water Flow for further discussion. The third term on the right represents liquid flux driven by a thermal gradient. A consensus on the formulation of D_{Tl} has not arisen in the literature (Prunty, 2009), but it can be loosely defined according to the mechanisms described in the previous section (viz. temperature effects on liquid water properties). Note also that the temperature effects on liquid flux are sometimes included in the formulation of K via fluid properties (e.g., viscosity).

The water vapor flux q_v is treated as simple diffusion

$$q_v = -D \frac{\partial \rho_v}{\partial z} \quad (3)$$

where ρ_v (kg m^{-3}) is the water vapor density and D ($\text{m}^2 \text{s}^{-1}$) is an effective molecular diffusivity.

In order to express q_v in terms of the same drivers given in [Equation 2](#), ρ_v is appropriately treated as a function of ψ and T . Note that gravity influences on q_v are generally ignored. Expanding ρ_v with respect to ψ and T gives

$$\frac{\partial \rho_v}{\partial z} = \frac{\partial \rho_v}{\partial \psi} \frac{\partial \psi}{\partial z} + \frac{\partial \rho_v}{\partial T} \frac{\partial T}{\partial z}. \quad (4)$$

Combining this expression with [Equation 3](#) then gives

$$q_v = -D \frac{\partial \rho_v}{\partial \psi} \frac{\partial \psi}{\partial z} - D \eta \frac{\partial \rho_v}{\partial T} \frac{\partial T}{\partial z}. \quad (5)$$

Here, consistent with many formulations in the literature, we add an additional term η , which has been proposed to account for increased vapor flux due to locally enhanced thermal gradients across air gaps (viz. air-filled pores) within the three-phase medium (Cass et al., 1984). [Equation 5](#) can then be simplified to

$$q_v / \rho_l = -D_{\psi v} \frac{\partial \psi}{\partial z} - D_{T v} \frac{\partial T}{\partial z}, \quad (6)$$

where $D_{\psi v}$ ($\text{m}^2 \text{s}^{-1}$) and $D_{T v}$ ($\text{m}^2 \text{s}^{-1} \text{K}^{-1}$) are termed the matric vapor and thermal vapor diffusivities, respectively, defined implicitly by [Equation 5](#). We divide here by ρ_l so that $D_{\psi v}$ and $D_{T v}$ provide volume fluxes equivalent to transport terms defined in [Equation 2](#) for liquid water.

Total mass of water in the soil system is the sum of the liquid and vapor mass components

$$\theta_l \rho_l + \theta_v \rho_v,$$

where θ ($\text{m}^3 \text{m}^{-3}$) is the volume fraction of the total soil volume occupied by a given component and subscripts are as defined previously. We assume all soil pore space is occupied either by liquid water or water vapor such that $\theta_l + \theta_v =$ the pore (or void) fraction of the total soil volume. Therefore, as θ_l increases, θ_v must proportionately decrease.

Using conservation of mass, the continuity equation can be expressed as

$$\frac{\partial}{\partial t} (\theta_l \rho_l + \theta_v \rho_v) = \nabla q_w, \quad (7)$$

where t (s) is time. In words, the change in water mass per soil volume with time is equal to the gradient in water mass flux. Expanding the left side of [Equation 7](#), using the dependency of ρ_v on ψ and T noted above and also the functional relationship between θ and ψ , we have

$$\begin{aligned} \rho_l \frac{\partial \theta_l}{\partial t} + \rho_v \frac{\partial \theta_v}{\partial t} + \theta_v \frac{\partial \rho_v}{\partial \psi} \frac{\partial \psi}{\partial \theta_l} \frac{\partial \theta_l}{\partial t} \\ + \theta_v \frac{\partial \rho_v}{\partial T} \frac{\partial T}{\partial t} = \nabla q_w. \end{aligned} \quad (8)$$

Finally, incorporating [Equations 1](#), [2](#), and [6](#), we have a general partial differential equation to describe transient water flow for unsaturated, nonisothermal conditions:

$$\begin{aligned} & \left(1 + \frac{\theta_v}{\rho_l} \frac{\partial \rho_v}{\partial \psi} \frac{\partial \psi}{\partial \theta_l} - \frac{\rho_v}{\rho_l} \right) \frac{\partial \theta_l}{\partial t} + \frac{\theta_v}{\rho_l} \frac{\partial \rho_v}{\partial T} \frac{\partial T}{\partial t} \\ &= \nabla \left[(K + D_{\psi v}) \frac{\partial \psi}{\partial z} + (D_{T l} + D_{T v}) \frac{\partial T}{\partial z} + Kk \right]. \end{aligned} \quad (9)$$

Note that we have divided all terms by ρ_l and used the relationship between θ_l and θ_v to replace $\partial \theta_v / \partial t$ with $-(\partial \theta_l / \partial t)$ in order to simplify the expression.

Heat flow

Ignoring radiation within the soil, the total flux of heat in the soil system is the sum of conduction heat transfer and both latent and sensible heat transfer via convection:

$$q_h = -\lambda \frac{\partial T}{\partial z} - \rho_l L D_{\psi v} \frac{\partial \psi}{\partial z} + c_l (T - T_0) q_w, \quad (10)$$

where q_h (W m^{-2}) is the total heat flux, λ ($\text{W m}^{-1} \text{K}^{-1}$) is the thermal conductivity of the soil, L (J kg^{-1}) is latent heat of vaporization, c_l ($\text{J kg}^{-1} \text{K}^{-1}$) is the specific heat of liquid water, and T_0 (K) is an arbitrary reference temperature. The first term on the right is simple Fourier conduction heat transfer, and λ is dependent on water content and temperature. The remaining terms on the right represent heat carried with the nonstationary component of the soil system – water. The first of these terms is diffusion of water vapor, with associated latent heat from phase change, according to the matric potential gradient. The diffusion vapor flux is a component of the flux given in [Equation 6](#). The rightmost term in [Equation 10](#) is the convective transfer of sensible heat associated with the mass water flux. Because the water flux is on a mass rather than a volume basis, it is appropriate to consider the specific heat of the liquid to determine the associated heat transfer. However, the quantity of heat must be determined by specifying some reference state $c_l T_0$.

The total heat stored (relative to the reference state) in the three-phase soil system includes both sensible and latent components:

$$(c_s \rho_b + c_l \rho_l \theta_l + c_v \rho_v \theta_v) (T - T_0) + L \rho_v \theta_v,$$

where c_s ($\text{J kg}^{-1} \text{K}^{-1}$) is the specific heat of the solid, ρ_b (kg m^{-3}) is the soil bulk density (mass of solid per total soil volume), and c_v ($\text{J kg}^{-1} \text{K}^{-1}$) is the specific heat of the vapor.

Using conservation of energy

$$\begin{aligned} \frac{\partial}{\partial t} [(c_s \rho_b + c_l \rho_l \theta_l + c_v \rho_v \theta_v) (T - T_0) \\ + L \rho_v \theta_v] = \nabla q_h. \end{aligned} \quad (11)$$

This is to say, the change in the quantity of heat stored per volume with time is equal to the gradient in total heat flux. The left side of this expression can be expanded in terms T and θ_l using previously discussed relationships for ρ_v and ψ with T and between θ and ψ

$$H_1 \frac{\partial T}{\partial t} + H_2 \frac{\partial \theta_l}{\partial t} = \nabla q_h, \quad (12)$$

where

$$\begin{aligned} H_1 &= C_b + [L + c_v(T - T_0)] \theta_v \frac{\partial \rho_v}{\partial T}, \\ H_2 &= [L + c_v(T - T_0)] \theta_v \frac{\partial \rho_v}{\partial \psi} \frac{\partial \psi}{\partial \theta} \\ &\quad + c_l \rho_l (T - T_0) - \rho_v [L + c_v(T - T_0)] - W \rho_l. \end{aligned}$$

The expression is simplified by considering a bulk volumetric heat capacity C_b ($\text{J m}^{-3} \text{K}^{-1}$) in place of the sum $c_s \rho_v + c_l \rho_l \theta_l + c_v \rho_v \theta_v$. We here also add an additional term W (J kg^{-1}) to account for the exothermic process of wetting the porous medium with changes in water content (Prunty, 2002).

Finally, combining Equations 10 and 12, we can describe transient heat flow in unsaturated, nonisothermal soil:

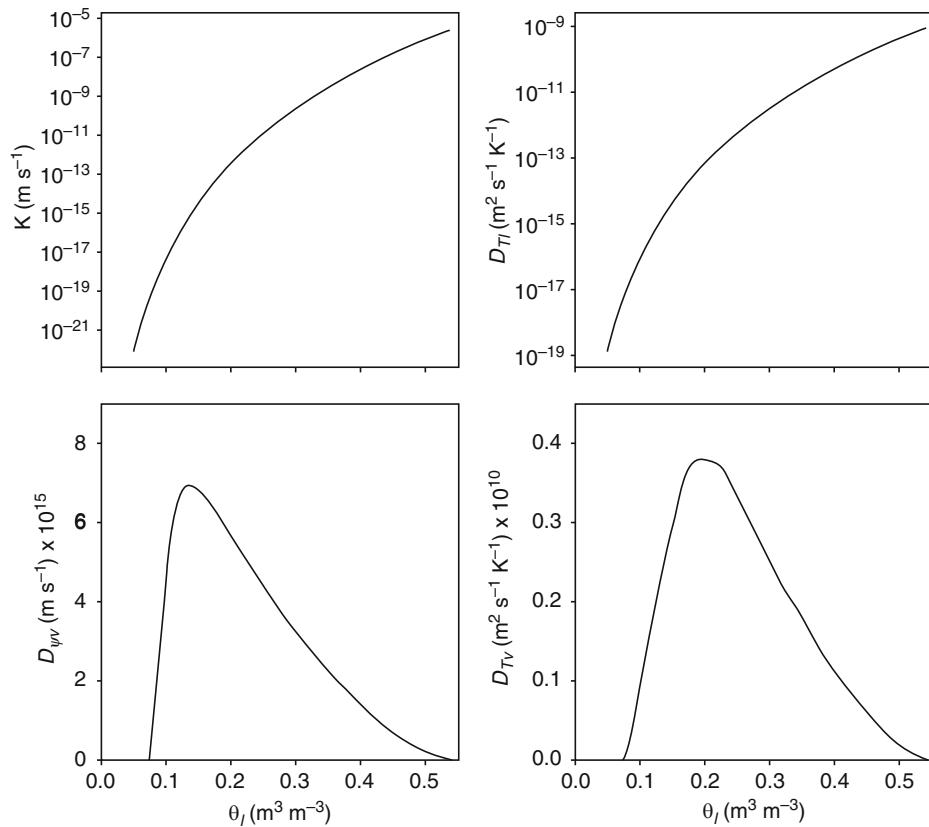

$$\begin{aligned} H_1 \frac{\partial T}{\partial t} + H_2 \frac{\partial \theta_l}{\partial t} &= \nabla \left[\lambda \frac{\partial T}{\partial z} + \rho_l L D_{\psi v} \frac{\partial \psi}{\partial z} \right. \\ &\quad \left. - c_l (T - T_0) q_w \right]. \end{aligned} \quad (13)$$

The q_w term in Equation 13 can be further expanded using Equations 1, 2, and 6.

Transfer coefficients for convective heat transfer

Insight about the relative magnitudes of liquid and vapor flux components for convective heat transfer is critical to understanding coupled heat and water transfer. Theory presented above provides a way to envision ψ and T gradients as drivers for these flux components. It is also important to recognize how the magnitudes of liquid and vapor fluxes vary with associated transfer coefficients, which greatly depend on, among other things, the soil water content (Nassar and Horton, 1997).

Figure 1 presents moisture transfer coefficients K , D_{Tl} , $D_{\psi v}$, and D_{Tv} as a function of θ_l for a silt loam soil over the range from completely dry to saturation (after Heitman

Coupled Heat and Water Transfer in Soil, Figure 1 Hydraulic conductivity (K), thermal liquid diffusivity (D_{Tl}), isothermal vapor diffusivity ($D_{\psi v}$), and thermal vapor diffusivity (D_{Tv}) as a function of soil liquid water content (θ_l). Transfer coefficients are based on the properties of a silt loam soil.

et al., 2008a). Several points are readily apparent: at very low water contents, convection through either liquid or vapor is minimal, as evidenced by the small magnitudes of all four transfer coefficients. When liquid water is absent or water content is very small, conduction must be the dominant mechanism for heat transfer. As water content begins to increase, all transfer coefficients increase, but the most pronounced increase is for vapor coefficients $D_{\psi v}$, and D_{Tv} . In this range, air-filled porosity remains high so as to readily allow diffusion (with rate also depending on drivers). Hence, while conduction may remain important, heat transfer may also occur with convection via vapor, particularly latent heat. As liquid water content continues to increase and air-filled porosity is diminished, $D_{\psi v}$, and D_{Tv} then decline. However, liquid transfer coefficients K and D_{Tl} continue to increase over the whole range in θ_l . Because liquid water carries with it only sensible heat, and because the vapor flux is limited, convection in wet soil occurs primarily as sensible heat alone.

Recent developments in measurement of latent heat fluxes

Measurement of all component fluxes for fully coupled heat and water transfer remains a challenging task (Jury and Lettley, 1979; Cahill and Parlange, 1998; Heitman et al., 2007). Soil heat flux measurement is typically limited to conduction heat flux via soil heat flux plates or other methods. See *Energy Balance of Ecosystems*. Liquid water flux has routinely been estimated from mass balance or by utilizing measured soil water potential and knowledge of the soil hydraulic conductivity function. See *Soil Water Flow*. Measurement of water vapor and latent heat flux has mostly been limited to above-ground approaches or gross estimates from weighing lysimeters. See *Lysimeters: A Tool for Measurements of Soil Fluxes*. However, a new technique has recently been developed to provide measurements of latent heat fluxes within the soil (Heitman et al., 2008b, c). This technique involves measuring the balance of sensible heat terms included in coupled heat and water transfer.

The basis for this approach begins with an approximation of [Equation 13](#) for a finite size soil volume and finite time increment. For short time steps (e.g., a few hours), we assume that only temperature T changes with time t on the left side of [Equation 13](#). We then take a single, measured heat capacity C_b to represent the soil. In making this assumption, we treat liquid and vapor concentrations as constant. While origination of the latent heat flux (viz. evaporation) within the soil volume does mean that liquid water is being changed to vapor, the net change in liquid and vapor content has a small influence on sensible heat storage. Exiting water vapor from within the soil volume is readily replaced by evaporation of small quantities of liquid water so that for a small time step, there is little net change in either vapor or liquid water contents in terms of their impact on C_b (for either component) or latent heat storage (for water vapor).

To complete the heat balance, we also must approximate the heat flux terms included in the right side of [Equation 13](#). It is possible to measure the conduction heat flux $-\lambda \partial T / \partial z$ by standard approaches. To approximate the gradient in conduction heat flux $\nabla(\lambda \partial T / \partial z)$ across the soil volume, $-\lambda \partial T / \partial z$ must be measured at multiple depths (the vertical boundaries for the soil volume of interest). In unsaturated conditions, where the soil latent heat flux is of significant magnitude, liquid mass flux and associated convective sensible heat transfer are relatively minor (as discussed in the previous section). The mass flux and thereby associated convective sensible heat flux with water vapor is also small, because of water vapor's relatively low heat capacity. Thus, the rightmost term of [Equation 13](#) is neglected. These assumptions lead to an approximate heat balance for the soil:

$$C_b \frac{\partial T}{\partial t} \simeq \nabla \left[\lambda \frac{\partial T}{\partial z} + \rho_l L D_{\psi v} \frac{\partial \psi}{\partial z} \right]. \quad (14)$$

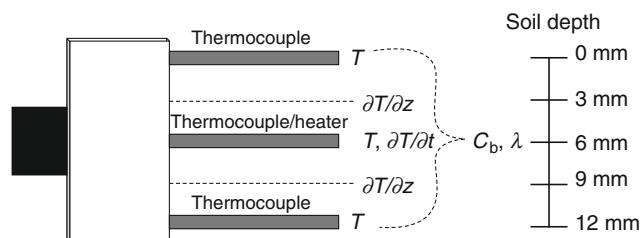

In this balance, only the latent heat flux associated with diffusion of water vapor is not directly measurable. However, by knowing the change in sensible heat storage and the gradient in conductive heat flux, this term can be determined as a residual to the heat balance. In practice, we represent this balance as

$$(G_0 - G_1) - \Delta S = LE, \quad (15)$$

where G_0 and G_1 (W m^{-2}) represent the heat fluxes ($-\lambda \partial T / \partial z$) at the upper and lower boundaries of our finite depth increment dz , respectively, ΔS (W m^{-2}) represents the change in sensible heat storage ($C_b \partial T / \partial t$) within dz , and E ($\text{kg m}^{-2} \text{s}^{-1}$) is the evaporation rate corresponding to the diffusion of water vapor within dz .

Changes in T and thermal properties (C_b and λ) with t and z form the basis of this approach. This information is required at the millimeter scale in order to account for penetration of the drying front and associated latent heat fluxes within the soil. The recent development of heat-pulse sensors ([Figure 2](#)) makes it possible to measure all of the required terms at a fine depth scale.

Heat-pulse sensors consist of three small (1.3-mm-diameter) needles. One needle contains a resistance heater

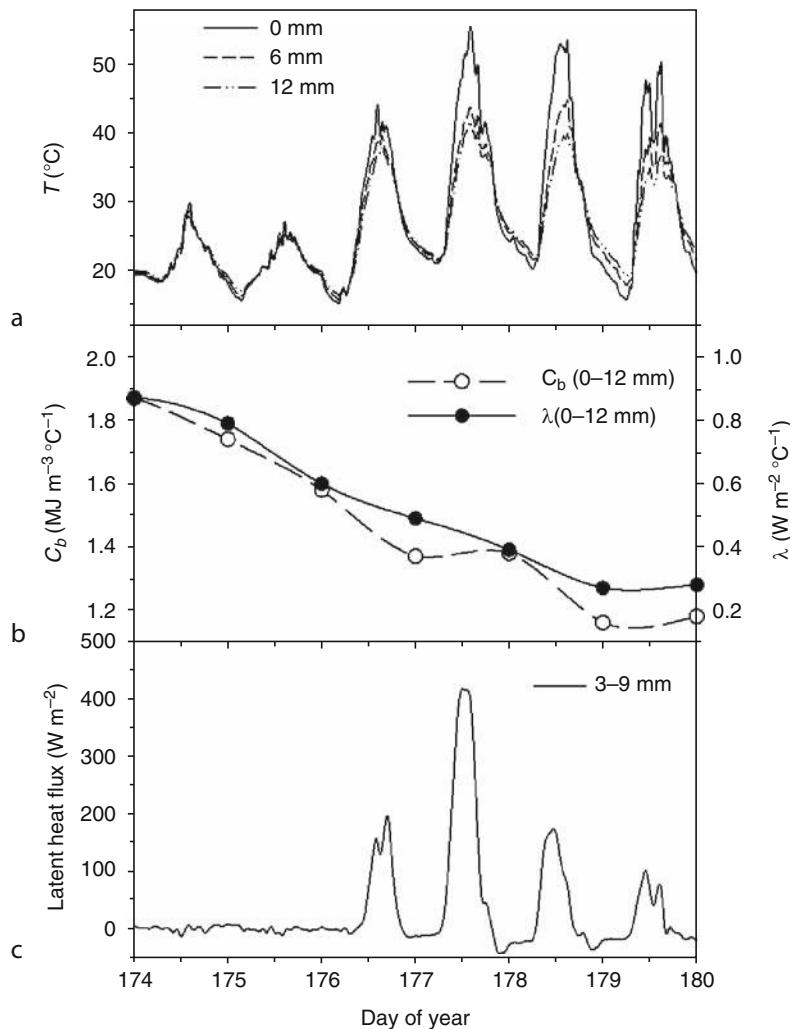

Coupled Heat and Water Transfer in Soil, Figure 2 Heat-pulse sensor as used for measurement of the soil sensible heat balance. Abbreviations are temperature (T), distance (z), time (t), volumetric heat capacity (C_b), and thermal conductivity (λ). The diagram is not to scale.

for applying a small heat input, while the remaining needles contain thermocouples (or thermistors) for measuring temperature response at a fixed distance (typically 6 mm) from the heater. The temperature response can be evaluated to determine C_b and λ . The temperature sensing needles can also be used to passively determine ambient temperature conditions within the soil in order to track temperature changes with time and depth ($\partial T/\partial t$ and $\partial T/\partial z$). [Figure 2](#) illustrates how parameters are collected by the sensor for calculation of the sensible components of [Equation 15](#).

Data (T , C_b , and λ) from a field experiment are shown in [Figure 3](#). These data illustrate a drying event following rainfall on day of year (DOY) 172. Here, the inter-diurnal trend in ambient T is upward at all depths as the soil dries. Drying also produces first rapid and then more gradual declines in soil water content-dependent C_b and λ .

Following the approach outlined above, these data are used for calculation of G_0 and G_1 at depths of 3 and 9 mm, respectively, and ΔS for the 3–9 mm depth increment. Then, from [Equation 15](#), we estimate the net latent heat flux LE for the 3–9 mm depth increment ([Figure 3c](#)).

Results show how the latent heat flux varies diurnally and also shifts in magnitude during the drying event ([Figure 3c](#)). The net latent heat flux for the 3–9 mm depth increment is near zero through DOY 176 with most of the latent heat flux originating in the 0–3 mm soil layer (classic Stage 1 evaporation). Thereafter, the net latent heat flux begins to grow in daily magnitude, illustrating the penetration of the drying front below the 3 mm depth. Summed over multiple depth increments, the net latent flux observed here is equivalent to the total net latent heat flux associated with water evaporation from the soil profile. Comparison of data collected with the sensible heat

Coupled Heat and Water Transfer in Soil, Figure 3 Measurements obtained with a heat-pulse sensor for computing [Equation 14](#): (a) soil temperature (T), (b) volumetric heat capacity (C_b) and thermal conductivity (λ), and (c) Latent heat flux. Data were collected in a bare soil field plot, following rainfall on day of year 172. The legends indicate distance below the soil surface.

balance method for determining the latent heat flux to lysimeters and above-ground approaches for total latent heat flux has generally been favorable.

Summary

Coupled heat and water transfer refers to the interconnectedness of heat and water transfer processes in soil. Water moving through soil carries with it heat, and soil water content influences soil thermal properties. Soil temperature gradients also drive water flow. Thus, coupling of soil heat and water transfer is a normal phenomenon in all natural and managed environments. By influencing microbial activity, plant water use, land-atmosphere exchange, and many other agrophysical processes, coupled soil heat and water transfer has implications at scales ranging from sub-millimeter to continental. These implications warrant careful consideration and study of coupled soil heat and water transfer. Coupled soil heat and water flow can be attributed to a variety of mechanisms. Convection of both sensible and latent heat serves as a primary linkage. Theory has been developed to describe mechanisms of flow. Yet, direct evaluation of the theory from measurements remains challenging, particularly evaluation of vapor flow components. Recent approaches developed to quantify latent heat fluxes within soil through use of a soil sensible heat balance offer some promise for assessing and refining theory. With new developments in measurement and continued interest from a range of scientific applications, coupled soil heat and water transfer will remain a challenging and important topic for study.

CRACKING IN SOILS

Pascal Boivin
 University of Applied Sciences of Western Switzerland (HES-SO), Geneva, Switzerland

Definition

Cracking refers to the forming of cracks in soils, due to soil shrinkage upon drying. This is considered at two

different scales, namely metric scale for soil horizon or profile, and infra millimetric scale for soil matrix, respectively.

Cracks

Cracks form in soils due to the shrink–swell movements of the soil plasma occurring with changes in water content. (The plasma was first defined by Brewer (1964). According to the SSSA glossary it is: “material, mineral or organic, of colloidal size and relatively soluble material that is not contained in the skeleton grains”). The swelling factors in the plasma are the phyllosilicates and the organic matter. Hence, cracking depends of the content in these constituents. Organic matter, however, also acts as a binding element, which stabilizes the soil structure (Kay, 1998).

At microscopic scale (thin soil sections), cracking was long ago observed as a consequence of soil drying (Brewer, 1964). Cracking is one of the processes generating soil structure and allowing its resilience (Kay, 1998). Micro cracks are structural pores according to Brewer’s classification. An increase in organic carbon content of the soil may result in an increase in plasma swelling and a decrease in bulk soil swelling (Boivin et al., 2009), thus an increase in micro cracking. Microscale cracking shows no preferential orientation.

At metric scale, large cracks (up to several centimeters wide) may open in soil horizons or profiles when the shrinkage is large enough to break the horizontal continuity of the soil. The volume of cracks can be easily estimated in the field (Abidine el and Robinson, 1971). This is generally observed with clayey soils containing phyllosilicates such as vertisols. Cracking causes soil subsidence and may induce preferential flow. Soil subsidence is an anisotropic shrinkage due to vertical collapse and horizontal cracking, which was described by Bronswijk (1991). Crack preferential flow was observed in the case of irrigated cracked soils (Tuong et al., 1996) and its characterization is reviewed by (Simunek et al., 2003; Allaire et al., 2009). The closure of cracks with time upon rewetting was poorly described. However, Favre et al. (1997) showed a complete crack closure after 2.5 h of irrigation in a vertisol.

Summary and conclusions

Cracking is induced by soil plasma volume change with water content and is a major soil structure resilience factor. Microscopic cracks are not preferentially oriented and represent a large part of the structural porosity. Macroscopic cracking is a particular case corresponding to clay phyllosilicate-rich soils. These cracks show a vertical preferential orientation, which may cause preferential flow.

CROP EMERGENCE, THE IMPACT OF MECHANICAL IMPEDANCE

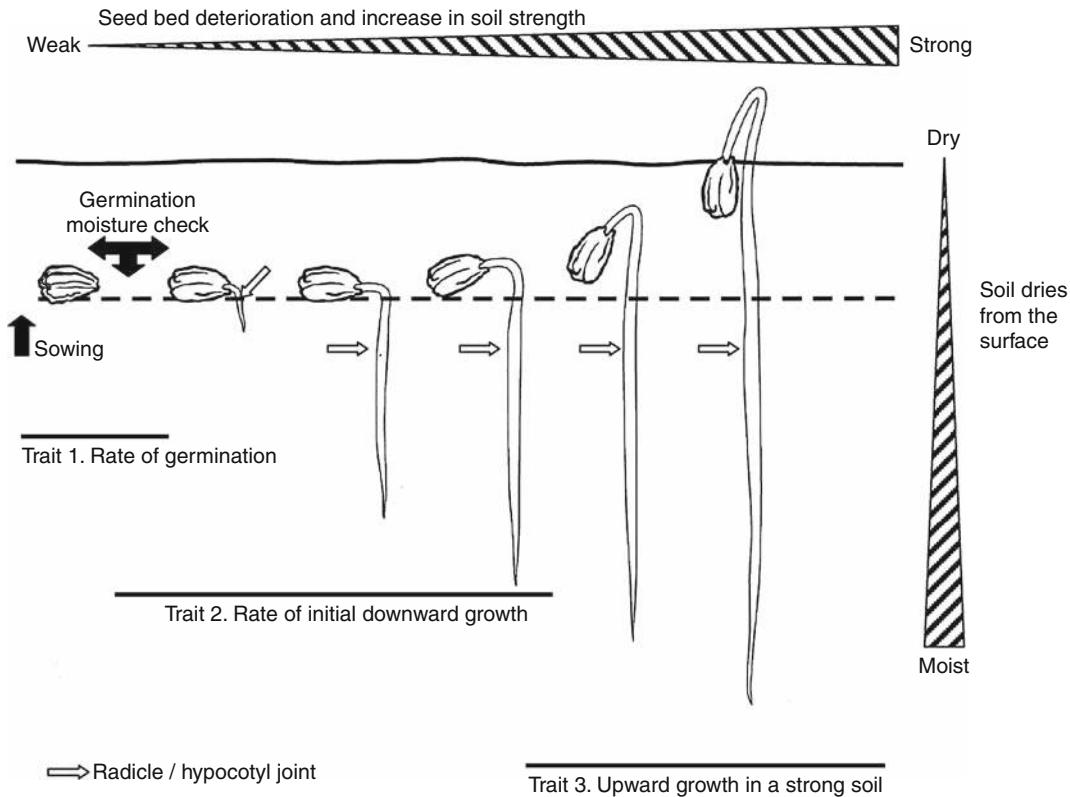

W. R. Whalley¹, W. E. Finch-Savage²

¹Department of Soil Science, Rothamsted Research, Harpenden, West Common, Hertfordshire, UK

²Warwick HRI, Warwick University, Wellesbourne, Warwick, UK

Definition and introduction

To emerge from a germinated seed, the shoot has to be capable of reaching the soil surface, while continued root growth is required to gain access to water in drying seedbeds. This is illustrated in Figure 1 where the seed must first germinate rapidly, then have rapid initial downward growth, and finally have high potential for upward shoot growth in soil of increasing impedance (Figure 1). Once a seed has germinated, seedling growth depends on temperature, water potential, and the mechanical strength of the seedbed (Collis-George and Yoganathan, 1985a, b; Finch-Savage et al., 1998; Townend et al., 1996; Whalley et al., 1999, 2001). Root and shoot elongation rate decrease with water potential in vermiculite (Sharp et al., 1988), but as soil dries it also tends to become stronger and mechanical impedance rather than water stress can become limiting (Weaich et al., 1992). Understanding the impact of mechanical impedance on seedling

Crop Emergence, the Impact of Mechanical Impedance, Figure 1 The phases of emergence in a drying seedbed of increasing mechanical impedance (Redrawn from Finch-Savage et al., 2010).

emergence can be difficult because soil strength and soil water status vary together. There is a need to disentangle the effects of water stress and mechanical impedance on emergence.

Soil strength and water status

The relationship between soil strength and water status is reasonably well understood (Whalley et al., 2007). In a seedbed, soil tends to be loose and its strength tends to result from capillary forces in the water menisci between soil particles. Whalley et al. (2007) showed that penetrometer resistance of loose soils is directly proportional to the effective stress, which in this case is the product of the degree of saturation and the matric potential. Penetrometer pressure of a soil can be greater than 1 MPa at a matric potential of -0.1 MPa (Mullins et al., 1992). Whalley et al. (1999) found that the penetrometer pressure of a sandy soil was 0.57 MPa at a matric potential of only -0.02 MPa. It is important to realize that matric potentials of -0.1 MPa or greater (i.e., in wetter soil) would have little effect on germination or seedling growth in the absence of mechanical impedance. Base water potentials for germination (i.e., the smallest water potential at which

germination can progress to completion (radical emergence)) are typically -1 MPa or less.

Soil strength and shoot elongation

In wheat (Collis-George and Yoganathan, 1985a, b), maize (Weaich et al., 1994), onion, and carrot (Whalley et al., 1999), elongation rate has a nonlinear dependence on mechanical impedance, so a small increase in strength of an initially weak seedbed is likely to have a large effect on emergence. For example, in onion and carrot, small differences in mechanical impedance result in a large reduction in shoot development. This behavior is similar to that observed in wheat (Collis-George and Yoganathan, 1985b) and maize (Weaich et al., 1996) coleoptiles, where small differences in the mechanical impedance of weak soils resulted in large differences in coleoptile elongation rate. Carrot shoots elongate from the tip shoots and increased in diameter in response to mechanical impedance, which is a trait associated with roots that elongate in strong soil (Atwell, 1990). Materechera et al. (1991) have suggested that the degree of thickening in seedling roots growing in strong soil can be used as a predictor of their ability to grow through strong soil. However, the thicker carrot shoots were less effective than their fine roots at

penetrating the strong sand, despite the observation that carrot shoots became even thicker in strong sand (Whalley et al., 1999).

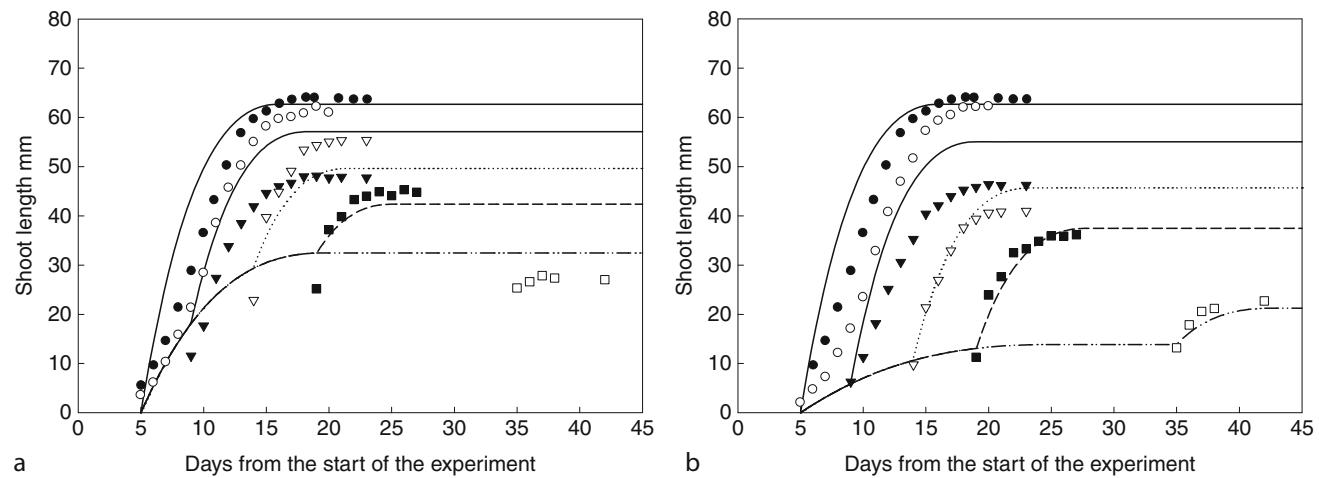

Temporal effects

The relationship between soil strength and water content in the seedbed is not constant in time. In comparison with carrot, onion shoots appear to be more effective at recovering following the removal of mechanical impedance (compare Figures 2 and 3). However, this recovery trait is not that well studied. When impedance is removed onion shoots elongate rapidly, whereas the initial recovery for carrot shoots is small. The differences between species in Figures 2 and 3 are likely to be due to the different elongation mechanisms. Removal of impedance and recovery is equivalent to soil weakening following rainfall. Flushes of emergence are often seen soon after rainfall and the recovery in shoot length in Figures 2 and 3 is a partial explanation.

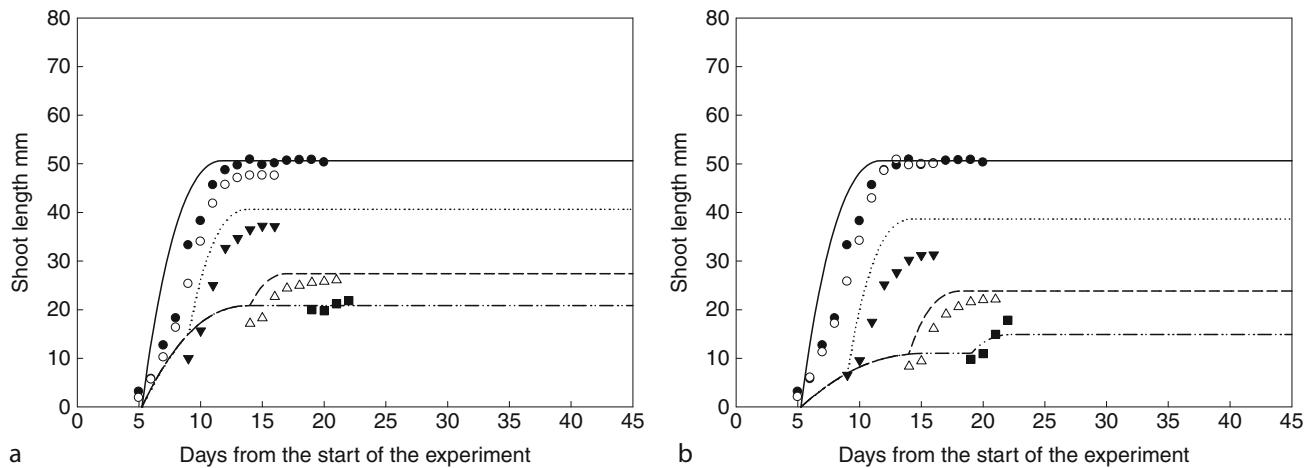

Critical stresses controlling emergence

It will be useful to explore the combinations of stress that are most important in an emerging crop. To do this a model will be of great value. The curves in Figures 2 and 3 were obtained from a shoot elongation model that predicts elongation rate depending on the particular combination of water stress, mechanical impedance, and temperature (see Whalley et al., 1999). Clearly, it is possible to have any combination is possible, but some combinations are likely to be more commonly associated with emergence problems. Even relatively wet soils can have high soil strength, for example, we have measured mean penetrometer pressures of 0.57 MPa and a range from 0.3 to

1.8 MPa in a sandy soil which was equilibrated to a water potential of -0.02 MPa. Under these conditions the model predicts that the effect of mechanical impedance will reduce shoot elongation in both carrot and onion so that the mean final shoot length is equal to a typical sowing depth of approximately 15 mm (i.e., 50% emergence). However, a water potential of -0.02 MPa will have a negligible effect on the numbers of both carrot (Finch-Savage et al., 1998) and onion (Finch-Savage and Phelps, 1993) seeds that would germinate and this is likely to be true for all crop seeds. There is a moisture sensitive block to germination (Finch-Savage and Phelps, 1993; Finch-Savage et al., 1998) that is likely to prevent germination in dry soils, so that seeds tend to germinate following rain or irrigation. As water evaporates from the surface of a wet and bare seedbed the hydraulic conductivity quickly falls to a very low value with decreasing surface water content. The low hydraulic conductivity of the dry surface will tend to reduce the rate of water loss from deeper layers, as, for example, in the results of Lascano and van Bavel (1986). Therefore after germination, the root will grow downward into increasingly wet soil and even when the soil surface becomes dry the seedling may not be water stressed, because the root is likely to be in contact with moist soil. Thus, in practice, for crop emergence in the post-germination phase, water stress may be less important than the effects of high soil strength due to the soil surface drying. This argument justifies placing a greater emphasis on mechanical impedance than water stress when developing models for pre-emergence seedling development. The seedling is only likely to experience very low water potentials in the early stages of development when the root is short or in arid climates.

Crop Emergence, the Impact of Mechanical Impedance, Figure 2 Recovery of onion shoots on sloping filter boards following exposure to mechanical impedance in sand cultures equivalent to penetrometer pressures of 0.19 MPa (a) or 0.53 (b) for 5 days \circ , 9 days ∇ , 14 days $_$, 19 days \blacksquare and 35 days \square . Data for seedlings which have never been impeded are also shown \bullet for purpose of reference. The curves shown were obtained using model for shoot elongation as a function of soil strength, water stress, and temperature (Whalley et al., 1999). Only one curve is shown for both the seedlings which were never impeded and the seedlings which were recovered from the impeding environment after 5 days because the time to germination is 5 days at 20°C (t_g). At time zero the experiment was started with ungerminated seeds.

Crop Emergence, the Impact of Mechanical Impedance, Figure 3 Recovery of carrot shoots on sloping filter boards following exposure to mechanical impedance in sand cultures equivalent to penetrometer pressures of 0.19 MPa (a) or 0.53 MPa (b) for 5 days ○, 9 days ▽, 14 days —, and 19 days ■. Data for seedlings which have never been impeded are also shown, ●, for reference. The curves shown were obtained using model for shoot elongation as a function of soil strength, water stress and temperature (Whalley et al., 1999). Only one curve is shown for both the seedlings which were never impeded and the seedlings which were recovered from the impeding environment after 5 days because the time to germination is 5.25 days at 20°C (t_g). At time zero the experiment was started with ungerminated seeds.

The effects of high soil strength in the surface of the seedbed can also affect the distribution of crop emergence times. For example, in Figures 2 and 3 the recovery in shoot length following the removal of mechanical impedance (e.g., after rain on a dry seedbed) appears to be possible for 20 or more days following germination. Variability in emergence times can be particularly important in vegetable crops where the proportion of the crop in high-value size grades (e.g., diameter of carrot) at harvest depends in large part on uniform emergence of the desired number of seedlings.

Conclusion

In summary soil strengths high enough to decrease emergence can occur from soil drying to matric potentials too high (i.e., soil too wet) to directly affect elongation. In temperate regions, soil strength is the critical stress that determines emergence in the seedbed. In much drier regions emergence may be more limited by germination.

Definitions

Crop responses: changes in the growth and functions of roots and shoots within a growing season and in the final crop yield.

Physical characteristics of soils: the characteristics, processes, or reactions of a soil that are caused by physical forces and are described by, or expressed in, physical terms or equations. Examples of physical properties are bulk density, water holding capacity, hydraulic conductivity, porosity, pore size distribution (Gregory et al., 2002) (see [Cropping Systems, Effects on Soil Physical Properties](#)).

Introduction

When climax vegetation has been on a site for many years, the soil usually is very heterogeneous and is considered to have a good structure for plant growth (Taylor and Brar, 1991). However, after a soil with climax vegetation is brought under cultivation, its heterogeneity usually is reduced. This reduction is mostly due to soil stirring by tillage and pressures from tires of tractors pulling the tillage implements or from the hooves of animals. The changes in soil structure will impose physical conditions influencing root growth and fluxes and thereby essential plant requirements as adequate quantities of

water, oxygen for aerobic respiration, and nutritive elements (Gliński and Lipiec, 1990; Bengough et al., 2006). Crop responses to soil physical conditions depend on the growing stage.

Germination, emergence, and crop establishment

Germination is the process in which a seed or spore emerges from a period of dormancy and is completed when the radicle (embryonic root) emerges from the seed covering structure; emergence is completed when the young shoot emerges through the soil surface. Soil physical conditions at and above planting depth (seedbed layer) are related most closely to the germination, and emergence (e.g., Tamet et al., 1996; Håkansson, 2005). Rapid germination, emergence, and root growth to the subsoil allows early crop establishment (Tisdall, 1996; Atkinson et al., 2009) that enables the plant to use the nitrogen released in the soil, resist fungal disease and pest attack, competition from weeds and roots in the subsoil to avoid waterlogging (Tisdall, 1996; Harris, 1996), increase solar radiation by the growing canopy, and hence is the key to high crop productivity (Cornish, 1984). The main soil physical requirements for germination and emergence include temperature, water content, oxygen availability, and soil strength (see [Root Responses to Soil Physical Limitations](#)).

Temperature

In cold climates, the rate of germination, emergence, and final stand establishment is slowed greatly by low seedbed temperatures. The minimum temperatures for root growth are about 5°C. Cold soil reduces the water uptake due to increased viscosity and cell membrane permeability, metabolic activity resulting in decreased nutrient uptake (Gliński and Lipiec, 1990). Low temperatures are most likely to reduce or stop final emergence when other adverse factors also operate (Hodges et al., 1994). Optimum seed zone temperature for a wide range of seedbed matric potentials (from –10 kPa to –500 kPa) and aggregate size distributions vary from 20°C to 30°C (Schneider and Gupta, 1985).

In hot regions, however, emergence can be hindered by adversely high seedbed temperatures. The maximum temperatures for root growth are from 35°C to 40°C. The mulching can promote the emergence by reducing soil temperatures near the surface and evaporation and hence delaying the onset of water stress and high mechanical impedance (Harris, 1996; Townend et al., 1996).

Root length compared to root weight is a more sensitive indicator of effects of soil temperature. In general, the optimum temperature for roots is somewhat lower than for shoots (Gliński and Lipiec, 1990). To characterize thermal conditions during the early crop growth, the temperature can be expressed in degree-days (one DD is a day with an average daily temperature of 1°C above a base temperature) (Whalley et al., 2000). Base temperatures of 5°C or 10°C are frequently used to calculate accumulated thermal

time and relate it with early plant growth and the development and proliferation of the root system. It helps farmers select the hybrids and varieties that are best suited to their climatic region.

Water

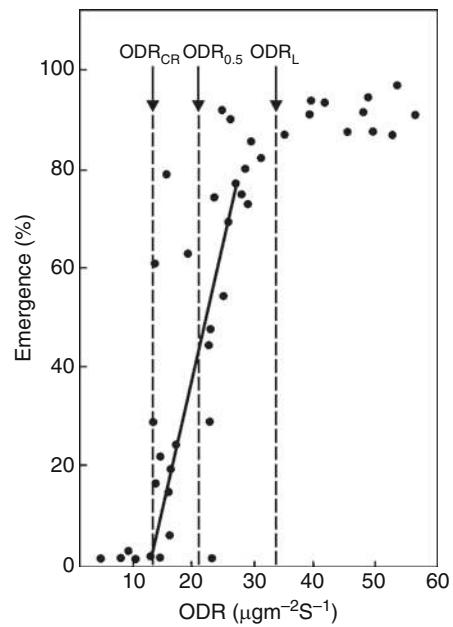

Most seeds must absorb about their own weight in water before they germinate. The water availability depends on soil characteristics, which control how tightly water is held, seed–soil contact areas, and evaporation. Finer-textured and well-structured soils hold water more tightly than coarse-textured soils with the same water content (Cornish, 1984). Irrespective of soil type, the plant-available water is between in situ field capacity and the permanent wilting point (water content at soil matric potential of -1.5 MPa). The seed–soil contact area decreases as soil aggregate size increases and when much undecomposed surface crop residue is present in the soil (Cornish, 1984; Atkinson et al., 2009). Moreover, a seedbed with finer aggregates compared with coarser aggregates results in lower evaporation. In moist soil, however, relative humidity around the seed can be sufficiently high due to vapor transport and then imbibition and germination can occur in the absence of seed–soil contact (Wuest et al., 1999). In dry surface seedbed layer, good crop emergence of small grain crops can be achieved, when the seed was placed directly onto a firm seedbed base and was covered by a 4-cm deep seedbed with $>50\%$ aggregates $<5\text{ mm}$ (Håkansson et al., 2002).

Aeration

Insufficient aeration for germination and emergence is usually caused by poor drainage and by a surface crust that can prevent gas exchange between the soil atmosphere and the air above. In case of direct seeding, insufficient aeration can occur, if the seed is pressed firmly into the wall or bottom of a slot, which is cut by the machine and simultaneously compacted. In the poorly aerated soil, biological activity can consume the limited supply of oxygen, in competition with seeds or seedling roots. From the review of Gliński and Stępniewski (1985) results that many plants as wheat, lettuce, carrot, and onion germinate well even at low oxygen concentration. Some plants, for example, rice, cucumber, and cockscomb preserve their germination ability even in completely anoxic conditions. The emergence of plants is preceded by a considerable development of the root system that needs oxygen supply. The effects of soil oxygen on seedling emergence are better described in terms of oxygen diffusion rate (ODR) than in terms of the oxygen concentration in the soil air. Figure 1 presents an example of the relationship between plant emergence of oats and ODR.

Strength

Soil strength is a measure of deformation resistance (mechanical impedance) and increases with increased soil bulk density or with decreased soil water content or matric

Crop Responses to Soil Physical Conditions, Figure 1 Final emergence of oats vs. oxygen diffusion rate: ODR_{cr} (the level making emergence impossible); $\text{ODR}_{0.5}$ (the value at which the number of emerging seedlings reaches 50% of the seed germination capacity), and ODR_L (causing a significant decrease in emergence relative to germination capacity) (after Gliński and Stępniewski, 1985).

potential. High soil strength is an important constraint to seedling emergence (see *Crop Emergence, the Impact of Mechanical Impedance*) and crop establishment failure. Soil strength of the preemergent shoot environment is more dynamic than that of the root environment and may increase exponentially with time (Weaich et al., 1996). Roots and shoots have to work very hard in strong soil to overcome mechanical impedance (Cornish, 1984). It was shown that germination, root elongation, coleoptile elongation, and emergence of wheat were not affected by soil strengths below 3.0, 2.3, 1.7, and 0.8 MPa, respectively (Jakobsen and Dexter, 1987). However, at strengths exceeding 5 MPa root growth will be nonexistent (Bengough et al., 2006).

Excessive soil strength above developing seedlings can be induced by soil compaction due to machinery traffic at seedbed preparation and sowing, the presence of large clods and crust (surface hard layer) (Håkansson et al., 2002). Large clods often occur in clay soils and their contribution can increase in compacted soil. Soil crusts are formed mostly in soils with low aggregate stability (e.g., silt soils) during irrigation or intense natural rainstorms shortly after planting followed by dry weather (see *Soil Surface Sealing and Crusting*). Impact of the crusts on crop emergence varies with the seed size. In general small seedlings from small seeds are more crust susceptible (e.g., alfalfa) than those from large seeds (e.g., maize).

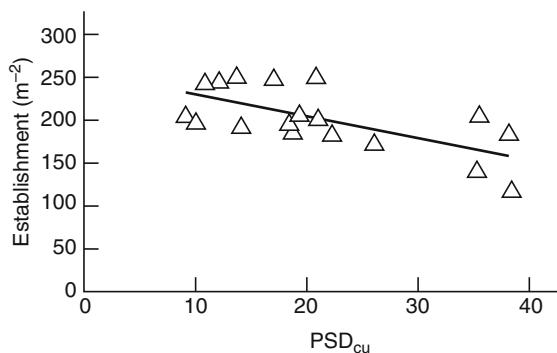

Also heavier seed of the same crop type, as observed for carrot, emerged better from deep sowing in crusted soil due to longer hypocotyls (part of a plant embryo or seedling plant that is below the cotyledons) and greater growth forces (Tamet et al., 1996). Mulches and conservation tillage practices with crop residues on the soil surface and liming of acid soils reduce soil crusting by decreasing raindrop impact and postponing surface drying.

The effect of soil strength on crop emergence depends on sowing depth. The negative effects of increasing soil strength on the emergence are greater at greater sowing depth (Lipiec and Simota, 1994). The risk of poor emergence due to surface layer hardening depended much more on the sowing depth than on the aggregate sizes of the seedbed (Håkansson et al., 2002).

Structure

The influence of a seedbed structure on crop establishment can vary greatly in terms of soil aggregation and subsequent pore size distribution that are largely influenced by cultivation. As shown by Atkinson et al. (2009) soil structures with larger pores are responsible for reducing establishment (Figure 2) due to mostly poor soil–seed contact and lack of water and nutrient capture from large pores. Therefore, press wheels and rolling are used to increase soil–seed contact and final emergence (Cornish, 1984; Håkansson et al., 2002). Incorporating the structural measurements of pore space of soil macrostructure improved predicting crop establishment based on bulk density and cultivation techniques (assigning lower value to less intensive cultivation) (Atkinson et al., 2009). Optimum structural conditions for establishment occurred between ranges for macroporosity of 10–19% and average pore size of 8–12 mm².

It is clear that the fine seedbed structures (<5 mm size) produce the greatest establishment (Håkansson et al., 2002; Atkinson et al., 2009). In particular it refers to sugar beet, cruciferous crops, and clover that have small seeds (1–5 mg seed⁻¹) and should be placed shallow (usually

Crop Responses to Soil Physical Conditions, Figure 2 Relation between wheat establishment and PSDcu (ratio of the size of pores at a 10% and 60% total macropore distribution, the larger the ratio, the greater the number of larger pores) (after Atkinson et al., 2009).

<3.5 cm). Large seed crops are less sensitive to sowing depth. Fine seedbed structures can be achieved through power harrowing and plowing. The poorest soil structure and seedbed performance were produced by disking and rolling (Cornish, 1984; Atkinson et al., 2009).

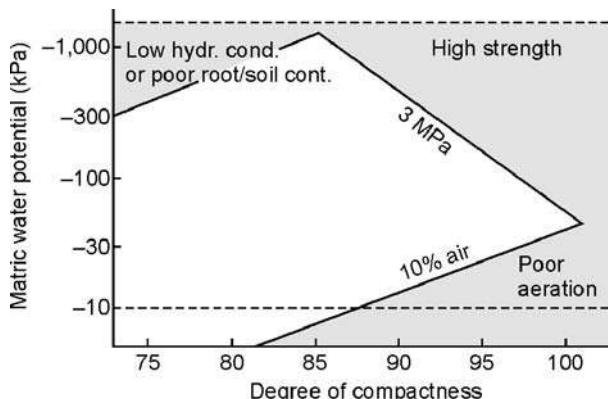

One important factor influencing emergence is soil puddling due to tillage when wet. This traditional practice for rice destroys soil aggregates in the seedbed layer and thereby disturbs emergence of wheat, which is often planted after rice (Tripathi et al., 2007). This study showed that incorporation of crop residue reduced change in soil physical properties and improved germination and yields.

The emergence may be limited by different physical factors depending on site conditions. In the semiarid tropics, it was primarily the large mechanical impedance in the sandy clay loam, whereas in the sandy loam – a combination of high temperature, water stress, and mechanical impedance. Cowpea compared to sorghum emergence was higher due to greater initial rates of root and shoot growth, which allowed it to avoid the greater stresses caused by temperature, drought, and mechanical impedance. The larger cowpea shoots were able to overcome greater mechanical impedance when they approached the soil surface. This aspect is of particular importance in hardsetting soils (Townend et al., 1996). Emergent seedlings of sorghum were often surviving on water taken up by the primary root alone, from moist soil at depth, because all other root initials at the base of the stem were surrounded by hot, dry soil (Harris, 1996). Low temperature and oxygen deficiency in the seedbed layer in cold and wet climate can be main factors limiting the early root and shoot growth.

Early crop growth can be influenced by soil physical characteristics acting independently or in combination. Due to this, it is often difficult to determine their relative contributions. Example would be supra-maximum temperatures ($>40^{\circ}\text{C}$) and high soil strengths experienced by the preemergent shoot in the semiarid tropics (Weaich et al., 1996).

Growth of established crops

Most important soil physical factors influencing growth of roots and shoots of established crops include water status, penetration resistance, and aeration. They are largely affected by alterations in soil structure due to compaction (e.g., Czyż, 2004; Usowicz and Lipiec, 2009) by agricultural machinery and tillage (e.g., Birkás, 2008). The penetration resistance of 3 MPa and air-filled porosity of 10% v/v are usually regarded as critical for plant growth. The results from Figure 3 indicate that as degree of compactness (i.e., ratio of the actual bulk density to a specified reference bulk density for the same soil, obtained by static load of 200 kPa when the soil is wet, Håkansson, 1990) increases, the range of matric potential, in which aeration and mechanical impedance do not limit root growth becomes narrower. The range is termed as least limiting water range (LLWR) and combines main soil

Crop Responses to Soil Physical Conditions,

Figure 3 Relationship between soil strength of 3 MPa and air-filled porosity 10% (v/v) in relation to degree of compactness and matric potential of the plow layer excluding the seedbed (0–5 cm). Problems for crop growth in the upper left corner of the diagram are likely due to mainly low unsaturated hydraulic conductivity and/or poor root-to-soil contact (after Håkansson and Lipiec, 2000).

physical characteristics to describe soil suitability for crop growth (Da Silva et al., 1997). The use of the degree of compactness instead of bulk density enhances the performance and applicability of the LLWR by reducing differences in its values between different soil types (Da Silva et al., 1997). In coarse-textured soils, root growth may be further restricted by rough surface of the sand particles, which resist particle displacement by slippage (Gliński and Lipiec, 1990).

In case of legume plants, soil compaction can decrease nodulation efficiency of the nodules in fixing nitrogen, N uptake, subsequent yield, and protein content of seed (Sweeney et al., 2006; Siczek, 2009). The quantity and distribution of nodules can be altered by controlling the wheel traffic (compaction) in ways, which have implications for increasing nitrogen fixation. Also colonization of dry edible beans by mycorrhizal fungi and the incidence of *Phytophtora* root rot of soybeans are influenced by soil physical properties induced by secondary tillage and traffic (Gliński and Lipiec, 1990).

Effect of soil structural discontinuity

Vertical

An important factor affecting root growth and water use in the field is vertical strength discontinuity. A sharp discontinuity occurs between aggregated seedbed layer and firm soil below (Lipiec et al., 2003b). Soil column experiment showed that root length of maize below the seedbed layer relative to total root length was less than 38% while water use was up to 74%. Total water use from the deeper soil and root water use efficiency were greater for the fine-than coarse-textured soils (Lipiec and Hatano, 2003).

Another discontinuity in soil profile is due to the presence of dense layers such as plow pans, fragipans,

duripans, fine-textured B-horizons, claypans, and high clay horizons developing in a relatively long time span (Lipiec et al., 2003b). They lead to a higher concentration of roots in upper part of the subsoil layer and lower – in deeper soil. Restricted root growth by the dense layers can be a consequence of too low porosity accompanied by insufficient oxygen supply, excessive mechanical impedance, and the absence of pores of diameters greater than root tips (Lipiec et al., 2003b). These parameters are used in modeling root growth and function (Lipiec et al., 2003a). In general, the effect of the dense layers on root growth increases with decreasing depth and thickness of the dense layer (Birkás, 2008). Under droughty conditions, limited root growth results in scarce water supply and consequently plant death (Cornish, 1984). In some soils, the physical constraints to root growth are accompanied by high soil acidity (Lipiec et al., 2003b).

The hindering effects of the subsoil dense layers can be enhanced by traffic of heavy machinery and remain many years or are even permanent, especially in non-swelling and shrinking coarse-textured soils and warm climates with shallow or without annual freezing (Sweeney et al., 2006; Håkansson, 2005) (see *Subsoil Compaction* and *Compaction of Soil*). Usually, dense layers can be localized in the soil profile by maxima of bulk density and soil strength (Lipiec and Hatano, 2003) or reduced aeration in wet soil (Gliński and Stępniewski, 1985). In well-structured and finer-textured soils, the increase in soil compactness can be partly compensated for by the development of a continuous macropore system (Lipiec and Hatano, 2003).

The separate the effect of subsoil dense layers on root growth and uptake functions can be quantified in the field by removing topsoil (Ishaq et al., 2001). Such approach is, however, expensive and difficult to perform. Therefore, column experiments with variously compacted soil layers are used to separate depth effects from strength effects (Busscher et al., 2000). Soil columns can be useful tool for measuring water uptake from particular depths after separation of the layers by, for example, thin perlite or wax-paraffin mixture layer (impermeable for water and allowing root growth) (Nosalewicz and Lipiec, 2002).

Horizontal

Horizontal soil strength discontinuity in cropfields results from mostly uneven distribution of wheel tracks (Raper, 2005; Sweeney et al., 2006) and affects root growth and function (see *Spatial Variability of Soil Physical Properties*). Reduced root growth of plants and associated water use in strong soil were partly compensated for in loose soil of the same plant (Figure 4).

Also water deficits in a soil surrounding part of a one plant root system induces increased water uptake from soil with better soil–water conditions (Šimůnek and Hopmans, 2009; Hu et al., 2009). In studying the effect of spatial distribution of mechanical impedance and aeration on root growth and function approaches with split root systems

in soil of varying bulk density and matric potential were useful (Whalley et al., 2000; Lipiec and Hatano, 2003).

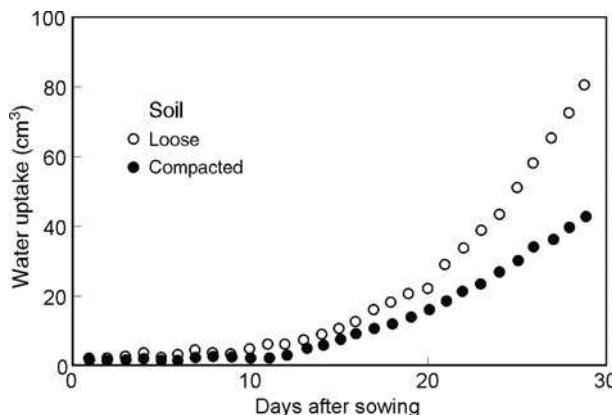

A survey of root growth functions showed that a greater bulk density led to increased water uptake rate (per unit of root) for bean, maize, barley, and rice (Lipiec and Hatano, 2003). This increase was mostly attributed to a greater root–soil contact and to a higher unsaturated hydraulic conductivity and a greater water movement toward the roots. However, increased water uptake rate was not sufficient to compensate entirely for the reduction in total root length and resulted in reduced total water uptake. Similarly, greater nutrient inflow rate per unit length and root–soil contact area without additional nutrient application were not sufficient to compensate for reduced root

size (Lipiec et al., 2003b). The above studies indicate a wide plasticity in root growth and water absorption in response to localized unfavorable soil physical conditions. Including the compensatory water uptake in models improves prediction of soil water content as compared to models accounting only for root distribution (Šimůnek and Hopmans, 2009).

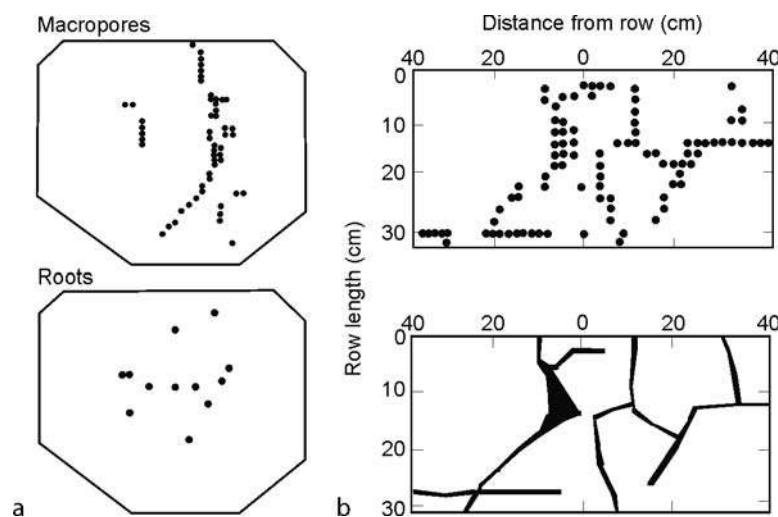

Role of pores

Root response to high soil strength depends on the presence and distribution patterns of pores having diameter equal to or greater than the root tip (approximately 200 µm). A soil matrix with a larger pore size, structural cracks, macropores, and wormholes will offer greater potential for undisturbed root growth because the roots can bypass the zones of high mechanical impedance (Gliński and Lipiec, 1990; Lipiec et al., 2003b).

Figure 5 illustrates similar distribution patterns of macropores and roots. The percentage of roots grown into existing pores and channels increases in deeper and stronger layers where they can be the only possible pathways for root growth. This preferential growth into macropores will lead to increasing critical limits of soil strength for root growth (2.5–3.0 MPa) (Håkansson and Lipiec, 2000). Larger pores can also benefit in poorly aerated soils since they drain at higher matric potential and remain air filled for longer compared to smaller pores (Whalley et al., 2000). This process results in decreasing critical values of air-filled porosity (10%) although part of the soil matrix can be anoxic (Håkansson and Lipiec, 2000). McQueen and Shepherd (2002) suggested the critical lower limit set of macropore volume ($>60 \mu\text{m}$) at 5% for cropped sites on poorly drained soil. An important property of the vertical biopores (made by soil fauna and plant roots) in deeper soil is that they are able to resist vertical

Crop Responses to Soil Physical Conditions,
Figure 4 Cumulative water uptake by split root system of wheat, halves of the same plant grown in loose silt loam (bulk density 1.28 Mg m^{-3}) and compacted (bulk density 1.58 Mg m^{-3}) at matric water potential -35 kPa (after Nosalewicz and Lipiec, 2002).

Crop Responses to Soil Physical Conditions, Figure 5 Distribution patterns of macropores and roots of maize: (a) pot experiment (after Hatano et al., 1988); (b) field experiment (after Tardieu and Manichon, 1986).

compression and they remain stable as the soil swells (Lipiec and Hatano, 2003).

Optimum root size

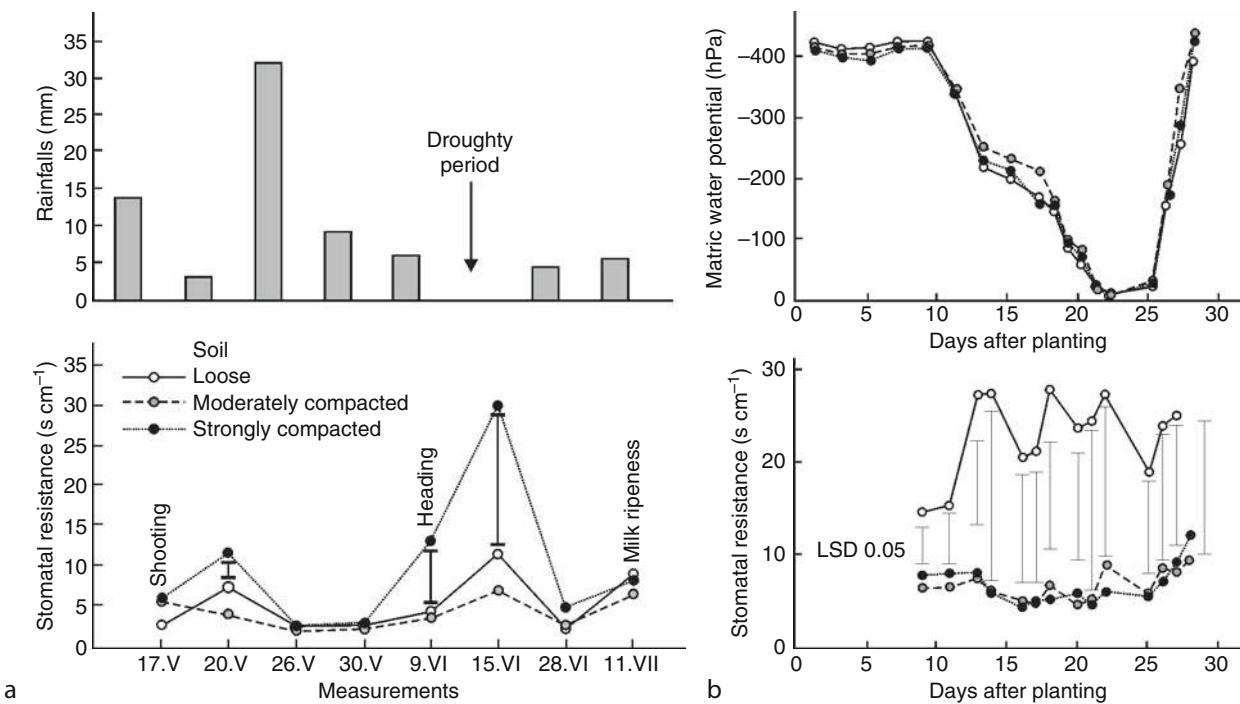

Optimum root size is not always the largest one and depends on the work to be done. For water uptake, the optimum root length density is of $1\text{--}6 \text{ cm cm}^{-3}$ of soil depending on soil type, crop type, and water status in a plant (Gliński and Lipiec, 1990). A relatively small root length density of 1 cm cm^{-3} of soil in winter wheat was capable of extracting most of the available water and for sorghum it was more than 2 cm cm^{-3} (Gliński and Lipiec, 1990), but complete uptake of soil P requires at least $10\text{--}20 \text{ cm cm}^{-3}$ depending upon plant species (Cornish, 1984). Lengths of $5\text{--}10 \text{ cm cm}^{-3}$ are common in surface soils. Root growth in excess of that needed to meet water and nutrient requirements can lead to dissipation of the products of photosynthesis. Therefore, under favorable conditions with a good supply of water (e.g., irrigated areas) and nutrients cultivars with less extensive and shallow root systems can be used whereas in dry areas – those with more extensive and deep root systems.

Root-to-shoot signaling

When soil physical properties suppress root growth and change root distribution, shoot growth, and functions may also be reduced (Sweeney et al., 2006) as an effect of

root-to-shoot signaling (Lipiec and Hatano, 2003; Dodd, 2005). Main shoot functions include photosynthesis and transpiration that are related to the leaf stomatal diffusive resistance. Figure 6a indicates the greater stomatal resistance of spring wheat in compacted than non-compacted soil, particularly in droughty periods. A substantial increase in the stomatal resistance of plants grown in most compacted soil also occurred with transient wetting (Figure 6b) and associated low air-filled porosity in laboratory experiment (Lipiec et al., 1996). Ali et al. (1999) reported that the increased leaf stomata resistance occurred even before a measurable change in leaf water potential.

Several mechanisms are suggested for stomata closure. One mechanism under poor aeration is reduced water flow through roots (Gliński and Stępniewski, 1985; Lipiec et al., 2003b). Accumulation of abscisic acid (ABA) in leaves seems to induce stomata closure through its effect on the potassium ion regulation of guard cell turgor (Tardieu, 1994). The stomata resistance of maize grown in poorly aerated soil was considerably higher in lower than upper leaves (Lipiec and Hatano, 2003) and may imply the upward movement of plant hormones or other substances to the shoots (Tardieu, 1994). This can be supported by study (Bennicelli et al., 1998) indicating that superoxide dismutase (SOD, metalloenzyme, protects aerobic organisms against oxygen-activated toxicity) activity in roots increased earlier (after 2 days of oxygen stress) while that one in the leaves started to increase later (after 8 days).

Crop Responses to Soil Physical Conditions, Figure 6 Stomatal resistance of spring wheat grown in field in relation to soil compaction and rainfalls (a) (after Lipiec and Gliński, 1997) and of maize grown in growth chamber (b) in relation to soil compaction and matric water potential (after Lipiec et al., 1996).

However, there were no detectable root-sourced signals of xylem-sap ABA concentration in wheat due to soil strength, despite changes in stomatal conductance (Whalley et al., 2006). Some authors (e.g., Tardieu, 1994) point out that ABA increase in plants grown in strong soil is a result of root dehydration due to a limited water supply to the roots. Horn (1994) indicates that ABA concentration in plants generally increased proportionally to previous maximum reduction of plant-available water. Although progress has been made toward description of root-to-shoot signaling in recent years still further research is needed to explain perception of soil physical stress by plants and the conversion of physical phenomena such as water and oxygen scarcity or temperature extremes into physiological responses (Lipiec et al., 2003b; Dodd, 2005; Whalley et al., 2006).

Yields

Compaction, tillage, and irrigation were applied in many experiments to get a wide range of soil physical conditions affecting crop yields. Response of crop yield to compaction is most often parabolic with the highest yield obtained on moderately compacted soil (Figure 7) (e.g., Håkansson, 2005; Czyż, 2004). However, in soil of relatively high initial soil compactness under droughty climatic conditions, the yield can decrease with increasing soil compaction (Lipiec and Hatano, 2003). The effects of soil and subsoil compaction by vehicles with high axle load (≥ 10 Mg) on crop yield remained for a number of years in spite of annual winter soil freezing (Håkansson, 2005).

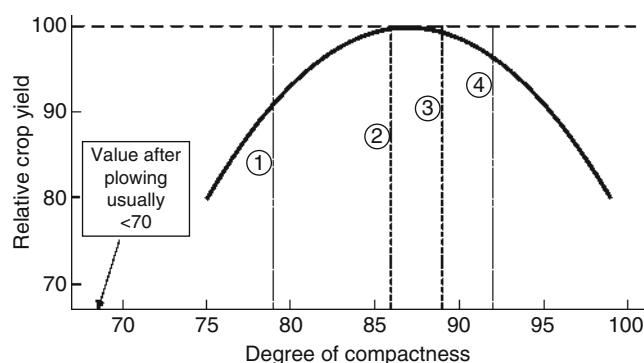

In study of Whalley et al. (2006) the yield of wheat was linearly related with soil strength (as manipulated by compaction and irrigation) and accumulated soil moisture data during growing season. Negative effect of excessive soil strength on barley yield was mostly reflected in years with

unfavorable sowing–shooting weather conditions (scarce rainfalls, high sunshine, and air temperature) (Lipiec et al., 2003b). This interactive effect is primarily important in predicting crop yield of coarse-textured soils where strength problems are enhanced by low available soil water content and rate of the soil water movement deeper in the soil profile (Busscher et al., 2001). In wet and compacted soil, crop yield can be reduced due to deficient soil aeration (Czyż, 2004) and associated low transpiration, shoot growth rates, wilting, leaf epinasty and senescence, and premature termination of growth (Gliński and Stepniewski, 1985). Regarding plant tolerance to deficient soil aeration, there is a wide spectrum of plants from entirely adapted hydrophytes (aquatic plants) to very sensitive crop species severely damaged after short periods (1–2 days) of deficient soil aeration.

Root crops are traditionally regarded as particularly sensitive to excessive strength because their harvestable products grow underground (Lipiec and Simota, 1994). A characteristic morphological response of sugar beets and carrots to mechanical impedance in compacted soil is their forking and fanging (Lipiec et al., 2003b) and decreased marketable yield (tubers > 35 mm) with potatoes. The reduction in root yield of the sugar beets was accompanied by a decrease in sugar content (Lipiec et al., 2003b) and increase in more harmful nonsugars (Gliński and Lipiec, 1990). The response of sugar beets yield to strength was less in dry season compared to wet season that implies the effect of excessive soil strength was masked by moisture deficit (Birkás, 2008). The yield of carrot and potatoes and the proportion of small and deformed roots and tubers that were unsuitable for processing grown in mechanically impeded soil decreased and increased, respectively (Lipiec and Simota, 1994; Dumitru et al., 2000).

The effect of tillage systems on crop performance is not uniform and depends on crop species, soils, climates and agro-ecological conditions (Alvarez and Steinbach, 2009). Under semiarid conditions conventional tillage and deep plowing are superior to conservation tillage (at least 30% of the soil covered by crop residues). The tillage effect is either closely linked to soil aggregation, hence water infiltration rate and water storage capacity, or indirectly related to soil and water conservation. In general, crop yield differences between tillage treatments were diminished when fertilizers were applied. Although conservation tillage is most cost effective farming practice thereby widely adopted, for example, in the USA, generalization should be avoided. Irrespective of management practices, crop yields are highly dependent on soil texture and associated soil water and nutrients storage during growing season.

Mathematical modeling of crop growth responses to soil physical conditions contributes to the better understanding of the complex and variable effects. Many authors indicate that under most conditions the soil water content or the soil water potential comes out to be of particular importance because they directly affect crop

Crop Responses to Soil Physical Conditions, Figure 7 Relative crop yield as related to the degree of compactness of the plow layer (5–25 cm) based on about 100 field trials in Sweden. The treatments were the following: (1) no compaction, (2) one pass, track by track, by a 2-Mg tractor with tire inflation pressure 70 kPa, (3) one pass, track by track, by a 3–3.5-Mg tractor with tire inflation pressure 140 kPa, (4) four passes by a 3–3.5-Mg tractor with tire inflation pressure 180 kPa (after Håkansson, 2005).

growth and yield and indirectly affect significant factors, such as aeration, mechanical impedance, and soil temperature. For this reason, crop yield is frequently predicted from interactions of soil water and plant transpiration and assimilation (Lipiec et al., 2003a).

Modifying soil physical conditions toward crop growth

Tillage, compaction, and crop residue management mostly influence soil physical conditions of the root zone.

Tillage and deep loosening

Moldboard plowing or other deep primary tillage is often used to loosen the topsoil. Because of the high cost of tillage, different limited (plowless) tillage managements are also used. Research indicates that effects of tillage systems on soil physical properties are not consistent (Håkansson, 2005; Strudley et al., 2008; Alvarez and Steinbach, 2009). More studies indicate greater soil bulk density and penetration resistance under limited tillage managements, particularly in the surface layer. In general, the soils under no-till compared to plowed are characterized by a greater number of longitudinally continuous earthworm channels utilized preferentially by roots as passages of comparatively low soil strength and good aeration.

Although deep soil loosening have consistently indicated decreased bulk density and penetration resistance along with increased infiltration and crop rooting its effects on soil structure and crop yield are not always positive (Håkansson, 2005; Raper, 2005). This is due to the limited reversibility since subsoiling or ripping may produce large voids between fairly large soil structure units (>2 mm), but compaction may alter smaller units (<1 mm). Moreover, once soil is deeply loosened, it will easily recompact if traffic is applied in the same area (Raper, 2005). The coarse-textured soils are less responsive to subsoiling than the fine-textured soils because of the low content of finer soil materials or organic matter to stabilize the pore system in the former (see *Hardpan Soils: Management*). Crop yields may not respond positively to deep loosening even though they may appear to be compacted when good fertilization and management practices are used on the plow layer (Håkansson, 2005) or due to the presence of old root channels and earthworm channels (Raper, 2005) (see *Earthworms as Ecosystem Engineers*).

Since deep loosening is expensive, it is often recommendable in case of very severe subsoil compaction (e.g., Munkholm et al., 2005; Håkansson, 2005) and only in a compacted wheel-track zone (Sweeney et al., 2006) or under the crop row, called “precision tillage” or “in-row subsoiling” (see *Precision Agriculture: Proximal Soil Sensing*). The cost of operation can be markedly diminished with crops grown in wide rows. Various aspects of profile modification and other ways to soften hard layers including water/crop management and soil amendments

are discussed in detail by Busscher et al. (2007) and Baumhardt et al. (2008).

Because of costly and limited reversibility of deep loosening and other solutions, the opportunities to minimize subsoil compaction are recommended. They include reduction of axle loads, ground contact pressure and traffic intensity, especially when soils are wet (Håkansson, 2005; Hamza and Anderson, 2005). On the base of measurements of soil displacement under the wheels of heavy vehicles in Sweden a limitation of the load to 6 Mg on a single axle load and 10 Mg on a tandem axle unit was recommended to minimize ground pressure (Håkansson, 2005). Soil compaction depends on the internal soil strength that is described by “precompression stress P_c .” To prevent soil against harmful compaction the concept of critical P_c values can be used as precaution to avoid soil compaction (Horn and Fleige, 2009) (see *Subsoil Compaction* and *Compaction of Soil*).

The area and volume of compacted soil can be considerably reduced by confining heavy field transport to permanent traffic lanes and by controlled traffic in which all traffic throughout the growing season is restricted to permanent, parallel tracks or by restricting traffic for all field operations carried out after crop establishment to the interrow zones (Håkansson, 2005).

Summary

The main soil physical conditions influencing crop growth include temperature, water content, oxygen availability, soil strength of seedbed layer at emergence, and soil below during later growth. Their effects are related to site conditions. For example, in cold climates low seedbed temperatures and/or oxygen deficiency while in hot climates by high temperatures and/or high soil strengths can slow emergence and final stand establishment greatly. An important factor affecting root growth and distribution in tilled soils is vertical and horizontal strength discontinuity. The vertical discontinuity occurs between aggregated seedbed layer and firm soil below and between the plow layer and plow pans. The horizontal discontinuity is mostly caused by a greater strength under machinery tracks. Root response to soil physical conditions depends on the presence and distribution patterns of pores larger than roots that allow bypass the zones of high mechanical impedance and low aeration. When soil physical properties suppress root size, shoot growth and functions are influenced due to root-to-shoot signaling. Main shoot functions include photosynthesis and transpiration that are related to the leaf stomatal diffusive resistance. Usually crop growth is influenced by soil physical characteristics acting in combination and thereby it is often difficult to determine their relative contributions. The soil water status plays a very important role since it affects other significant soil physical factors such as aeration, strength, and temperature. The soil physical conditions are mostly influenced by tillage, compaction, and crop residue management. Further research is needed to explain the

perception of soil physical stress by plants and the conversion of physical phenomena into physiological responses.

Definition

Interdisciplinary agrophysics, on the basis of fundamental studies on physical properties of plants and agricultural crops, provides other disciplines of agricultural sciences with methods and spectacular research results that are applied in the design and production of agricultural machinery and in its operation during the harvest and postharvest processing of agricultural products. During this operation, *Crop yield losses* appear and they often drastically decrease total yield. Comprehensive agrophysical studies on plants and agricultural products conducted in the aspect of implementation of their results in agricultural practice are able to mitigate crop yield losses.

Introduction

Almost all crop plants have retained, to a lesser or greater extent, atavistic features and tend to shed their seeds as soon as they have attained full ripeness, in order to ensure continuation of the species. Breeders of new cultivars have long observed that phenomenon and undertake efforts aimed at its limitation, though with varying degree of success. Seed losses at the stage of ripening and harvest reach the level of over a dozen, and often several dozen percent of the total yield, which on the global scale gives a hard to estimate reduction of yields actually obtained compared to those predicted during the vegetation of crops.

One of the highly important elements leading to the limitation of those losses is acquisition of in-depth knowledge of the physical properties of such crop plants at various stages of seed ripeness, and proper utilization of the results of such studies in the selection of the time of harvest and in the adaptation of harvesting machines to the specific character of the crop plants and to the structure of the plant canopy.

Cereals and grasses

In the production of cereals and seed grasses, the most important traits include the mechanical properties of stems (significant for the limitation of lodging) and the bond force between the kernel and the spike or the panicle. Highly susceptible to cracking and seed shedding are the fruits of cruciferous plants (siliques) and of large-seed leguminous plants (pods). Similar phenomena occur in seed production of vegetables, medicinal plants, and industrial plants.

The utilization of results of agrophysical studies for the limitation of quantitative losses of seeds cannot be accepted as a success in itself, as there remains another element, no less important, i.e., qualitative losses defined

as damage of various kinds. Damage to seeds is caused by the particular subassemblies of harvesting machinery whose operating parameters are not adapted to the mechanical strength of seeds of various plant species or cultivars. In this respect, the results of agrophysical studies provide information on the values of forces characterizing the mechanical strength of the seeds that cannot be exceeded in the course of harvesting, transport, drying, and storage to obtain material of high quality, both with respect of raw material and of the end product.

Agrophysical studies conducted so far at various research centers have demonstrated that knowledge of the physical properties of plants and agricultural products may constitute the basis for the development of new technologies of seed production with maximum limitation of quantitative and qualitative losses. Some of such solutions have been implemented at full-scale production, bringing measurable economic advantages.

Such a final effect can be achieved through highly detailed laboratory examinations of plant material, taking into account the agricultural techniques applied, the anatomical-morphological features, variety-related traits, stage of ripeness, various levels of moisture, plant protection agents, and preparations applied at the final phase of ripening. Once the results of such comprehensive studies are known, they are tested on the micro-scale on experimental lots, and then on larger field areas, using harvesting machines in order to identify the required settings of their subassemblies or implementing required adaptations. After applying necessary corrections and repeated testing, the results of agrophysical studies can be made available to producers as a new and proven technology of seed acquisition ([Table 1](#)).

Optimization of production of cereals and seed grasses is practically impossible without knowledge of the

Crop Yield Losses Reduction at Harvest, from Research to Adoption, Table 1 Some mechanical properties of cereal plants and seed grasses

Plant	Kernel-spike bond force (N)	Coefficient of variation V(%)	Susceptibility to seed shedding	Resistance to static loads (N)	Deformation (%)	Energy (mJ)

physical properties of the plants during their ripening and harvest. Knowledge of the limit values of particular traits permits such preparation of agricultural machinery and tools that, in spite of the highly complex interrelations of numerous factors, will permit maximum limitation of quantitative losses while ensuring high quality of sowing material (Arnold et al., 1958; Zoerb, 1960; Hill, 1975).

The susceptibility of cereal and grass kernels to shedding with relation to moisture, i.e., with progressing ripening, varies greatly for the particular species, which is reflected in the values of the kernel-ear bond force (Szot and Reznicek, 1984). That value varies within the range of 0.91–2.90 N for cereals, while for grasses the corresponding range is 0.22–0.48 N (Szpryngiel, 1991). Those values are characterized by notable variability resulting from the genetic traits, cultivation environment, moisture, and phases of ripeness of the plants (Debrand, 1980). Therefore, during the period of ripening the unfavorable phenomenon of seed shedding takes place under the effect of atmospheric factors. In this respect, cereals are notably less susceptible to seed shedding when compared with seed grasses. With a drop in seed moisture, all grass species distinctly weaken the bond between the kernel and the torus within a very short time (even just a few hours), which may cause seed losses of even up to several dozen percent of the yield (Szpryngiel, 1976; Szpryngiel, 1983). Hence, the selection of the date of harvest requires constant monitoring of both the level of seed moisture and of the stage of ripeness. Amaranth can be classified as a specific cereal plant. It provides high yields, but on the condition that its combine harvest is performed when the leaves have been frost bitten or dried, i.e., in late autumn. If such conditions do not occur, two-stage harvesting is applied, consisting in cutting off the panicles for drying and subsequent threshing (Szot, 1999).

The harvest of cereal plants often involves damage to the grain, lowering the quality of the yield. This is related with the resistance of seeds to mechanical loads occurring in the combine harvester (Arnold and Roberts, 1969; Szot, 1984). Apart from the genetic traits, that resistance is affected by moisture and by the environmental conditions under which the crops are cultivated. Hence the significance of proper selection of operating parameters of harvester subassemblies.

Very dry seeds are brittle and crack easily, while wet seeds display plastic properties and a subject to permanent deformations. The lowest level of damage to seeds is observed when the seeds are in the elastic or elasto-plastic state.

Leguminous Plants

Information significant for the limitation of quantitative losses in the production of leguminous plants includes the force and energy of pod cracking (Table 2).

The values of those traits form broad ranges, which differentiates the particular species in terms of the level of seed losses in the course of ripening and harvest. Species characterized by the highest susceptibility to pod cracking

Crop Yield Losses Reduction at Harvest, from Research to Adoption, Table 2 Mechanical properties of some leguminous plants and rapeseed pods

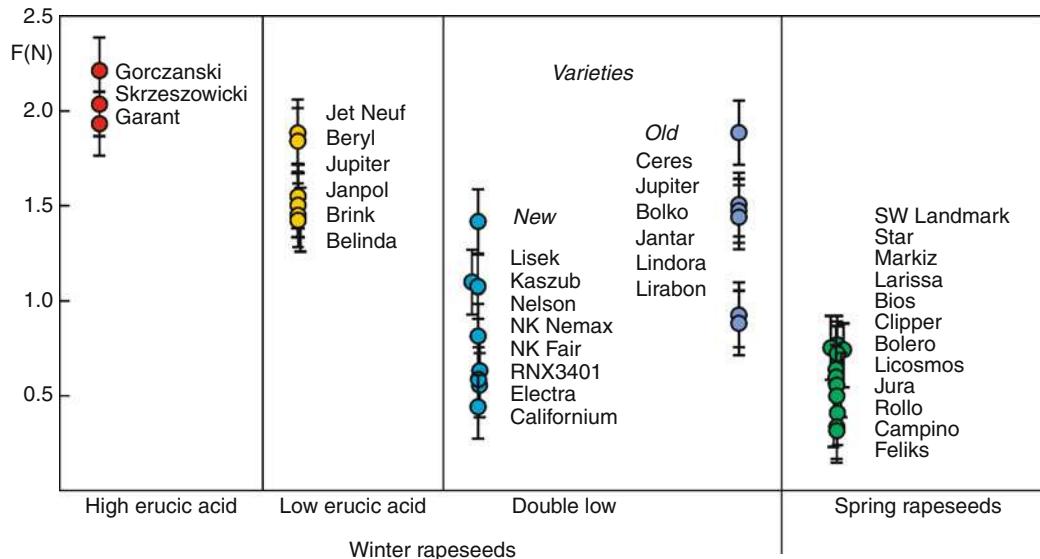

Plant	Cracking force (N)	Cracking energy (mJ)
Broad bean	1.40–1.60	0.72–0.89
Peas	0.32–1.23	0.15–0.40
Beans	0.81–1.24	0.41–0.52
Lupine	1.40–1.80	1.50–1.65
Soybean	1.43–2.02	0.80–1.85
Lentil	0.71–1.21	0.51–1.00
Winter rapeseed	0.42–2.21	6.01–16.03
Spring rapeseed	0.41–0.83	6.02–9.45

and seed shedding include pea, lentil, and beans. More resistant species include broad bean and some lupine cultivars. Choosing suitable parameters of operation of machines used for harvesting those crops will permit considerable limitation of seed losses (Sosnowski, 1991; Dobrzański and Szot, 1997; Szot et al., 2005).

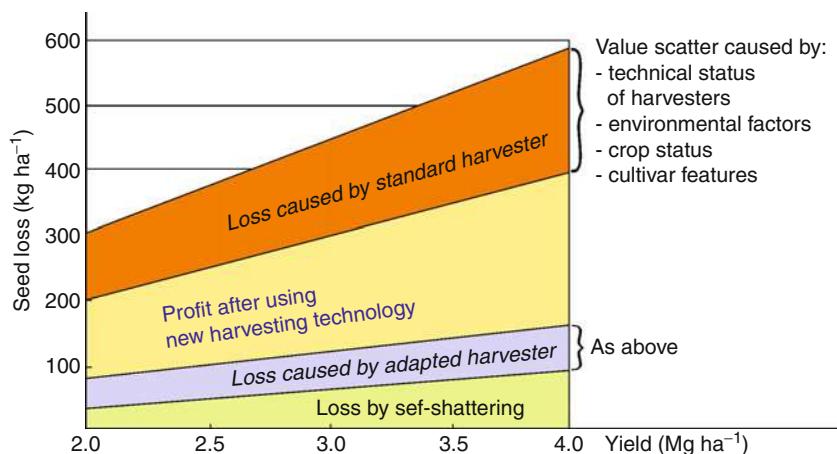

Rapeseed

Rapeseed is a crop that has an increasing economic importance. One of the unfavorable features of that plant, often of fundamental importance in determining the profitability of its cultivation, is the susceptibility of its pods to cracking and seed shedding (Josefsson, 1968; Loof and Jonsson, 1970; Kadkol et al., 1986). The primary factors causing the variability of rapeseed pod strength are the genetic traits, moisture, stage of ripeness, physical condition of the canopy, and atmospheric conditions. Hence, a considerable variability of the mechanical properties of rapeseed pods can be observed even within individual cultivars (Reznicek, 1978; Szot et al., 1991). The lowest values of force causing pod cracking, both for the winter and spring forms of rapeseed, are on average equal to 0.4 N. Whereas, the range of those values for winter rapeseed reaches up to 2.2 N, while for spring rapeseed only to 0.8 N. The values of pod cracking energy correspond to those ranges of force variability. The broader range of values for the winter forms of rapeseed is related with the large numbers of cultivars, including ones that are much more resistant to pod cracking. High erucic acid varieties of rapeseed were cultivated first, then improved varieties with low erucic acid, and nowadays there are so-called double low varieties, i.e., seeds with low erucic and low glucosinolate content. Significant variability of force values causing cracking of pods was observed within these varieties (Figure 1).

A comprehensive study on the physical properties of rapeseed, taking into account all the factors and numerous cultivars, has been conducted within the territory of Poland (Szot et al., 1991). The results obtained were used for the development of a new technology for the acquisition of rapeseeds. That technology provided for the application of suitable settings and adaptations of the particular

Crop Yield Losses Reduction at Harvest, from Research to Adoption, Figure 1 Mean values of force causing cracking of rape pods.

Crop Yield Losses Reduction at Harvest, from Research to Adoption, Figure 2 Relations between rapeseed seed losses and seed yields in combine harvest based on agrophysical research and effects of implementations at rapeseed producing farms.

subassemblies of the combine harvester, taking into account the inter-variety variability of plants and all external factors on the day of the harvest. As a result, based on the fundamental studies of the physical properties of rapeseed and the modification of the operating parameters of the harvester, an economic effect was achieved in the form of maximum limitation of qualitative and quantitative losses of seeds without any additional financial outlays (Szpryngiel et al., 2004). An illustration of those comprehensive studies and the test implementations is given in Figure 2.

Conclusion

Summing up, it should be stated that the application of results of agrophysical research on cereal plants, seed grasses, large-seed leguminous plants, and rapeseed in

agricultural production brings or may bring measurable economic effects. The most visible effects of such activities are observable in relation to rapeseed, as fundamental research and test implementations have resulted in the development of a new technology for the harvest of that crop, ensuring maximum limitation of qualitative and quantitative losses of seeds without any additional financial outlays. Prior to the implementation of that technology, proven and irreversible quantitative losses of seeds were up to, or even above 20% of seed yield, and damage to the seeds often disqualified the material harvested as consumption or sowing material. Therefore, comprehensive agrophysical studies on plants and agricultural products conducted in the aspect of implementation of their results in agricultural practice should be considered as useful and profitable.

CROPPING SYSTEMS, EFFECTS ON SOIL PHYSICAL PROPERTIES

Stephen H. Anderson

Department of Soil, Environmental and Atmospheric Sciences, University of Missouri, Columbia, MO, USA

Synonyms

Crop rotations; Farming systems; Soil management; Soil productivity; Sustainable cropping systems

Definition

Aggregate stability: The proportion of aggregates in soil that do not easily crumble, disintegrate, or slake (Soil Science Society of America, 2008).

Bulk density: Mass of dry soil per unit volume.

Crop rotation: A land management system in which a sequence of crops is grown in a recurring succession (Soil Science Society of America, 2008).

Hydraulic conductivity: The parameter that represents the ability of soil to conduct water; a proportionality factor in Darcy's Law. It is equivalent to the flux of water per unit gradient of hydraulic potential (Soil Science Society of America, 2008).

Infiltration rate: The amount of water entering a specified area of soil per unit time (Soil Science Society of America, 2008).

Penetration resistance: Force per unit area for penetration of soil by a cone (Soil Science Society of America, 2008).

Physical properties: Those characteristic properties and processes of a soil caused by physical forces. Examples of physical properties include porosity, bulk density, hydraulic conductivity, pore-size distribution, and aggregate stability (Soil Science Society of America, 2008).

Pore-size distribution: Volume fractions of various pore sizes in a soil, includes various size ranges (Soil Science Society of America, 2008).

Porosity: Volume of pores divided by the bulk volume of the soil sample.

Soil water characteristic: Relationship between soil-water content and soil-water matric potential. Also referred to as the water retention curve or the water release curve (Soil Science Society of America, 2008).

Introduction

Development of tillage devices was critically important for early crop production systems because shallow placement of seeds helps to protect them and enhances germination (Hillel, 1998). Human-pulled traction spades evolved to animal-drawn plows, and eventually to modern mechanical tractor-drawn tillage equipment. Tillage systems include the mechanical manipulation of soil for any purpose, but agricultural tillage usually refers to modifying soil conditions, crop residues and/or weeds, and/or incorporating agrichemicals for crop production (Soil Science Society of America, 2008).

A significant challenge of these tillage systems was accelerated soil erosion (Gantzer et al., 1991), which encouraged the development of conservation tillage systems such as no-till to reduce soil disturbance and enhance residue cover. Modern cropping systems include conservation tillage for residue management to minimize soil erosion. Deep tillage systems for crop production have been developed to remove the effects of subsoil compaction or hardpans (Hamza and Anderson, 2005).

Cropping system practices known to influence soil physical properties include crop type (Scott et al., 1994), cultivation (Gantzer and Blake, 1978), and application of organic residues (Gantzer et al., 1987). Tillage systems have long been evaluated as a method to improve cropping systems and their associated soil physical properties.

Cropping systems affect soil organic matter content, which in turn strongly influences soil physical properties. Cropping systems that take land out of native vegetation reduce soil organic matter. Turnover of organic matter from an Alfisol developed under prairie vegetation by cropping was primarily from the rapid fraction with a half-life of 10–15 years (Balesdent et al., 1988). The slow or stable fraction, which constituted about 50% of the current level of organic matter, had nearly a complete turnover period of 600 years.

Changing tillage systems or crop rotations can enhance the accumulation of soil organic carbon. Evaluating a global database of 67 long-term experiments, West and Post (2002) found that a change from conventional tillage to no-till can sequester an average of $57 \text{ g C m}^{-2} \text{ year}^{-1}$. Changing to a more complex rotation can sequester an average of $20 \text{ g C m}^{-2} \text{ year}^{-1}$ excluding corn–soybean (*Glycine max* L.) rotations.

Addition of organic manures as part of cropping systems has been shown to result in increased soil organic matter content. Many reports have shown that these organic manure additions increase water-holding capacity (Hudson, 1994), porosity, hydraulic conductivity, infiltration capacity, and water-stable aggregates while decreasing soil bulk density and surface crusting (Haynes and Naidu, 1998).

Aggregates and aggregate stability

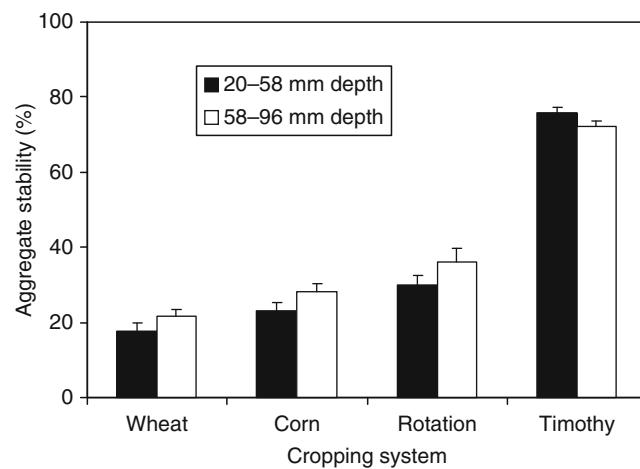

Comparing no-till dryland cropping systems after 12 years in eastern Colorado, USA, Shaver et al. (2002) found that macroaggregates ($>0.25 \text{ mm}$) made up a higher percentage of total aggregates in continuous cropping, wheat–corn–fallow, or wheat–sorghum (*Sorghum bicolor* L.)–fallow cropping systems compared to a traditional wheat fallow system (Shaver et al., 2002). More soil macroaggregates were attributed to greater levels of crop residue and subsequent soil organic matter production. Greater proportions of macroaggregates provided a greater opportunity to capture a higher proportion of precipitation and a more rapid capture of precipitation, which should improve long-term grain productivity of these cropping systems.

The influence of long-term cropping systems on soil aggregate stability was evaluated in Sanborn Field in central Missouri, USA by Rachman et al. (2003). Over 100 years of continuous cropping to timothy (*Phleum pratense* L.) produced higher aggregate stability compared to continuous corn (*Zea mays* L.) or continuous wheat (*Triticum aestivum* L.; Figure 1). This effect was observed in both the 2- to 6-cm (three to four times) and 6- to 10-cm (two to three times) depths. Rachman et al. (2003) speculated that more development of root binding in the timothy plots without annual tillage helped enhance aggregate stability. Annual tillage and exposure to raindrop impact during fallow periods for the corn and wheat plots decreased aggregate stability.

In the same study (Rachman et al., 2003), changing cropping systems from continuous corn or wheat to a three rotation of corn–wheat–red clover (*Trifolium pratense* L.) increased aggregate stability by 29% and 67%, respectively (Figure 1). Possible reasons for the increase in aggregate stability for the rotation plots include bonding material produced by red clover and canopy protection during the fallow period. Organic matter decomposition can be increased with red clover since it fixes nitrogen. The microbially mediated activity of decomposing organic matter produces polymers that bind soil particles together, which slows the rate of aggregate wetting and decreases the extent of slaking (Rachman et al., 2003).

Soil strength

Soil strength measured using a fall-cone penetrometer was found to be nearly five times greater for no-till management compared to conventional tillage management for coastal plain soils in Maryland, USA (Hill, 1990). These

Cropping Systems, Effects on Soil Physical Properties,

Figure 1 Aggregate stability values of two soil depths, 20–58 mm and 58–96 mm, for selected cropping systems in Sanborn Field, Missouri, USA ($n = 8$; Rachman et al., 2003). Bars represent the standard error of the mean. (Reprinted with permission from the Soil Science Society of America.)

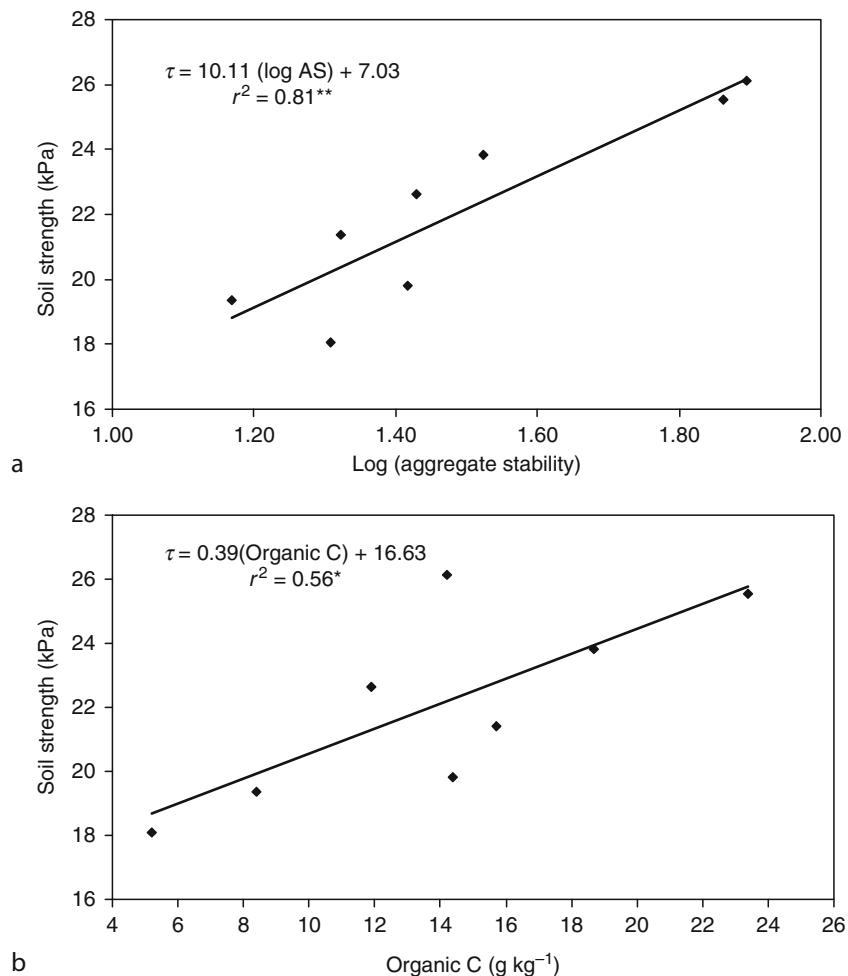

differences were attributed to higher soil bulk density for this treatment since no-till did not receive tillage compared to the conventionally tilled treatments.

The effect of long-term (100 year) cropping systems for Sanborn Field on soil shear strength was also evaluated using a fall-cone device (Rachman et al., 2003). Continuous cropping to timothy produced 27–33% greater soil strength compared to continuous wheat or continuous corn. The 3-year rotation of corn–wheat–red clover was also 14–19% higher compared to the wheat and corn plots. Rachman et al. (2003) speculated that higher organic carbon may have enhanced soil strength; strength was linearly related to organic carbon ($r = 0.75$; Figure 2). Soil strength was also linearly correlated with the log of aggregate stability ($r = 0.90$; Figure 2). Annual tillage for the continuous wheat and corn plots resulted in lower organic carbon, aggregate stability, and soil shear strength.

Bulk density and porosity

Alegre and Cassel (1996) found in the humid tropics that land cleared with bulldozers for continuous cropping systems (1.63 g cm^{-3}) significantly increased bulk density by 12% compared to traditional slash-and-burn systems (1.46 g cm^{-3}). If land is cleared with bulldozers, additional soil management is needed to remove the negative effects of mechanical land clearing. Use of agroforestry systems with cover crops and trees may actually improve soil physical properties (Alegre and Cassel, 1996).

Comparing 6-year old agroforestry (pin oak, *Quercus palustris* Muenchh.) and grass-legume buffers to a corn–soybean rotation under no-till management, Seobi et al. (2005) found that buffers decreased soil bulk density by 2.3%. However, coarse macroporosity (60- to 1,000- μm diam.) increased by 33% for the buffer treatments. Comparing land under row crop management to

Cropping Systems, Effects on Soil Physical Properties, Figure 2 Fall-cone soil shear strength vs. (a) the logarithm of aggregate stability (20–58 mm depth) and (b) organic C ($n = 4$; Rachman et al., 2003). * and ** Significant at the 0.05 and 0.01 probability levels, respectively. (Reprinted with permission from the Soil Science Society of America.)

native and restored prairie sites, Udwatta et al. (2008) found a 19% increase in bulk density throughout the surface 40 cm for a corn–soybean rotation compared to a native prairie site. These differences were attributed to five times lower macroporosity ($>1,000 \mu\text{m}$ diam.) for the cultivated site.

Shaver et al. (2002), in comparing no-till dryland cropping systems after 12 years, found that soil bulk density decreased and soil total porosity and effective porosity (total porosity minus water content at -10 kPa) increased for continuous cropping and wheat–corn–fallow cropping systems compared to a traditional wheat fallow system. These changes in physical properties were attributed to the continuous cropping and wheat–corn–fallow cropping systems returning more residue to the soil. The effects of these cropping systems on soil physical properties may often only be observed after several years.

Water retention and pore-size distribution

Evaluation of soil water retention can be used to determine soil pore-size distributions (Anderson et al., 1990). Crop management and landscape effects on water retention and pore-size distributions were evaluated by Jiang et al. (2007). After 14 years of management, they found significantly higher soil water retention for the Conservation Reserve Program system and hay crop management sites compared to a mulch till corn–soybean rotation from saturation to -1.0 kPa within the upper 10-cm soil depth. Jiang et al. (2007) also found 50% higher macroporosity ($>1,000 \mu\text{m}$ diam.) plus coarse mesoporosity (60- to $1,000\text{-}\mu\text{m}$ diam.) for the 10-cm soil depth in the Conservation Research Program treatment compared to the hay, no-till corn–soybean–wheat rotation, and the mulch till corn–soybean rotation treatments.

Assessing piedmont and coastal plain soils in Maryland, USA, Hill (1990) compared pore-size distributions between conventional tillage and no-till treatments after 11–12 years of management. A significantly larger volume of total pores and pores $>3.0 \mu\text{m}$ in diameter were found for the conventional tillage compared to no-till management for the coastal plain sites. Even though the no-till treatment had less volume for plant available water storage compared to conventionally tilled plots, corn production was higher with no-till probably due to better infiltration, less runoff, and less evaporation (Hill, 1990).

Hydraulic conductivity and infiltration

Evaluating historic crop management plots on Sanborn Field, Anderson et al. (1990) found that annual additions of manure (13.5 Mg ha^{-1}) for 100 years increased saturated hydraulic conductivity by about nine times. These differences were attributed to higher numbers of earthworms, which increased due to the higher amounts of organic matter in these plots.

Crop management and landscape effects on soil saturated hydraulic conductivity were evaluated for claypan

soils in Missouri, USA by Jiang et al. (2007). They found that hydraulic conductivity was 16 and 10 times higher under a Conservation Reserve Program system and hay crop management compared to a mulch till corn–soybean rotation at the backslope position, where the argillic clay subsoil horizon was closest to the surface. At the same site, infiltration was higher for perennial cropping systems such as Conservation Reserve Program and hay crop management compared to annual cropping systems such as mulch till and no-till corn–soybean rotations and a no-till soybean–corn–wheat rotation (Jung et al., 2007). Differences were attributed to lower antecedent soil water content in the spring for the perennial cropping systems.

After 13 years, Blanco-Canqui et al. (2004) evaluated saturated hydraulic conductivity for three tillage systems (no-till, chisel plow, moldboard plow) for two crops (corn, soybean) compared to continuous fallow plots. Crop had a greater effect on hydraulic conductivity compared to tillage with corn management decreasing conductivity compared to soybean management. All tillage and crop management systems had greater hydraulic conductivity compared to fallow management.

No-till management systems have been found to decrease runoff and increase infiltration compared to conventional tillage systems. Edwards (1982) found that no-till, with its increased number of macropores, decreased runoff by 20 times compared to conventional tillage in Ohio, USA. In western Nigeria, Lal (1997) found that tillage management significantly affected infiltration. In an 8-year experiment, no-till management significantly increased infiltration compared to a moldboard plow–harrow–ridge till treatment. In the humid tropics, Alegre and Cassel (1996) found reduced infiltration (35 mm h^{-1}) for mechanically cleared land for continuous cropping systems compared to traditional slash-and-burn systems (420 mm h^{-1}). They suggest use of agroforestry systems with cover crops and trees to improve soil physical properties.

Rachman et al. (2004) found that narrow, stiff-stemmed perennial grass hedges used as vegetative terraces significantly improved water infiltration compared to a traditional corn–soybean rotation on soils formed in deep loess. They found stiff-stemmed hedges had six times higher quasi-steady infiltration rates compared to row crop areas. These differences were attributed to significantly higher macroporosity under grass hedges.

Summary

Soil physical properties are significantly affected by cropping systems, especially tillage management. Tillage usually reduces soil bulk density and increases soil porosity initially; however, tillage decreases soil organic matter, which can also affect bulk density and porosity. Less frequent tillage and crop rotations with legumes enhance aggregate stability. No-till management tends to increase soil bulk density, increase soil strength, decrease total porosity, increase saturated hydraulic conductivity, and

increase infiltration (for well-drained soils). Enhancing residue cover is an important issue for modern conservation crop management systems in order to minimize soil erosion caused by tillage.

CULTIVATION UNDER SCREENS, AERODYNAMICS OF BOUNDARY LAYERS

Josef Tanny

Institute of Soil, Water, and Environmental Sciences,
Agricultural Research Organization, The Volcani Center,
Bet Dagan, Israel

Definitions

Cultivation. The process of growing agricultural plants.

Screen. A porous material made of knitted or woven plastic threads. Screens are usually deployed above crops to protect them from various external hazards.

Aerodynamics. Study of air motion and its interaction with bodies in the flow.

Boundary layer. The layer of air adjacent to a bounding surface.

Introduction

The area of agricultural crops grown under screens and within screenhouses is constantly increasing. This is especially true in regions where climatic and environmental conditions, such as high radiation loads during certain seasons, water scarcity, wind and hail storms, and environmental pressure of insects, adversely affect competitive year-round production. The increased use of screenhouses by growers triggered the expansion of research on the effects of various screens on microclimate and on crop water use, as well as on produce quality and quantity. The ultimate goal is to optimize the design and use of screens to obtain high-quality yields. Research on screenhouse microclimate can be traced back to the beginning and middle of the twentieth century (Jenkins, 1900; Stewart, 1907; Waggoner et al., 1959), but only during the past few decades, with the progress of electronic measurement systems and data-processing capabilities, has a much better understanding of the screenhouse environment been achieved.

Screen constructions used to protect crops can be divided into two major categories: (1) horizontal screen covers without sidewalls, deployed at some height above the canopy top; (2) screenhouses consisting of a horizontal screen cover and screened sidewalls. Both types partially isolate the crop system from the outside environment. One major isolating factor is the resistance to transport of momentum, heat, and matter through the screen; this may impair proper ventilation and cause excessive temperature and humidity under the screen. Limited ventilation can also reduce the supply of CO₂ below adequate levels, thus inhibiting photosynthesis and consequently reducing production. On the other hand, reduced wind speed and temperature and increased humidity (or lower vapor pressure deficit) reduce the drying power of the air boundary layer near the plants, and may contribute to water saving. Thus, knowledge of aerodynamic properties of boundary layers along screens covering plant canopies is required for proper performance of the crop system.

The air flow along horizontal screens can be divided into two regions: above and below the screen. Above the screen, a boundary layer flow is established adjacent to the porous surface below, with the far edge of the boundary layer being the free atmosphere above. In this region, we anticipate the prevalence of the logarithmic wind profile, typical of turbulent flows along flat surfaces. Below the screen, the flow may be more complex and may strongly depend on the thickness of the air gap between the canopy top and the screen cover. The close proximity of the canopy elements may also influence the air flow characteristics. For open, uncovered canopies, this region is known as the “roughness sub-layer” where the roughness elements of the canopy (e.g., leaves and stems) control the flow properties. In this region, either logarithmic profile or channel flow profile or some combination of both is possible.

Other parameters influencing the flow properties along screens are the canopy morphology, the crop leaf area index, and the screen porosity, i.e., the ratio of open area to total screen area. Obviously, screens with higher porosity will have a smaller effect on the wind profile as compared with an uncovered canopy.

Theory and methods

The literature on cultivation under screens is focused on quantifying the effect of screens on micro-climate, air flow, and transport above the protected canopy. Hence, this section will briefly review the principles of boundary layer flows above plant canopies.

The wind speed profile in the surface layer above a canopy or a horizontal screen cover can be described (Stull, 1988) by

$$u(z) = \frac{u_*}{k} \left[\ln\left(\frac{z-d}{z_0}\right) + \Psi_M \right], \quad (1)$$

where u is the mean horizontal wind speed, z is the height above the ground, and k is the von-Karman constant ($= 0.41$).

The aerodynamic properties of the boundary layer flow are u_* , the friction velocity which represents the vertical transport of momentum by the turbulent flow; d , the zero-plane displacement which represents the vertical displacement of the wind profile by the canopy elements; z_0 , the roughness length, representing the surface roughness due to the canopy.

The function Ψ_M represents the stability of the air layer above the surface, either the canopy or the screen cover. Under neutral conditions, $\Psi_M = 0$ and the well-known logarithmic wind profile is resumed. Under such conditions, zero wind speed is achieved at $z = d + z_0$. Under stable conditions, $\Psi_M > 0$ and vertical transport is inhibited. Stable flow takes place when cooler (and heavier) air underlies warmer (and lighter) air. Over soil or vegetated surfaces such a situation may occur during clear nights where radiation to the sky cools down the earth's surface. Under unstable conditions, $\Psi_M < 0$ and vertical transport

may be enhanced. Unstable conditions prevail when warmer air underlies cooler one. This usually occurs due to daytime heating of surfaces by solar radiation. Under both non-neutral conditions the log-linear wind profile ([Equation 1](#)) prevails.

Usually, the aerodynamic properties for a specific crop system (e.g., a given crop, a forest canopy, or an orchard covered by a screen) are determined by fitting the wind speed profile equation ([Equation 1](#)), to the wind profile actually measured by anemometers at several levels above the crop or the screen cover. The aerodynamic properties are then used to calculate the aerodynamic resistance which controls vertical transport across the boundary layer. Different expressions are given in the literature for the aerodynamic resistance under unstable, neutral, and stable conditions (Monteith and Unsworth, [2008](#); Stull, [1988](#); Tanny et al., [2009](#)).

Aerodynamic properties of boundary layers above screens

Literature studies were mainly aimed at investigating the effect of screens on the aerodynamic properties (Tanny and Cohen, [2003](#)) and comparing the properties obtained under different crop systems and screens' dimensions (Tanny et al., [2009](#)).

A comparison between aerodynamic properties of boundary layers over covered and uncovered citrus trees was conducted under stable conditions (Tanny and Cohen, [2003](#)). A relatively small shading screen covered few citrus trees and was surrounded by a large uncovered orchard. The screen inhibited the turbulent transport by reducing the friction velocity, u_* . The screen cover reduced the roughness length z_0 , reflecting the difference between the flat and relatively smooth screen surface and the irregular rough surface of the exposed canopy. Over the covered trees, the zero-plane displacement d was larger than over uncovered ones. This was due to the effect of the screen in displacing the wind profile upward. All these effects caused the aerodynamic resistance to be significantly higher over the covered trees as compared to the exposed ones. The increased resistance may be one of the reasons for the reduced crop water consumption observed over covered crops. See, for example, Tanny et al. ([2006](#)) for a banana plantation.

The effect of stability was considered only for the covered citrus trees (Tanny and Cohen, [2003](#)). As expected, stable conditions inhibited the turbulent transport in comparison to unstable conditions. The roughness length decreased and zero-plane displacement increased with increasing stability. Corresponding values of aerodynamic resistance increased with stability. These results showed that roughness length and zero-plane displacement are stability-sensitive properties and do not depend only on geometric surface properties. Unstable flows induce more intense motion in the leaves and the canopy, and a more wave-like motion of the screen than stable flows, thereby increasing the surface roughness. Unstable conditions

enhance the vertical motion of air, which may also contribute to the larger friction velocity and lower values of the zero-plane displacement and aerodynamic resistance.

Different crop-screen systems are characterized by different aerodynamic properties. Properties over a small shade net, covering several citrus trees, were compared with those over a large screenhouse covering a pepper plantation (Tanny et al., [2009](#)). Under stable conditions, normalized aerodynamic properties, including the aerodynamic resistance, were the same at both settings. Under unstable conditions, the boundary layer over the large screenhouse was characterized by a lower aerodynamic resistance and a more intense turbulent transport. Tanny et al. ([2009](#)) suggested that the main reason for this difference is the different interaction of the screen and crop elements in the two settings with the vortices characterizing unstable winds.

Properties of the flow below the screen

The flow below the screen may be more complex than the flow above. Screen, canopy, and the distance between them may influence the flow structure and properties.

Measurements within an insect-proof screenhouse in which pepper was grown (Tanny et al., [2003](#); Möller et al., [2003](#)) have shown that at the leeward half of the screenhouse, airflow direction was essentially opposite to the external wind. On the other hand, in a banana plantation, covered with a much more porous screen, air flow directions inside (at the center) and outside were nearly the same (Tanny et al., [2006](#)). The difference can be attributed to the effect of the screen porosity on air flow patterns. Denser screens may induce larger resistance to the wind, thus causing a more significant deflection of wind streamlines around the screenhouse. Streamline deflections are associated with pressure gradients which may cause counter flow within the structure.

Turbulence characterization was reported for a banana screenhouse, in the air gap between the crop and the screen (Tanny et al., [2006](#)). Mean value of the turbulence intensity was 0.49 ± 0.12 . This suggested that Taylor's hypothesis of frozen turbulence was marginally satisfied (Willis and Deardorf, [1976](#)). Spectral energy density was plotted against frequency; slopes of regression lines were very close to the well-known slope of $-\frac{5}{3}$, typical of the inertial sub-range in steady state boundary layers (Stull, [1988](#)).

During the past 2 decades a new view of canopy flow has emerged, namely, the mixing layer analogy (Raupach et al., [1996](#)), suggesting that the flow above canopies resembles that of a mixing layer rather than a surface layer. This type of flow is associated with well-organized eddies of whole canopy scale resulting from Kelvin–Helmholtz hydrodynamic instabilities. To distinguish between surface layer and mixing layer flows, Raupach et al. ([1996](#)) presented a comparison between several statistic flow properties in the two flow configurations. For example, their Table II shows that in the surface layer

$\sigma_u/u_* = 2.5$, whereas in the mixing layer $\sigma_u/u_* = 1.7$, where σ_u is the standard deviation of the horizontal velocity. Corresponding average values within a large banana screenhouse measured by the present author were: $\sigma_u/u_* = 2.8 \pm 0.67$ at 5 m height and $\sigma_u/u_* = 2.65 \pm 0.65$ at 3.55 m height (where \pm is standard deviation) with trees' height of 3.1 m. These values are much closer to those of a surface layer than a mixing layer, suggesting that this type of flow prevails within the screenhouse.

Summary

Cultivation under screens is becoming more and more popular among growers due to its favorable effects on yield quality, production scheduling, and relatively low cost, as compared to plastic greenhouses. The screens inhibit the exchange of momentum, heat, matter, and radiation between the crop and the atmosphere. Scientific literature demonstrates the increased aerodynamic resistance over covered crops as compared to exposed ones. The higher resistance modifies the crop microclimate under the screen and thus may be partially associated with water saving and increased water use efficiency. Further research is needed to optimize screenhouse design for specific crops in given climatic regions.

D

DARCY'S LAW

The basic law describes the flow of water or other liquids in permeable materials (e.g., soil, porous rock, concrete, timber, or other porous material). Darcy's law tells that the water flux q (m s^{-1}) at any point is proportional to the gradient of the water potential at that point and the coefficient of proportionality is the water conductivity coefficient:

$$\vec{q} = K(\psi) \cdot \text{grad}\psi$$

where: q is the water flux [m s^{-1}], $K(\psi)$ is the water conductivity coefficient [m s^{-1}] and ψ is the soil water potential [m].

DATABASES ON PHYSICAL PROPERTIES OF PLANTS AND AGRICULTURAL PRODUCTS

Agnieszka Kaleta, Krzysztof Górnicki
University of Life Sciences (SGGW), Warszawa, Poland

Definition

Physical properties of plants and agricultural products can be defined as the characteristics of described materials that are independent of the observer, measurable, can be quantified, and define the state of the material but not how it attained that state.

Introduction

Physical properties describe the unique, characteristic way a plant or agricultural product responds to physical treatments, for example, thermal, mechanical, or electrical processes. Knowledge of physical properties of described materials is essential for the design of equipment for their handling, storage, and processing. Data on physical properties of plants and agricultural products are needed as input to models predicting the quality and behavior of produce in preharvest, harvest, and postharvest situations. The properties of discussed materials are affected by many factors such as moisture content, growing location, growing year, and cultivar. Many properties also depend on other properties. Physical properties can change during processing operations.

Physical characteristics

The size of spherical particles like peas is easily defined by a single characteristic (its diameter). Complete specification of the form of the objects irregular in shape theoretically requires an infinite number of measurements. However, three mutually perpendicular axes account for some 93% of variation in volume (Mohsenin, 1986). Length, width, and thickness (m) are commonly used that correspond to major, intermediate, and minor axes, respectively. The dimensions increase linearly with increasing moisture content. The dimensions range approximately: (1) length: 0.8×10^{-3} – 18.5×10^{-3} m for seeds and grains, 8.6×10^{-3} – 26.3×10^{-3} m for fresh blueberries, cherries, cranberries, grapes and pistachio nuts, 43.2×10^{-3} – 94×10^{-3} m for fresh apples, peaches, pears, plums, potatoes, and tomatoes, (2) width: 0.6×10^{-3} – 11×10^{-3} m for seeds and grains, 11.4×10^{-3} – 17.8×10^{-3} m for fresh blueberries and cherries, 40.6×10^{-3} – 83.8×10^{-3} m for fresh apples, peaches, pears,

plums, potatoes, and tomatoes, (3) thickness: 0.4×10^{-3} – 10.0×10^{-3} m for seeds and grains, 6.35×10^{-3} – 17.8×10^{-3} m for fresh blueberries, cherries, and cranberries, 38.1×10^{-3} – 76.2×10^{-3} m for fresh apples, peaches, pears, plums, potatoes, and tomatoes. The size of irregularly shaped non-isometric object is a statistical parameter that depends on the direction of measurement. To reduce the resultant scatter in measured diameters, the size of object is expressed in a standardized form. An *equivalent diameter* is one of these forms. The volume diameter (diameter of the sphere having the same volume as object) is the most frequently used definition. For grains, the volume occupied by 1,000 kernels is commonly measured. The *geometric mean diameter* ($d_{eg} = (abc)^{1/3}$, where a is the longest intercept, b is the longest intercept normal to a , c is the longest intercept normal to a and b) is used sometimes. Both diameters increase slightly with the increase of moisture content (linear function). The equivalent diameter for seeds and grains ranges approximately from 0.99×10^{-3} to 9.81×10^{-3} m. The geometric mean diameter ranges approximately: for seeds and grains: 2.93×10^{-3} – 8.33×10^{-3} m, for fresh blueberries and cherries: 10.4×10^{-3} – 17×10^{-3} m, for fresh apples, peaches, plums, pears, potatoes, and tomatoes: 43.4×10^{-3} – 73.7×10^{-3} m. A monodisperse material is characterized uniquely by the size of individual particles. A polydisperse material is characterized by a *particle size distribution* and by a *mean particle size*. Particle size distribution represents the relative amount of material defined either by the number of particles, their surface area, volume, or mass as a function of the particle size. The mean particle size represents the average value for the whole population of particles. *Roundness (angularity)* of an object is most commonly defined as the ratio of: (1) the largest projected area of object in natural rest position to the area of the smallest circumscribing circle, or (2) an average radius of corners or edges to the radius of the largest inscribed sphere. Roundness values differ for both of the above methods. *Sphericity* is most commonly defined as the ratio of: (1) the volume of an object to the volume of the smallest circumscribing sphere, or (2) the equivalent diameter (or the geometric mean diameter) of the object to the diameter of the smallest circumscribing sphere. Sphericity values differ for each of the above methods. Higher values of sphericity and roundness indicate that the object's shape is closer being spherical. Sphericity increases linearly with increasing moisture content. Sphericity ranges approximately: for seeds and grains: 0.58–0.93, for fresh apples, apricots, blueberries, cherries, peaches, and pears: 0.90–0.99. *Surface area* is the area of the outer surface of an object (m^2). *Specific surface area* is defined as the ratio of the surface area of an object to the volume of an object (m^{-1}). Both characteristics depend on linear dimensions of solids and on their moisture content. Surface area of fruits increases linearly with their increasing mass. For seeds and grains, surface area ranges approximately from 3×10^{-6} to 240×10^{-6} m^2 and specific surface area ranges approximately from

500 to $6,060 \text{ m}^{-1}$. *Volume* is defined as the amount of three-dimensional space occupied by an object (m^3). Volume of the solid depends on its linear dimensions, surface area, moisture content, and temperature. Volume ranges approximately: for seeds and grains: 0.5×10^{-9} – 369×10^{-9} m^3 , for fresh blueberries, coffee beans, cherries, and pistachio nuts: 0.3×10^{-6} – 4.5×10^{-6} m^3 , for fresh apples, peaches, pears, plums, potatoes, and tomatoes: 44.2×10^{-6} – 349×10^{-6} m^3 . For grains, the *mass* of 1,000 kernels is commonly measured (kg). Its value is an indicator of the grain size, which can vary relative to growing conditions and maturity, even for the same variety of a given crop. The 1,000-grain mass increases linearly with increasing moisture content and it ranges approximately from 3×10^{-3} to 440×10^{-3} kg. The mass ranges approximately: for fresh blueberries, cherries, cranberries, grapes, pistachio nuts, coffee beans, and walnuts: 0.15×10^{-3} – 7.5×10^{-3} kg, for fresh apples, apricots, peaches, pears, plums, potatoes, and tomatoes: 18.1×10^{-3} – 286×10^{-3} kg. The *solid (true) density* is the mass of solid divided by the volume occupied by the solid excluding the intergranular spaces (kg m^{-3}). True density of grains decreases linearly with increasing moisture content (the changes are not significant). True density can be treated as a measure of, among others, maturity (blueberries, peas, peaches, tomatoes), starch content (potatoes), and peel thickness (grapefruits). True densities range approximately: for seeds and grains: 700 – $2,000 \text{ kg m}^{-3}$, for fruits and vegetables: 700 – $1,200 \text{ kg m}^{-3}$, for wood: 400 – $1,300 \text{ kg m}^{-3}$. *Bulk density* is the mass of a group of individual particles divided by the space occupied by the entire mass, including the air space (kg m^{-3}). The bulk density gives an idea of the storage space required for a known quantity of a particular, for example, grain. The bulk density can be affected by the following factors: mass of particles, their shape and dimensions, particle size distribution, the method used for filling the container, moisture content of particles, the amount and size distribution of foreign materials (chaff, fines, broken grains, and weed seeds). For example, a container filled using a spreader gives a higher bulk density than a container filled using a spout, the presence of foreign materials that are finer and heavier than grain kernels increases bulk density. The bulk density of some grains increase with an increasing moisture content whereas it decreases for some other grains. The bulk densities range approximately: for clean seeds and grains: 240 – 910 kg m^{-3} , for fruits and vegetables: 220 – 830 kg m^{-3} . The *porosity (decimal)* is defined as the ratio of the intergranular volume to the total volume occupied by the particles (i.e., the volume of particles plus the intergranular volume). Porosity depends on true and bulk density of material. Porosity allows fluids to flow through a mass of particles referred to as a packed bed. Beds with low porosity are more resistant to fluid flow and thus are more difficult to dry, heat, or cool. The porosity for clean seeds and grains ranges approximately from 0.26 to 0.80. *Shrinkage* is the decrease in volume of the material during processing such as drying. When moisture

is removed from material, there is a pressure imbalance between inside and outside of the material. This causes contracting stresses leading to material shrinkage or collapse. Shrinkage is defined as the ratio of the volume at a given moisture content to the initial volume of material before processing. Shrinkage depends mainly on moisture reduction (in the empirical formulas linear dependence is mostly assumed) and composition and structure of the material. Data on physical characteristics of plants and agricultural products have been compiled and further details can be taken from Mohsenin (1986), Cenkowski and Zhang (1995), Kaleta (1996), Kudra (1998), Pabis et al. (1998), Sablani and Ramaswamy (2003), Wilhelm et al. (2004), and Jayas and Cenkowski (2006).

Aerodynamic properties

The drag force, F_r ($F_r = C\rho_f A_p v^2$, where ρ_f is the fluid density, A_p is the projected area normal to direction of motion, v is the relative velocity between main body of fluid and object), exerted on an object held in a free stream depends on dimensionless *drag coefficient* C . Drag coefficient depends on the shape of the particle and the state of its surface, and on the Reynolds number Re . The drag coefficients for particles with regular geometric shapes are usually shown on log–log plot, as a function of Re . For turbulent flow and for the values of Re characteristic for the processes of cleaning, separating, and pneumatic transporting, the dependence of drag coefficient on Re can be neglected. The drag coefficients for agricultural products range approximately from 0.16 to 0.44 (Mohsenin, 1986; Kaleta, 1996; Jayas and Cenkowski, 2006). A free-falling body ceases to accelerate after some time and the body reaches a constant *terminal velocity*, at which the net gravitational accelerating force equals the resisting upward drag force. This velocity can be calculated theoretically for particles with regular geometric shapes. For irregularly shaped particles, the terminal velocity is determined experimentally. The terminal velocities range approximately (Mohsenin, 1986; Kaleta, 1996; Jayas and Cenkowski, 2006): for seeds and grains: 4.0–18.3 $m s^{-1}$, for fresh blueberries, cherries, cranberries, grapes, and pistachio nuts: 9.7–22.6 $m s^{-1}$, for fresh apples, apricots, peaches, plums, and potatoes: 22.9–41.5 $m s^{-1}$.

Thermal properties

Specific heat (heat capacity) is the heat required to increase the temperature of one unit of mass by 1° ($J kg^{-1} K^{-1}$). The specific heat depends on: composition of the material, moisture content, and temperature (in heat transfer problems of biological materials usually constant pressure prevails). Specific heat can be computed from the following equations: (1) for temperature above freezing: $c = 837 + 33.5M_w$ (Siebel, 1892), $c = 1424X_c + 1549X_p + 1675X_f + 837X_a + 4187X_w$ (Heldman and Singh, 1981), $c = c_s + 4186M_d$, (2) for temperature below freezing $c = 837 + 12.56M_w$ (Siebel, 1892),

where M_w is the moisture content, % w.b., M_d is the moisture content, d.b., X is the mass fraction of each constituent: carbohydrate (c); protein (p); fat (f); ash (a); water (w), c_s is the specific heat of the dry solid. The specific heat is most commonly calculated from regression equations obtained from empirical data (linearly increasing trend with increasing moisture content and increasing temperature is generally reported). Its value ranges approximately: for wood: 1,880–2,970 $J kg^{-1} K^{-1}$, for dry mass of plants, seeds, and grains: 990–2,050 $J kg^{-1} K^{-1}$, for fresh fruits and vegetables: above freezing: 3,140–4,100 $J kg^{-1} K^{-1}$, below freezing: 1,670–2,390 $J kg^{-1} K^{-1}$. The *thermal conductivity* ($W m^{-1} K^{-1}$) of a material is a measure of its ability to conduct heat. It defines the amount of thermal energy that is transmitted within a unit time and through a unit cross-sectional area when the temperature gradient across a body is a unit degree ($q = -k\nabla T$, where q is the heat flux, k is the thermal conductivity, ∇T is the temperature gradient). The thermal conductivity depends on the composition of the material, moisture content, temperature, and structure of the material including any factor that affects the heat flow path through the material (percent void spaces, shape, size, and arrangement of void spaces, heterogeneity, impurities, particle to particle contact, and fiber orientation). Theoretical models for the prediction of thermal conductivity of plants and agricultural products are based on the composition of material or on the arrangement and geometry of phases present in the material, but they lack accuracy (Sweat, 1992; Kudra, 1998; Saravacos and Maroulis, 2001; Sahin and Sumnu, 2006). Therefore, the thermal conductivity is most commonly calculated from regression equation (linearly increasing trend with increasing moisture content, increasing temperature, and increasing bulk density is generally observed). For high moisture materials below freezing, thermal conductivity increases with a decrease in temperature and a sudden jump in its value can be observed at freezing point. The thermal conductivity ranges approximately from 0.110 to 0.720 $W m^{-1} K^{-1}$ for wood and from 0.280 to 0.640 $W m^{-1} K^{-1}$ for fresh fruits and vegetables (above freezing). The *thermal diffusivity* ($m^2 s^{-1}$) is defined as the ratio of thermal conductivity to the product of density and specific heat. It relates the ability of material to conduct the heat to its ability to store the heat. Thermal diffusivity may be considered as the rate at which heat propagates (diffuses) through a material. The relationship between the moisture content and the thermal diffusivity is rather not a linear function (in the narrow range of moisture content, however, most commonly linear regression is applied). The thermal diffusivity ranges approximately: for wood: 0.94×10^{-7} – $2.2 \times 10^{-7} m^2 s^{-1}$, for seeds and grains: 0.81×10^{-7} – $1.64 \times 10^{-7} m^2 s^{-1}$, for fresh fruits and vegetables: 0.78×10^{-7} – $2.69 \times 10^{-7} m^2 s^{-1}$. Data for specific heat, thermal conductivity, and thermal diffusivity of plants and agricultural products have been compiled from Mohsenin (1980), Sweat (1992), Pabis et al. (1998), Kaleta (1999), Sablani and Ramaswamy (2003), and Jayas

and Cenkowski (2006). Regression equations for the prediction of these thermal properties can be found in the same bibliography. If the temperature of an object changes due to the heat transfer, then the heat transfer involves a transfer of sensible heat. The exchange of energy that occurs during a change in phase (without a temperature change) is called the latent heat. The *heat of fusion (solidification)* is the heat exchange during the phase change from liquid to solid. *Latent heat of vaporization* is the energy to change a liquid to vapor. The heat of vaporization is about seven times more than the heat of fusion, which is five times more than raising the temperature (sensible heating) by 100 K (Wilhelm et al., 2004). For materials of moisture content below approximately 0.14 d.b., to overcome the attractive forces between the adsorbed water molecules and the internal surfaces of material extra energy is needed in addition to the heat required to change the water from liquid to vapor (Pabis et al., 1998). Plants and agricultural products freeze at lower temperatures than pure water (approximately 269.5–272.8 K) due to the presence of solutes and solids in the water (*freezing point depression*) (Kaleta, 1999). Plants and agricultural products are living organisms and they must consume energy to maintain their life processes. They do this by a process of combustion that burns sugar to produce CO₂ and *heat of respiration*. Heat of respiration depends on product, its maturity, storage time (either an increase or a decrease) and increases exponentially with temperature. High respiration rate causes rapid deterioration in product quality (Mohsenin, 1980; Wilhelm et al., 2004).

Hygroscopic properties

The relation between material moisture content and air humidity is described by the drying equilibrium, which results from the fact that liquid moisture trapped in fine capillaries exerts a vapor pressure lower than that of liquid with a free surface. Drying equilibrium is determined experimentally by allowing sufficiently long contact of the bone dry material with air at a given humidity. Points obtained for various air humidities at the same temperature form the isotherm called the *equilibrium moisture content* (EMC) – equilibrium relative humidity (ERH) relationship (EMC represents the moisture content that the material will attain if dried for an infinite time at a particular relative humidity and temperature). The thermodynamic equilibrium can be obtained by moisture desorption (drying) or adsorption, therefore, the respective isotherm is strictly called either a desorption, or adsorption (Kudra and Strumillo, 1998). Desorption isotherms usually give higher moisture content than adsorption isotherms, which results in a hysteresis loop. The composition of the product, its temperature, storage time, drying temperature, and the number of successive adsorption and desorption affects hysteresis. Typical plants and agricultural products desorption/adsorption isotherms are S-shaped and they may be described by a number (~80) of mathematical relations (most of them are semiempirical or empirical equations with two or three fitting parameters).

The commonly used equations are: the Langmuir, Brunauer–Emmett–Teller (BET), Iglesias–Chirife, the modified Henderson, Chen, Chung–Pfost, Halsey, Oswin, and Guggenheim–Anderson–de Boer (GAB) (Rizvi, 1992). Constants of selected equations for the isotherm of various grains and seeds are given by Kaleta (1996), Pabis et al. (1998), and Jayas and Cenkowski (2006). The mechanism of moisture movement during the falling rate period of plants and agricultural products drying is mainly by diffusion. This can be described by Fick's law. Water can move in a solid in the form of liquid and/or vapor. The overall (total) *coefficient of water diffusion* is the sum of the liquid and vapor diffusion coefficients. Water diffusivity in solids depends on their temperature, moisture content, and structure. The overall coefficient of water diffusion (m² s⁻¹) is described by a number of semiempirical or empirical equations (Cenkowski and Zhang, 1995; Pabis et al., 1998; Saravacos and Maroulis, 2001). The Arrhenius-type equation to describe the relationship between diffusion coefficient and temperature and exponential relationship between coefficient and moisture content is mostly used. Shrinkage influences the water diffusion coefficient.

Mechanical properties

The coefficient of friction of the plants and agricultural products is necessary in designing of conveying, transporting, and storing structures. The *friction coefficient* is defined as the ratio between the friction force (force due to the resistance of movement) and the normal force on surface of contact (e.g., wall of the silo). Two types of friction coefficients are considered, the *static coefficient* determined by the force capable to initiate the movement and the *dynamic coefficient* determined by the force needed to maintain the movement of products in contact with the surface, which depends on the type and nature of the material in contact. An increase in coefficients of static and dynamic friction for various grains with increase in moisture content (mostly linear) is mostly observed. Both coefficients depend on the product and surface material. The friction coefficient ranges approximately (Mohsenin, 1986; Sablani and Ramaswamy, 2003; Jayas and Cenkowski, 2006): for seeds and grains: 0.11–0.76, for fresh apples and tomatoes: 0.24–0.88, for wood shavings and chopped grass, straw, and hay: 0.20–0.80. The *angle of natural repose* is the angle formed between the element of a cone and the base of piled cone (the angle with the horizontal at which the product will stand when piled). The properties of the particles forming medium (dimensions, shape, surface frictional properties, deformation ability) influence the value of this angle. The angle of repose increases with an increase in moisture content. Its value for grains ranges approximately from 17° to 45° (Mohsenin, 1986; Sablani and Ramaswamy, 2003). The other mechanical properties of plants and agricultural products can be measured by uniaxial compression, uniaxial tension, shear, and bending. The type of loading, preparation of the specimen,

loading rate, strain (deformation) rate, and other factors are dependent upon the product and desired use of the data (details are given by Mohsenin (1986), Cenkowski and Zhang (1995), and Wilhelm et al. (2004)).

Electromagnetic properties

Electromagnetic radiation is transmitted in the form of waves and it can be classified according to wavelength and frequency. The electromagnetic spectrum is very broad (from the shortest cosmic rays to the longest electric waves). Only a few specialized, narrow regions are utilized in plants and agricultural products applications. These include visible light, infrared, and microwave frequencies. When radiation of a specific wavelength strikes an object, it may be reflected, transmitted, or absorbed. The interaction of visible light and matter is referred to as a *color*. Most of the plants and agricultural products are opaque, they do not allow any transmission of light but absorb and/or reflect all the light striking. If all the visible light is absorbed, the object appears black. If all the visible light is reflected, the object appears white. The selective absorption of different amounts of the wavelength in the visible region determines the color of the object because reflected wavelengths are visible to the observer (e.g., green object reflects the green light spectrum but absorbs violet, blue, yellow, orange, and red). The color of a product is affected by the surrounding lighting intensity and wavelength. Thus, the color an observer perceives of an object can be influenced by changing the ambient light. For this reason, optical properties of product are considered as they interact with light. The human perception of color is highly subjective. Therefore, instrumental methods for color measurement have been developed (Munsell, CIE, CIE $L^*a^*b^*$ (CIELAB), Hunter Lab, and Lovibond). The color of an object is measured and represented by spectrophotometric curves, which are plots of fractions of incident light (reflected or transmitted) as a function of wavelength throughout the visible spectrum. Further details about color are given by Wilhelm et al. (2004) and Sahin and Sumnu (2006). In microwave heating, the dielectric properties of interest are the dielectric constant and the dielectric loss factor. *Dielectric constant* is the ability of a material to store microwave energy. *Dielectric loss factor* is the ability of a material to dissipate microwave energy into heat and this parameter is a measure of microwave absorptivity. As microwaves move through the object, the rate of heat generated per unit volume decreases. For materials having a high loss factor, the rate of heat generated decreases rapidly and the penetration depth of energy decreases. *Power penetration depth* (m) is the depth at which power decreases to e^{-1} of its original value. It depends on both dielectric constant and dielectric loss factor. Dielectric properties of plants and agricultural products depend on moisture content, temperature, composition and physical structure of the material, and the frequency of the oven. At low moisture content, variation of dielectric constant

and dielectric loss factor with moisture content is small. The increase in moisture content increases dipolar rotation and therefore both dielectric properties increase. The temperature dependence of dielectric properties depends on the ratio of bound to free moisture content. If the water is in bound form, the dielectric properties increase with increasing temperature. For the free water, the dependence on the temperature is opposite. At frequencies of home type microwave oven and at ambient temperature, the dielectric constant ranges approximately from 45 to 75 and the dielectric loss factor ranges approximately from 15 to 20 for seeds, grains, and fresh fruits and vegetables (Sahin and Sumnu, 2006).

Conclusions

Physical properties describe the unique, characteristic way a plant or agricultural product responds to physical treatments. Knowledge of these properties constitutes important engineering data in design of machines, processes, and controls and it is necessary for determining the efficiency of a machine and an operation and for evaluating the quality of the final product. Much of the data in the literature is of limited value because not enough supporting data are included, such as detailed product description, temperature, and error in measurement. The product description should include the cultivar, moisture content, maturity, and any pretreatment. Details of the experiment should include sample size, surface conditions, porosity, fiber orientation, sampling procedure, and process variables. The description should provide sufficient detail so that the reader can duplicate exactly the entire experiment. Insufficient description of product and process variables causes very often that data taken from several published sources differ a lot.

Data on physical properties of plants and agricultural products are scattered in an enormous number of scientific papers. Therefore, there is an urgent need to set all the data in order. This may enable some kind of systematization and generalization. Up to now, such extensive, well elaborated databases on all physical properties of plants and agricultural products do not exist and therefore the most important data available in the literature have been summarized in this contribution to give a good start point for such a database for future.

DATABASES OF SOIL PHYSICAL AND HYDRAULIC PROPERTIES

Attila Nemes
Crop Systems and Global Change Laboratory,
USDA-ARS, Beltsville, MD, USA

Definition

In this chapter, we review databases of international interest that contain significant quality and quantity of soil physical and hydraulic information – with a special emphasis given to soil hydraulic properties.

Introduction

Soil–plant–atmosphere modeling, weather and climate prediction, erosion modeling, and nutrient management advisory are examples for studies that require knowledge of soil physical and hydraulic properties. However, many such properties are costly and tedious to measure both in the field and in the laboratory. For this reason, the number of samples for which soil physical properties are determined in a particular laboratory or institute is usually limited. It has been recognized that collecting such fragmented data into larger databases can benefit all contributors and beyond. By establishing larger, national, or international scale databases, access to larger quantity and variety of data is facilitated; a wider range of methods can be examined and compared, and the user can derive conclusions that may be more widely applicable. In this chapter, the history, structure, contents, and availability of international databases of soil physical and hydraulic properties are summarized; certain data standardization issues are discussed; and a few challenges and database limitations are highlighted.

History of soil physical and hydraulic databases

Storage and retrieval of soil physical data developed with the advances made in (computerized) storage of information; first ASCII files replaced laboratory notebooks, but spreadsheets soon followed. Searchable relational database programs are the platform of choice today for modern databases.

For some countries, data collections at the national or regional scales have existed for decades. Examples for data collections of soil physical properties in particular countries, of which extensive research has been reported, include the databases of Australia (McKenzie et al., 2008), Belgium (Vereecken et al., 1989; Cornelis et al., 2001), Brazil (e.g., Tomassella et al., 2000, 2003), France (Bruand et al., 2004), Germany (Horn et al., 1991; Krahmer et al., 1995), Hungary (Rajkai et al., 1981; Nemes, 2002), the Netherlands (Wösten et al., 2001), Poland (Gliński et al., 1991), and the USA (Rawls et al., 1982; Soil Survey Staff, 1997). Some of these data collections, however, represent only certain region(s) of the listed countries.

Upon recognition of the strengths of and need for combining available data, some data collections were formed by individual scientists following an extensive literature search for the desired data (e.g., Rawls et al., 1982, 1998). Other data collections were formed by an open call and volunteered data by scientists from various parts of the World. The resulting Unsaturated Soil Hydraulic Database (UNSDODA) (Leij et al., 1996) and Grenoble Catalogue of Soils (GRIZZLY) (Haverkamp et al., 1998) were the first two truly international soil hydraulic databases. Different funding agencies also recognized the need for joint efforts and provided funds to support collection and analyses of data of different contributors (e.g., Hydraulic Properties of European Soils (HYPRES), Wösten et al., 1999). The International Soil Reference and Information Centre

(ISRIC) has assembled two databases that contain soil hydraulic properties and that are of international use. At the request of the Global Soil Data Task (GSDT) of the Data and Information System of the International Geosphere Biosphere Programme (IGBP-DIS), ISRIC prepared a uniform soil data set for the development of pedotransfer functions, which we will call the IGBP-DIS database (Tempel et al., 1996). Staff at ISRIC has also made available different versions of a global soil profile database that was developed in the framework of a project entitled “World Inventory of Soil Emission Potentials” (WISE, Batjes, 2002a, b, 2008). The WISE and IGBP-DIS databases contain, among many other attributes, soil physical and hydraulic data that originate from other independent international data sources like the Food and Agriculture Organization (FAO) (Food and Agriculture Organization, 1989) and the ISRIC Soil Information System. However, the majority of the IGBP-DIS database, and a lesser part of the WISE database originate from the National Soil Survey Characterization database (NSSC) of the U.S. Department of Agriculture Natural Resources Conservation Service (USDA-NRCS) (Soil Survey Staff, 1997) that holds data primarily of U.S. soils. While the NRCS-NSSC database is mostly a national scale database for the USA, it is discussed together with the above international databases due to its sheer size ($>100,000$ samples), the wide variety of soil types it covers, and the variety of measured and derived data that are available. Despite being a U.S. national database, the NRCS-NSSC database still includes a limited amount of data from other countries.

It is commonly seen that tropical countries, emerging market countries, and newly industrialized countries are underrepresented either in such international databases or only limited amount of detailed soil physical and hydraulic data are available for them – with only a few countries as exceptions. This has been recognized by several authors (e.g., Nemes et al., 2001; Batjes, 2002a) and some of the implications have been discussed by Tomasella et al. (2003) or De Condappa et al. (2008). Differences in environmental factors that influence soil development are such between the tropical and temperate climate zones that conclusions resulting from soils research may not always be applicable across climate zones. However, projects are increasingly being initiated to expand knowledge on soil hydraulic characteristics of soils in tropical and subtropical countries. The Soil Physics Research Unit of the University of Ghent, for example, is in collaboration with several local scientists to assemble data collections for Chile, Congo, Kenya, Syria, and Tanzania and aims to extend such collaboration to additional countries (Dr. W. Cornelis, 2009, personal communication). Similar projects are in progress – or data collections exist – in Burundi (Bagarello et al., 2009), Cuba (Dr. M.E. Ruiz Perez, 2009, personal communication) or Iran (B. Ghanbarian, 2009, personal communication).

The WISE and IGBP-DIS databases also contain data for tropical and subtropical countries. The amount and detail of physical and hydraulic properties for these soils

vary greatly, but WISE (version 1.1) has such data for ~1,000 soil horizons from 17 countries and IGBP-DIS contains such data for ~900 horizons from 24 countries. India, Israel, China, Brazil, Peru, Botswana, Indonesia, Thailand, Turkey, Columbia, Cuba, and Kenya are best represented in one or both of these two databases. Upgraded versions of WISE (versions 2.1 and 3.1) tend to contain soil hydraulic data for more samples from tropical and subtropical countries; however, information on the water retention curve is limited to fewer points.

In many cases, however, data collected by different scientists or institutions remain fragmented. For example, large amounts of soil physical data have already been collected in Iran, but the data appear to remain stored and utilized by individual research groups locally (B. Ghanbarian, 2009, personal communication). The situation appears to be similar in Indonesia as well (Suprayogo et al., 2003); but this phenomenon is not unique for these countries.

Database structure, contents, and limitations

International databases of soil physical and hydraulic properties typically comprise of multiple interconnected tables, linked by identifiers that are either a unique number or a unique combination of information on the sampled location, and the soil horizon/layer. The complexity of the cited databases differs greatly. Some database properties, advantages, and disadvantages are listed in Table 1.

The range of properties that they cover varies; some of the databases are rich in information about the environment of the sampled location, the methodology used at sampling and measurements, while others contain less information. Some of the databases contain measurements of the same property or characteristic measured under different conditions. Examples are the NRCS-NSSC database with some properties determined under different conditions (e.g., bulk density of oven dried soil vs. wet soil at -33 kPa pressure) or calculated for different fractions of the soil; or the UNSODA database in which hydraulic characteristics are determined for many samples under both wetting and drying conditions and/or in situ (field) or in the laboratory. The location of the reported soils may or may not be spatially referenced, it varies from database to database. The UNSODA database, for example, is not spatially referenced, while the HYPRES database contains the originally available spatial coordinates for most samples. It is also of concern what areas and types of soil the databases actually represent. Users of databases often equate the represented area or soil types with the named source area (e.g., HYPRES – European, Rawls et al. (1982) – U.S.). However, inhomogeneity is often seen in databases in terms of geographical distribution or the representation of soil types, which both can have potentially significant consequences (cf. Nemes et al., 2009). Local experimental preferences can also bring, for example, textural or geographical imbalances to databases. One such example is cited by Nemes et al. (2009): fine-textured salt-affected soils are typically

	Database size	Database size, ease of availability	Limited $q(h)$ points, no $K(s)$, $K(\theta)$	Limited access/availability	Limited $\theta(h)$ points, no $K(s)$, $K(\theta)$	Limited $\theta(h)$ points, no $K(s)$, $K(\theta)$
Notes	Built-in reporting with graphics	Three countries and one U.S. state dominate	Different measurement conditions exist	Sample geographic distribution varies	Includes much of NRCS-NSSC	Earlier versions stored $\theta(h)$ at more pressures

overrepresented in Hungarian data collections due to special interest by generations of scientists, despite the fact that such soils represent only a fraction of the area of Hungary.

In terms of hydraulic properties, the range and detail of data that each international database covers varies. The NRCS-NSSC database is the largest original data collection that contains soil hydraulic data. Those are, however, typically limited to two or three water retention points (-10 , -33 , and $-1,500$ kPa) and no hydraulic conductivity data is available. For some of the samples more water retention points exist. On the contrary, the UNSODA and HYPRES databases contain, for most soils, water retention measured at least at 4–8 pressures. More than half the samples in HYPRES and UNSODA also have information on saturated hydraulic conductivity – and fewer on unsaturated hydraulic conductivity. Since most of the soils in IGBP-DIS and some in WISE originate from the NRCS-NSSC database, the availability of water retention data resembles that of NRCS-NSSC. However, a significant portion of the non-U.S. soils in these two databases has four to eight points of the water retention curve measured and available. WISE (version 3.1) contains water retention data at only 3 pressures; which are standard pressures, however. The HYPRES database appears to be the largest international collection of detailed soil water retention and hydraulic conductivity measurements on undisturbed samples. The availability of field measurements of soil hydraulic properties is typically very limited; the UNSODA database holds probably the only substantial collection of field measured soil hydraulic data. Users of the original measured data need to be aware that replicate measurements are often stored for the soil samples.

Data compatibility and standardization

All the listed international databases of soil physical properties are being frequently used in transnational research. Due to the history of international data collections and the existence of various measurement methods and standards worldwide, compatibility of data between databases has always been a concern. Often, even within a database it is of concern. In the simplest cases, conversion is simply a matter of unit conversions (e.g., K(s) expressed in cm/day or in mm/h); in other cases, it requires the use of an empirically developed conversion factor to achieve compatibility (e.g., organic carbon vs. organic matter content). A more difficult task is to convert information that is based on, for example, a complex set of criteria (e.g., national soil classification into World Reference Base for Soil Resources (WRB) or Soil Taxonomy classifications). The availability of multiple methods that seemingly determine the same property warrants that the measurement results are often difficult to compare. Often such methods (1) apply different sampling techniques (e.g., disturbed or undisturbed sample; soil core or soil clod); (2) are used under different environmental conditions (field or

laboratory measurements; different states of wetness at measurement); or (3) are based on entirely different theoretical backgrounds (e.g., soil particle-size measurements by pipette/hydrometer methods vs. the laser diffraction method). Even if the same measurement technique is used, the use of different standards in different countries or laboratories can make data conversion a daunting task, as witnessed by, for example, the rich literature on converting and/or standardizing particle-size distribution (e.g., Nemes and Rawls, 2004 and therein).

Standardization of data has been handled differently in the different international databases. In the NSSC database, standardization took place at the measurement level, since measurements were typically taken according to one set of standards (Soil Survey Staff, 2004). In other cases, data have been assembled from various sources and have either been standardized by the managers of the database (HYPRES, Wösten et al., 1999; Nemes et al., 1999) or such standardization has not taken place (UNSDA, WISE, IGBP-DIS). However, in HYPRES, the original data format and description has also been conserved to allow any future reassessment or reclassification of the data. Documentation of the original data source(s) and of the actual database should be consulted carefully for a better understanding of applied data standards.

Water retention and hydraulic conductivity data that originate from different countries/institutions were typically not measured at standard pressure values. Some projects require that such data are standardized (e.g., Wösten et al., 1999). Their standardization usually takes place by applying one of the continuous water retention and hydraulic conductivity models, most frequently the coupled Mualem–van Genuchten model (Mualem, 1976; van Genuchten, 1980). When any such standardized data are used, it needs to be considered that even such advanced equations do not always fit perfectly to the measured data.

Database availability

While their documentation is publicly available, availability of data of some of the listed databases is limited by license agreements or the need for an agreement with the author(s) or owners (e.g., Rawls et al., 1982 data; HYPRES). Others are free to obtain from the authors or are readily available online for running queries or downloading data (e.g., GRIZZLY; NRCS-NSSC, <http://ssldata.nrcs.usda.gov/>; UNSODA, <http://www.ars.usda.gov/Services/docs.htm?docid=8967>; WISE, <http://www.isric.org/>; IGBP-DIS, <http://www.isric.org/>). Regardless of which data source is being used, source organizations require the user to cite the source of data in their works.

Additional challenges, future needs

Existing databases provide invaluable information to many environment-related studies, but future data collections should address particular needs in order to advance further. One of the concerns is of course the completeness

of data sets. While additional properties of historic data are unlikely to be recovered, new data collections should put emphasis on completeness in terms of frequently used information. This does not only cover laboratory measurements but also information collected in the field upon profile description and sampling.

With the emergence of global positioning devices, spatial referencing should present only a small challenge in the future. Knowing the spatial location of sampled profiles will help in improving the accuracy of new maps. Improving the distribution of samples in sparsely sampled areas could also help in drawing more reliable conclusions for many areas. Hence, related studies that visit and explore previously un-surveyed areas are strongly encouraged. Along with the spatial expansion, a temporal expansion should also be explored. It is known that some soil properties change temporally on a human timescale; sometimes even within days or weeks (e.g., by tillage practices). Often there is an annual cycle involved. Such changes are typically seen in cultivated areas and in areas with cyclic freeze–thaw conditions. A one-time measurement will not represent local conditions well throughout the year. So far, only a limited number of studies explored such variable soil hydraulic conditions via periodic sampling of the same soils. Many modeling-based studies rely on information from large databases, and such temporally variable properties are not currently represented in such databases. Measurement and documentation of temporally variable soil physical and hydraulic properties is encouraged.

Structural development influences the physical behavior of the soil through influencing the characteristics of the void space. Therefore, information on soil structure should be logged for the benefit of future users. Characterization of the void space in soils using modern imaging techniques is also gaining popularity. Once these techniques will become more affordable and more widely applicable, such information could be stored along with other soil physical data. Knowing the architecture of void space in the soil is essential in advancing our knowledge about solute transport; but such knowledge has long been only inferred indirectly from the characteristics of the solid phase of soils.

It has been recognized in the past that while laboratory measurements give us an understanding of characteristics and processes in the soil, they do not always provide full and unbiased information about soil conditions in the field. Hence, studies that involve *in situ* measurements are of special interest, since they may provide more insight into true field conditions and our understanding about the differences in field and laboratory conditions. It has also been recognized that the use of different techniques to determine a particular property or characteristic can pose a challenge while forming conclusions from such data. However, it also provides a great opportunity to examine differences among such techniques and to explore pathways and interpretations between them.

Hence, documentation on how data were collected should always be passed along with the data itself.

Summary and conclusions

We attempted to give a summary of significant – primarily international – sources of soil physical and hydraulic data. Historic soil physical and hydraulic data are being used in a variety of ways worldwide. Their advanced, well-documented, and searchable storage and management is therefore essential for the success of future applications. Though soil hydraulic properties are time consuming to measure, decades of research yielded a wealth of such information that are stored in national/provincial and international databases. The presented databases differ in their source area, extent, structure, applied methodology, level of detail, and in many additional factors. Completeness of data records is also a great challenge; and so is an equal representation of different areas and soil types. Regardless, whether used alone or combined with other data sources such data collections present great opportunities and an invaluable resource for many researchers, educators, practitioners, and policy makers worldwide. Use of these and other databases however, requires caution; interpretations and conclusions have to be drawn with care.

DESERTIFICATION: INDICATORS AND THRESHOLDS

Max Kuderna¹, Adam Zsolnay²

¹wpa Beratende Ingenieure GmbH, Vienna, Austria

²German Research HelmHoltz Zentrum, Center for Environmental Health, München, Germany

Synonyms

Land degradation; Soil degradation

Definition

Desertification is a process by which susceptible areas lose their productive capacity. Desertification means land degradation in arid, semiarid and dry subhumid areas resulting from various factors, including climatic variations and human activities. While land degradation occurs everywhere, it is only defined as “desertification” when it occurs in dry lands.

Introduction

Land degradation and desertification is a paramount international problem, and indicators have been developed to follow it (Doran and Parkin, 1996; Middleton et al., 1997; Dregne, 1986). Many are based on plant communities, or soil loss or salinity.

However, indicators they tend to monitor the status quo over large time periods and are more suitable for crisis assessment than for risk prevention. They are also poorly suited for the sensitive monitoring of the success of remediation efforts.

Therefore, the UN Convention to Combat Desertification (UNCCD) and other organizations have emphasized the continuing need for indicator development based on the mechanisms of land degradation, which are known and have been the object of many studies. In view of

global change, such indicators are especially needed. Changes will often be slow and subtle. An early warning system is required to indicate the need for countermeasures, while they are still economical.

In response to this need, INDEX (acronym for Indicators and Thresholds for Desertification, Soil Quality, and Remediation), a specific targeted research project (STREP) dealing with “Research on mechanisms of desertification and soil quality” was initiated and carried out within the Sixth Framework of the European Commission.

Indicator development: a methodological outline

Indicators for desertification can be applied at different spatial and temporal scales (Figure 1). The goal within INDEX was to investigate the possibility of developing indicators, which reflect ecological quality at the soil level rather than at the more traditional field and catchment levels.

The indicator development was attained in five steps, which narrowed down an initial list of 100 soil parameters to finally three indices, using the following procedure:

1. Analysis of a broad range of parameters on various degraded soils
2. Testing the parameters on a variation of pressure levels
3. Temporal and spatial verification
4. Practical aspects of parameter application as an indicator
5. Combining the remaining parameters into indices using factorial analysis.

Step 1: Tested soil parameters included

- Soil microbiological parameters (bulk functions such as microbial biomass carbon and soil respiration, as well as enzymatic activities and molecular biological parameters)
- Humus parameters (bulk humus, humo-enzymes, and available humus)
- Physical parameters (such as particle size stability, hydraulic parameters, and pore size distribution)

A complete list of all performed analysis is given in [Appendix A](#).

Step 2: The testing was performed on soils from sites across Europe (listed in [Appendix B](#)), where a variation of influencing factors (“pressures” according to the European Environmental Agency’s DPSIR concept – see [Figure 2](#)) related to soil deterioration and desertification could be observed either because of a natural variation along a catena or because of different experimental treatments. The following types of pressures were taken into consideration:

Type I: lack of vegetation as the result of desertification processes

Type II: soil erosion

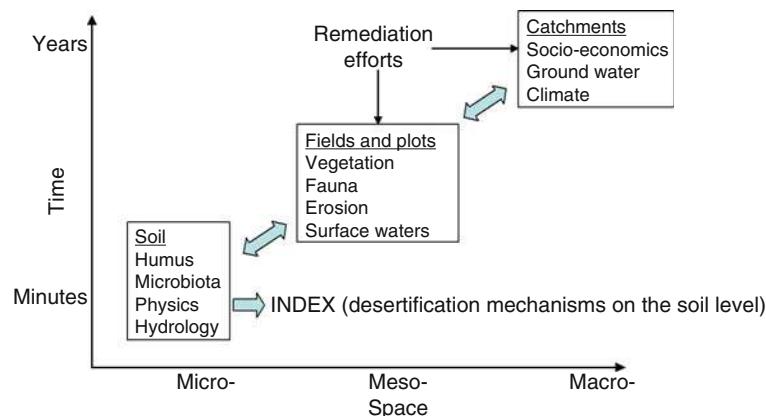

Type III: agricultural management

Only those soil parameters were selected as potential indicators, which reacted logically according to a change of the pressure level.

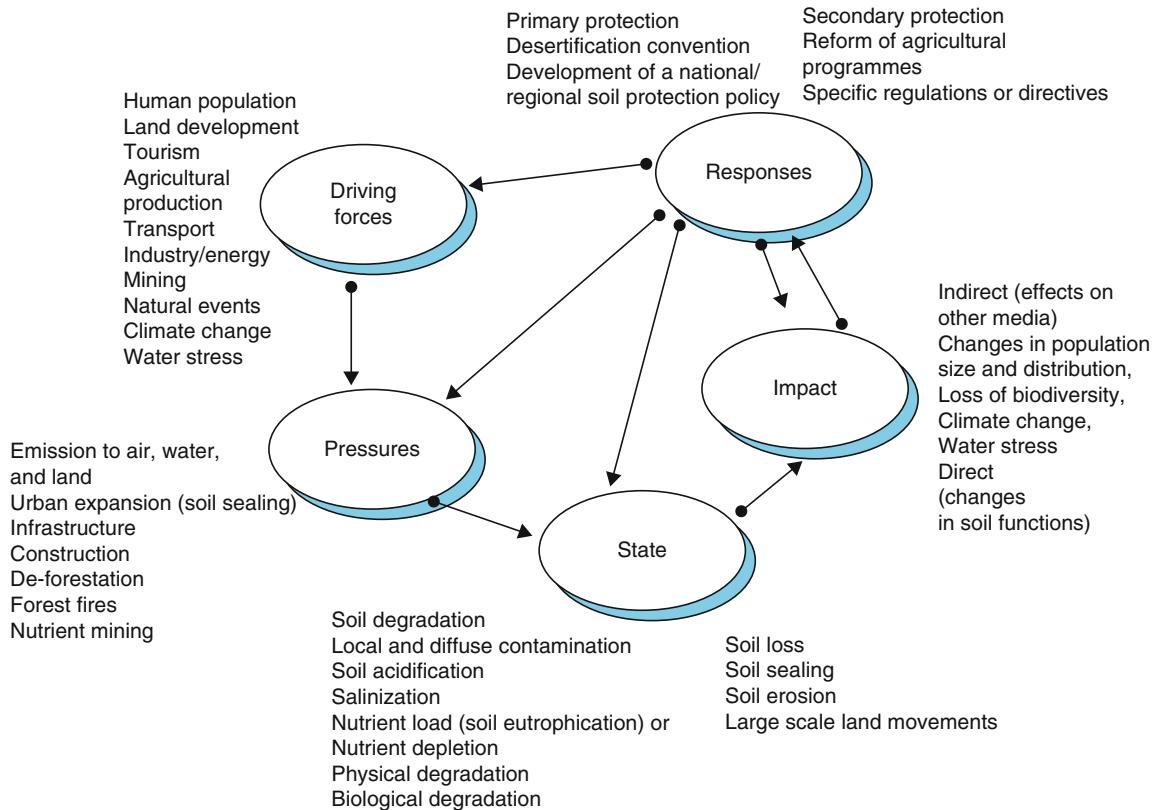

Step 3: Only those parameters, which gave reproducible results from subsequently taken soil samples over the period of 1½ years and on verification sites, which have not been used for *step 2* were considered sufficiently robust and were retained.

Step 4: This was used to eliminate such parameters, which caused experimental difficulties or required very complicated analytical procedures. [Table 1](#) shows the remaining parameters after *step 4*.

Step 5: This step combined these parameters ([Table 1](#)) to three indices (one for each pressure type), applying a factor analysis for *type I* and *type III* sites in order to reduce dimensionality. For pressure *type II*, a single parameter remained from *step 4*, so no factor analysis was required. At sites of *type I* the first factor accounted for 65–92% of the variation according to the sampling site and date. In most cases, however, only one factor was extracted, and this was used as the appropriate index. At sites of *type III* only one factor was extracted, which explained 57–99% of the variation according to the site and the sampling date.

Desertification: Indicators and Thresholds, **Figure 1** The various temporal and spatial scales of possible indicators of soil quality.

Desertification: Indicators and Thresholds, Figure 2 The European Environmental Agency's (EEA's) DPSIR concept as applied to soil degradation processes. Indicators as investigated in the Indicators and Thresholds for Desertification, Soil Quality, and Remediation (INDEX) project reflect the soil state and pressure state relationships.

Desertification: Indicators and Thresholds, Table 1 Selected soil parameters according to pressure type

I: Lack of vegetation as the result of desertification processes	II: Soil erosion	III: Agricultural management
Basal respiration	% particles <0.01 mm in pyrophosphate	β -Glucosidase activity
Microbial biomass carbon		Urease activity
ATP		
Basic phosphatase activity		
Proteins		
β -Glucosidase activity		
Fluorescence efficiency		

A brief explanation on selected parameters

Microbial biomass carbon. This indicates the amount of living microorganisms in soil and reacts to soil degradation processes (Smith et al., 1993; Garcia et al., 2002). It is determined by a fumigation-extraction procedure (Sims and Haby, 1971).

Basal respiration in soil. This parameter indicates the activity of heterotrophic microorganisms and was frequently used to indicate the biological state of soils

(Nannipieri et al., 1990; Pascual et al., 2000). The basal respiration was determined for incubated samples by measuring CO₂ release with a CO₂ IR detector.

ATP. Adenosine triphosphate (ATP) is used by living organisms as a transmitter of energy. It therefore indicates microbial activity on a general level. ATP was extracted by a method described by Webster et al. (1984).

Proteins. Water-soluble proteins (albumin was measured as a representative) are an important labile N-source for living organisms. They were determined according to Lerch et al. (1992).

Urease activity. Under the umbrella term "urease," we include all those hydrolases capable of acting on the C–N (non-peptide) bonds of linear amides. They are exocellular enzymes of a basically microbial origin, as has been demonstrated by several researchers (Ceccanti and Garcia, 1994).

Phosphatase activity. The agronomic and biotechnological importance of phosphatase is that it activates the transformation of organic into inorganic phosphorous, thus making it available to plants. The phosphatase detected in acid soils is normally acidic, while in basic soils it is usually alkaline (Dick and Tabatabai, 1993).

Glucosidase activity. Glucosidase is an enzyme acting the hydrolysis of the glucosidase bonds of the long

carbohydrate chains. The hydrolysis of these substrates play an important role in the microorganisms' attainment of energy from the soil and has shown to perform as a biomarker for degradation processes (Pascual et al., 2000).

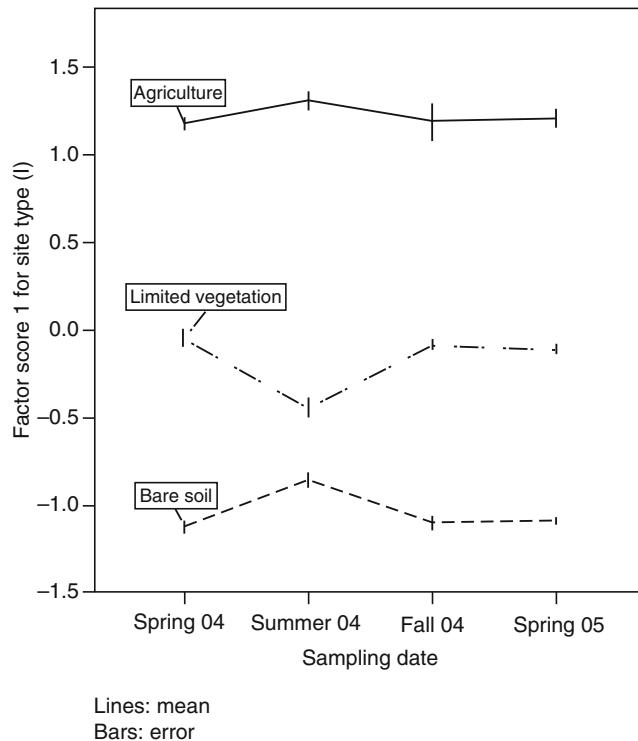

Fluorescence efficiency. Mobile humus in the humus fraction will react more sensitively than other components such as the humic acids. It is also known as dissolved organic matter (DOM) and is a poorly defined pool of compounds, which are available for biogeochemical processes (Zsolnay, 2003). One simple way to obtain it is by aqueous extractions. Its organic carbon content can be quantified, and qualitatively characterized with its UV absorption and fluorescence emission spectra. An interesting parameter is the fluorescence efficiency, which is proportional to the quantum yield (Ewald et al., 1988).

Applications of the indices

Sites with a lack of vegetation as the result of desertification processes (site type I)

Figure 3 gives an example from the Puch experimental site (Germany), where the highest values were found at the agricultural plot, the lowest values at the bare soil and the plot with limited vegetation in between. Although the variation of vegetation has been induced artificially at this site, the index developed gives a clear pattern showing how the soil quality reflects the differences in plant cover.

Very similar results were obtained at various catenae in Spain. Figure 4 gives an example of the application of the

Desertification: Indicators and Thresholds,
Figure 3 Differentiation of treatments at Puch by the first factor.

first factor to the Santomera catena: highest values were found at the forest site, lowest at the bare site, while the site with shrub had values in between them.

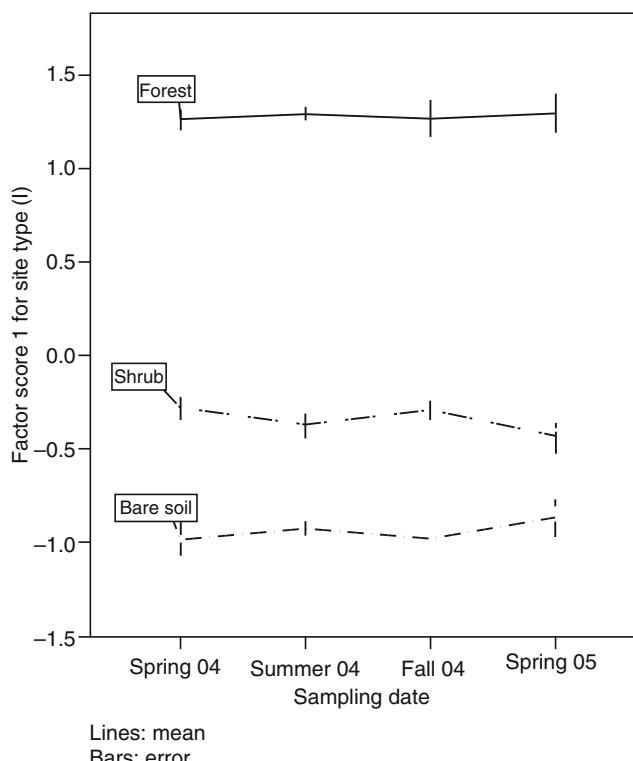

At the Carcavo catena (Spain) the index differentiated between (1) a revegetated site, (2) an abandoned site with natural vegetation, and (3) a degraded soil located in a very barren part of that landscape. Furthermore, the effect of exposition could clearly be seen. The indicator showed that the soil from a north slope had distinctly higher values than that from a south slope. Figure 5 displays the first factor scores for this site.

Sites with soil erosion (type II)

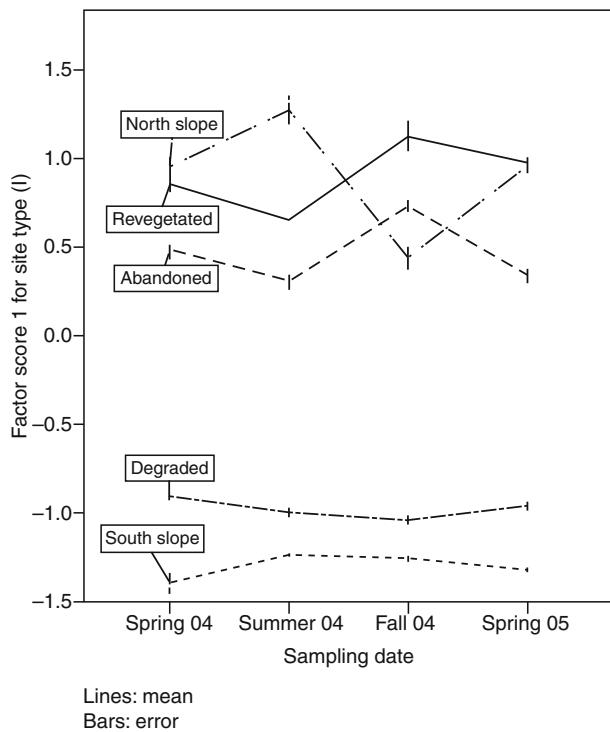

Figure 6 illustrates the application of the indicator to a catena near Gödöllő (Hungary). At sites of type II, soil erosion is not linked to a major variation of plant cover. At the Gödöllő catena, all three locations have been used for agriculture. As the indicator was only measured once in 2004 and in 2005, time series were not possible, but Figure 6 displays box plots of the values obtained during the 2 years.

Sites with different types of agriculture (type III)

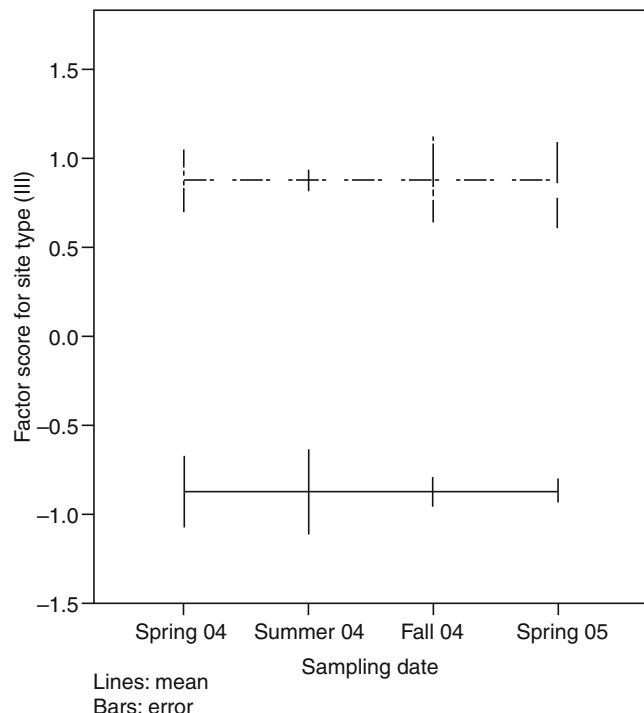

The type of agriculture (organic vs. conventional) was clearly distinguished at the soil level by the applied indicator. Figure 7 shows the results for the sites in Tuscany (Italy) as an example.

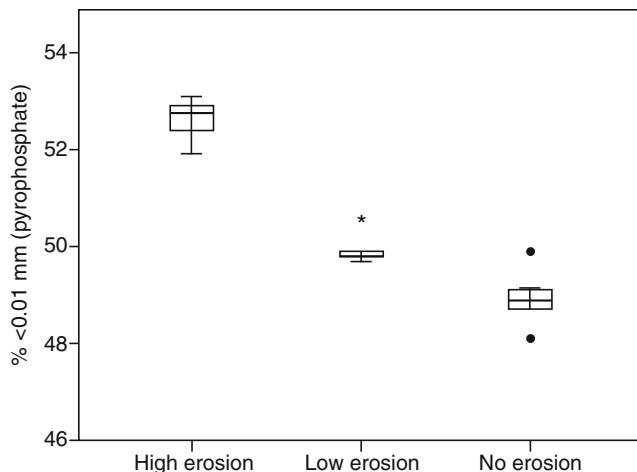

Desertification: Indicators and Thresholds,
Figure 4 Differentiation of different vegetation types along the Santomera catena by the first factor.

Desertification: Indicators and Thresholds,
Figure 5 Differentiation of sites along the Carcavo catena by the first factor.

Desertification: Indicators and Thresholds,
Figure 7 Differentiation of organic farming and conventional agriculture at sites in Tuscany.

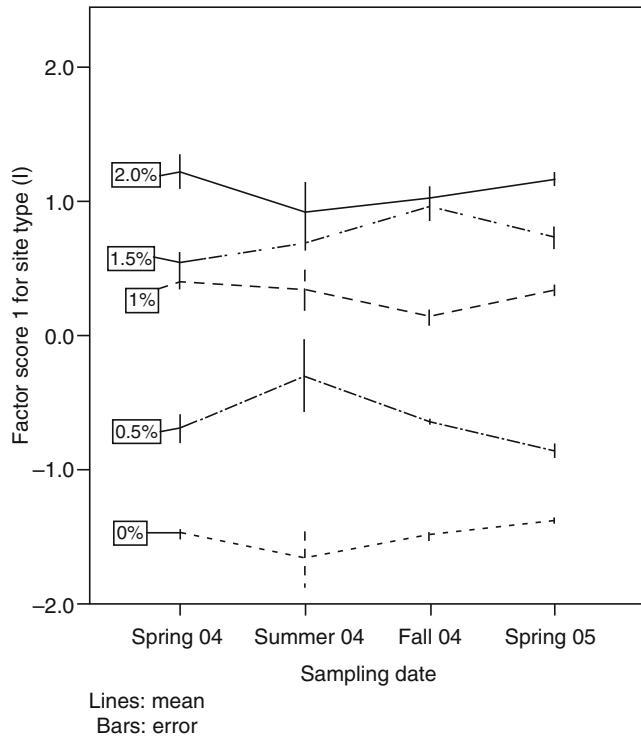

Desertification: Indicators and Thresholds,
Figure 6 Differentiation of soils with different degrees of soil erosion along a Catena near Gödöllö.

Effects of soil remediation

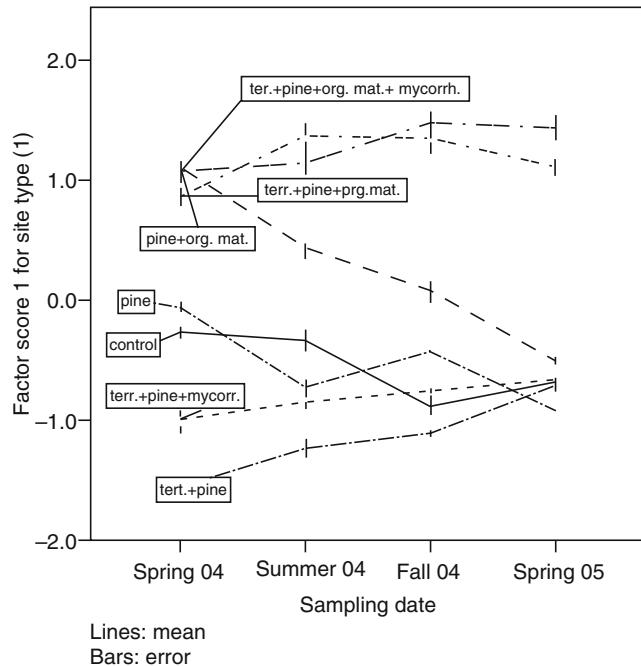

The index developed for sites where desertification was linked to the density of vegetation (sites of *type I*), proved to be very suitable for monitoring the effects of soil remediation. In the case of the Abanilla experimental site,

different amounts of organic matter (municipal solid waste) were added 18 years ago (percentages in [Figure 8](#) give the quantities incorporated into the upper 15 cm of the soil). No further remediation action has taken place since. The application of the index leads to the conclusion that an addition of up to 1.5% of organic matter had a strong lasting effect. However, a further increase of organic matter addition did not cause additional major soil improvements over a long time period and could therefore be avoided for economical reasons.

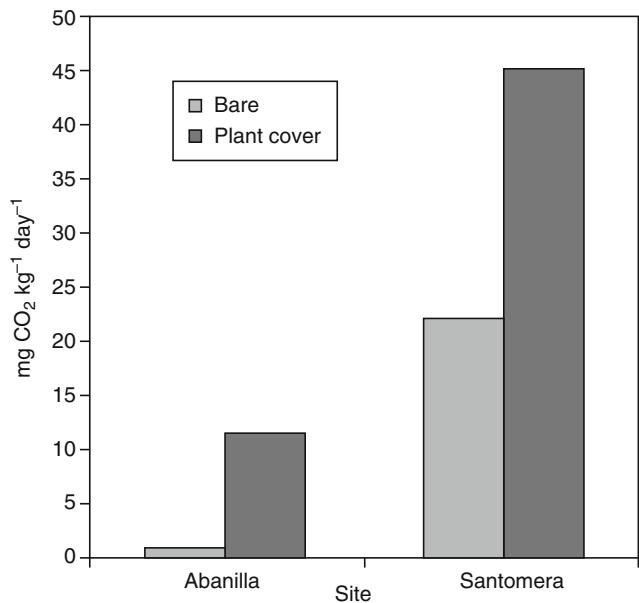

At the Aguilicho experimental site, the effects of reforestation, terracing, application of mycorrhiza, and the addition of organic matter have been tested in various combinations. The index shows ([Figure 9](#)), that only the combination of reforestation (pine), organic matter addition, and terracing had a lasting effect. Terracing and reforestation alone or together did not yield better results than the control, indicating the need for organic matter addition. However, without terracing, organic matter addition and reforestation did not have a positive effect. This inference may be attributed to erosion effects on the steep terrain, which are prevented by the terraces, which also improve water retention. Addition of mycorrhiza had no major effect as compared to treatments with no mycorrhiza. Again, this example demonstrates that the index is a sensitive tool to monitor if and how soil quality is improved by remediation measures in a region with a threat of desertification.

Desertification: Indicators and Thresholds, Figure 8 Effect of different levels of organic matter addition on the soil index at Abanilla experimental site.

Desertification: Indicators and Thresholds, Figure 9 Effect of reforestation, organic matter addition, mycorrhiza application, and terracing on the soil index at Aguiluco experimental site.

Desertification: Indicators and Thresholds, Figure 10 Soil respiration increases with plant cover density. Bare soils at one site, however, may have higher values than locations with plant cover at another.

Limitations

A universal approach comparing soil degradation across all sites was not tenable. Figure 10 gives an example: soil respiration values increased with plant density at each site, but for example, the bare location at Santomera had higher respiration values than the location with high plant coverage at Abanilla, which is only a few kilometers away.

For this same reason, no universal thresholds for the indices here can be established, but measurements have to be made relative to those local reference plots. In case of a soil remediation, this would imply for instance that the success of any remediation has to be proven against control plots. If the degree of soil degradation or desertification needs to be monitored, the index may be used for indicating different degrees of degradation along a catena or within a landscape. It can also be used to follow temporal changes at a given location.

Summary

The developed indices are well suited to indicate differences of soil degradation as related to desertification processes and the effects of remediation. They are sensitive and react quickly to changes in soil management. Although they are relatively robust to seasonal influences, repeated measurements in time are recommended. Fortunately, the indices are relatively inexpensive and can be done without great effort. Threshold values, however, need to be deduced from local reference sites, as the indices only work on a relative scale.

Microbial parameters

Total organic carbon, humic substances, carbon, water-soluble carbohydrates, proteins, biomass carbon, accumulative respiration, basal respiration, qCO₂, ATP, dehydrogenase activity, urease activity, BAA protease activity, β-glucosidase activity, basic phosphatase activity, Shannon–Weaver index of diversity.

Humus parameters

Bulk: Total organic carbon, total inorganic carbon, total pyrophosphate extractable carbon, total pyrophosphate extractable carbon > 10,000 Da, total nitrogen

Enzyme activities in pyrophosphate soil extracts: β-glucosidase, phosphatase, urease, protease BAA

Pyrolytic indices of soil: Mineralization index: furfural/pyrrole, humification index: benzene/toluene, mineralization index: pyrrole/phenol, energetic index: aliphatic/aromatic

Pyrolytic Indices of pyrophosphate extracts: Mineralization index: furfural/pyrrole, humification index: benzene/toluene, mineralization index: pyrrole/phenol, energetic index: aliphatic/aromatic, β-glucosidase activity in the stable humic complex after IEF (isoelectric focusing), carbon percentage of the stable humic complex (bands 3 and 4) after IEF, with respect to the total IEF located carbon, relative content of β-glucosidase activity of the stable humic complex (bands 3 and 4) with respect to the total carbon content in the soil extract (fraction > 104 Dalton)*1,000, β-glucosidase: specific enzyme activity in dialyzed soil extracts (fraction > 104 Dalton) *1,000

Aqueous (0.1 N CaCl₂) extracts: WEOC (water extractable organic carbon) in extraction solution, WEOC per gram dry soil, UV absorption of solution ($\lambda = 254$ nm), summed emission fluorescence ($\lambda_{\text{ex}} = 254$ nm; $\lambda_{\text{em}} = 300$ –480 nm), lower emission fluorescence ($\lambda_{\text{ex}} = 254$ nm; $\lambda_{\text{em}} = 300$ –345 nm), higher emission fluorescence ($\lambda_{\text{ex}} = 254$ nm; $\lambda_{\text{em}} = 435$ –480 nm), absorptivity (UV/DOC), relative summed emission fluorescence (SF/DOC), relative lower emission fluorescence (L/DOC), relative higher emission fluorescence (H/DOC), humification Index (H/L), and fluorescence efficiency (SF/UV)

Physical soil parameters

Pore volume, total cumulative volume, specific surface area, pore radius average, moisture retained by disturbed samples, particle size (0.01 mm) in water (A), particle size (0.01 mm) in pyrophosphate (B), dispersion factor short = A/B, aggregate stability (Sekera optical method).

Rheological parameters

Water content of soil suspension, maximum of shear stress vs. time function, initial shear stress, area of thixotropic loop in low shear region from 0.1 to 10 s⁻¹, extrapolated yield value from shear stress vs. shear rate function, slope of the linear part of down flow curve (shear stress vs. shear rate function).

Appendix B: List of testing and verification sites

Sites for parameter testing (step 2)

Country	Location	Variation of treatments (pressures)	Type of site
Germany	Puch	Agricultural mismanagement and absence of vegetation	Agricultural field
Hungary	near Gödöllö	Soil erosion	Agricultural catena
Italy	Basilicata	Different agricultural practices under arid climate	Agricultural field
	Tuscany	Different agricultural practices under moderate climate	Agricultural field
Spain	Abanilla	Erosion and mismanagement	Catena
	Carcavo	Revegetation of a degraded forest	Degraded forest catena
	Santomera	Deforestation	Forest plots
	Santomera	Erosion and mismanagement	Catena

Sites for spatial verification (step 3)

Country	Location	Variation of treatments (pressures)	Type of site
Cyprus	Zygi	Different agricultural practices under arid climate	Agricultural field
Austria	Mistelbach	Soil erosion	Agricultural catena
Italy	Agri Basin	Erosion and mismanagement	Catena

Sites with specific soil remediation measures

Country	Location	Tested remediation measures
Spain	Abanilla	Addition of various amounts of organic matter Aguilucho Terracing, reforestation, organic matter addition, mycorrhiza

DIELECTRIC PROPERTIES OF AGRICULTURAL PRODUCTS

Stuart O. Nelson, Samir Trabelsi
U.S. Department of Agriculture, Agricultural Research Service, Russell Research Center, Athens, GA, USA

Synonyms

Electric permittivity

Definition

Dielectric properties. Those characteristics of poorly conducting materials that determine their interaction with electric fields.

Introduction

Dielectrics are a class of materials that are poor conductors of electricity, in contrast to materials such as metals that are generally good electrical conductors. Many materials, including living organisms and most agricultural products, conduct electric currents to some degree, but are still classified as dielectrics. The electrical nature of these

materials can be described by their dielectric properties, which influence the distribution of electromagnetic fields and currents in the region occupied by the materials, and which determine the behavior of the materials in electric fields. Thus, the dielectric properties determine how rapidly a material will warm up in radio frequency or microwave dielectric heating applications. Their influence on electric fields also provides a means for sensing certain other properties of materials that may be correlated with the dielectric properties, by nondestructive electrical measurements. Therefore, dielectric properties of agricultural products may be important for applications in the agricultural industry that will benefit consumers in general.

Further definitions

A few simplified definitions of dielectric properties are necessary for meaningful discussion of their applications. A fundamental characteristic of all forms of electromagnetic energy is their propagation through free space at the velocity of light, c . The velocity of propagation v of electromagnetic energy in a material other than free space depends on the electromagnetic characteristics of that material and is given as

$$v = \frac{1}{\sqrt{\mu \epsilon}} \quad (1)$$

where μ is the magnetic permeability of the material and ϵ is the electric permittivity. For free space, this becomes

$$c = \frac{1}{\sqrt{\mu_0 \epsilon_0}} \quad (2)$$

where μ_0 and ϵ_0 are the permeability and permittivity of free space. Most agricultural products are nonmagnetic, so their magnetic permeability has the same value as μ_0 . These materials, however, have different permittivities than free space. The permittivity can be represented as a complex quantity

$$\epsilon = \epsilon' - j\epsilon'' \quad (3)$$

where $j = \sqrt{-1}$. The complex permittivity relative to free space is then given as

$$\epsilon_r = \frac{\epsilon}{\epsilon_0} = \epsilon'_r - j\epsilon''_r \quad (4)$$

where ϵ_0 is the permittivity of free space, the real part ϵ'_r is called the dielectric constant, and the imaginary part ϵ''_r is the dielectric loss factor. These latter two quantities are the dielectric properties of practical interest, and the subscript r will be dropped for simplification in the remainder of this article. The dielectric constant ϵ' is associated with the ability of a material to store energy in the electric field in the material, and the loss factor ϵ'' is associated with the ability of the material to absorb or dissipate energy, that is, to convert electric energy into heat energy. The dielectric loss factor, for example, is an index of

a material's tendency to warm up in a microwave oven. The dielectric constant is also important because of its influence on the distribution of electric fields. For example, the electric capacitance of two parallel conducting plates separated by free space or air will be multiplied by the value of the dielectric constant of a material if the space between the plates is filled with that material.

It should also be noted that $\epsilon = \epsilon' - j\epsilon'' = |\epsilon| e^{-j\delta}$ where δ is the loss angle of the dielectric. Often, the loss tangent, $\tan \delta = \epsilon''/\epsilon'$, or dissipation factor, is also used as a descriptive dielectric parameter, and sometimes the power factor, $\tan \delta / \sqrt{1 + \tan^2 \delta}$, is used. The ac conductivity of the dielectric σ in S/m is $\sigma = \omega \epsilon_0 \epsilon''$, where $\omega = 2\pi f$ is the angular frequency, with frequency f in Hz. In this article, ϵ'' is interpreted to include the energy losses in the dielectric due to all operating dielectric relaxation mechanisms and ionic conduction.

Agricultural products

Dielectric properties of agricultural products have been of interest for many years (Nelson, 2006). One of the earliest applications of such electrical properties was the study of dc electrical resistance of grain for rapidly determining its moisture content. In later work with radio-frequency (RF) measurements, changes in the capacitance of sample-holding capacitors, when grain samples were introduced between the capacitor plates, were correlated with grain moisture content and used for grain moisture measurement. The subsequent development of electrical grain moisture meters has been described in earlier reviews (Nelson, 2006).

The use of the dielectric properties of grain for moisture measurement has been the most prominent agricultural application for such data. In the early work, no quantitative data on the dielectric properties of the grain were reported. Interest generally focused on the influence of a grain sample on the response of an electrical circuit, and the instrument readings were calibrated with values measured by standard procedures for moisture determination. The need for quantitative values of the dielectric properties arose from research on the application of RF dielectric heating to agricultural problems. The first quantitative data on the dielectric properties of grain were reported for barley along with a method for reliable measurement of those properties in the 1-MHz to 50-MHz frequency range (Nelson et al., 1953). Quantitative dielectric properties data, obtained for similar reasons, were soon reported in Russia for wheat and other grain and crop seeds (Knipper, 1959). Extensive measurements on grain and crop seed in the 1-MHz to 50-MHz range, taken over a decade of research on RF dielectric heating applications, were summarized and made available for use in electric moisture meter design and other applications (Nelson, 1965).

The other principle application for dielectric properties of agricultural materials has been for use in research on potential dielectric heating applications. One of these applications was the possible selective dielectric heating

for control of insects that infest stored grain (Nelson and Whitney, 1960; Nelson, 1996).

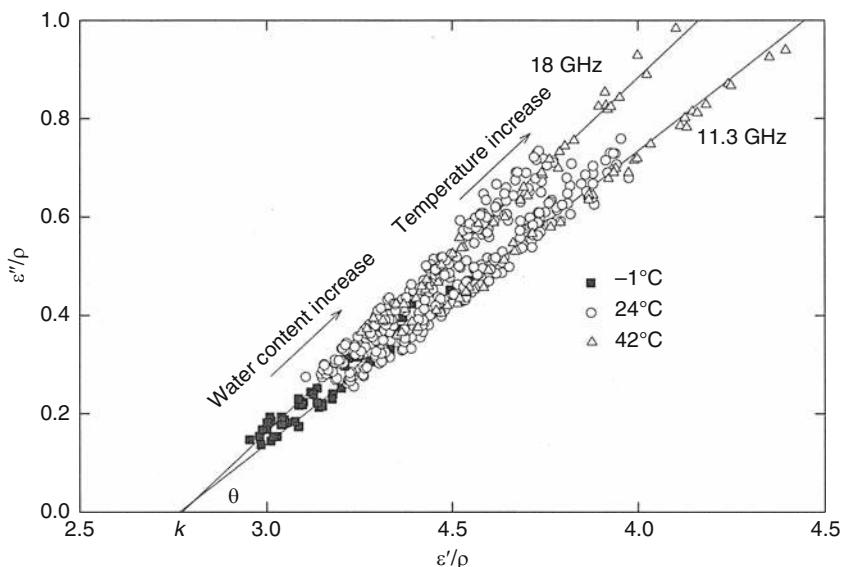

The principles governing the interaction between materials and RF and microwave electric fields, as influenced by the dielectric properties, have been detailed in a recent review article (Nelson, 2006). The same article included a review of principles and techniques for dielectric properties measurements at frequencies ranging from audio frequencies through radio frequencies well into the microwave region. Sources of dielectric properties data for a number of agricultural products will be identified in this article, and some typical data for such dielectric properties will be presented here.

Cereal grains and oilseeds

Dielectric properties of grain and seed over wide ranges of frequency and moisture content have been summarized previously, and graphical and tabular data are available for reference (ASAE, 2000). Models for calculating dielectric constants of many cereal grains and soybeans as functions of frequency, moisture content, and bulk density have been reported (Nelson, 1987; Kraszewski and Nelson, 1989; ASAE, 2000). Some recent dielectric spectroscopy measurements (Nelson and Trabelsi, 2006) on ground hard red winter wheat at frequencies from 10 MHz to 1,800 MHz over the temperature range from 25°C to 95°C were reported (Nelson and Trabelsi, 2006). The earlier reported data were useful to those developing improved grain and seed moisture meters. The recent measurements were part of a study to improve understanding of the temperature dependence of grain permittivity.

Although grain moisture meters, which sense the moisture content through correlations between the RF dielectric properties of the grain and its moisture content, have been in common use for more than 60 years, more recent advances have been reported in use of higher frequencies in the microwave range for grain and seed moisture sensing (Trabelsi et al., 1998). The basis for one such application is illustrated in Figure 1. Here, the dielectric constant and loss factor of hard red winter wheat, each divided by bulk density ρ of the grain, are plotted in an Argand diagram in the complex plane. Note that, at a given frequency, all of the points, regardless of moisture content and temperature, lie along a straight line. The slope of the line increases with frequency and pivots about a point on the $\epsilon''/\rho = 0$ axis that represents the ϵ'/ρ value for completely dry or very cold grain. The equation of the straight line provides a means for determining the bulk density of the grain independent of moisture content and temperature and also provides a basis for sensing moisture content independent of density from the measured permittivity at a single frequency (Trabelsi et al., 1998). This microwave-sensing technique should be useful for monitoring moisture content in moving grain and other particulate materials, since it offers a density-independent method for sensing moisture content in granular and particulate materials.

Another application for dielectric properties of grain was involved in the study of high-frequency dielectric heating for the selective heating of stored-grain insects (Nelson, 1996). In this instance, the dielectric properties of hard red winter wheat and a common stored-grain insect, the rice weevil, *Sitophylus oryzae* L., were measured over a broad range of frequencies and compared to

Dielectric Properties of Agricultural Products, Figure 1 Complex-plane plot of the dielectric constant and loss factor, divided by bulk density, for hard red winter wheat of various moisture contents and bulk densities at indicated temperatures for two frequencies, 11.3 GHz and 18.0 GHz (Trabelsi et al., 1998).

determine the frequencies for optimally heating the insects. Results of that study are summarized in [Figure 2](#). Because the loss factor is the dominant characteristic determining the energy absorption and heating, the frequency range between about 10 MHz and 100 MHz provides the best opportunity for selective heating of the insects.

Fruits and vegetables

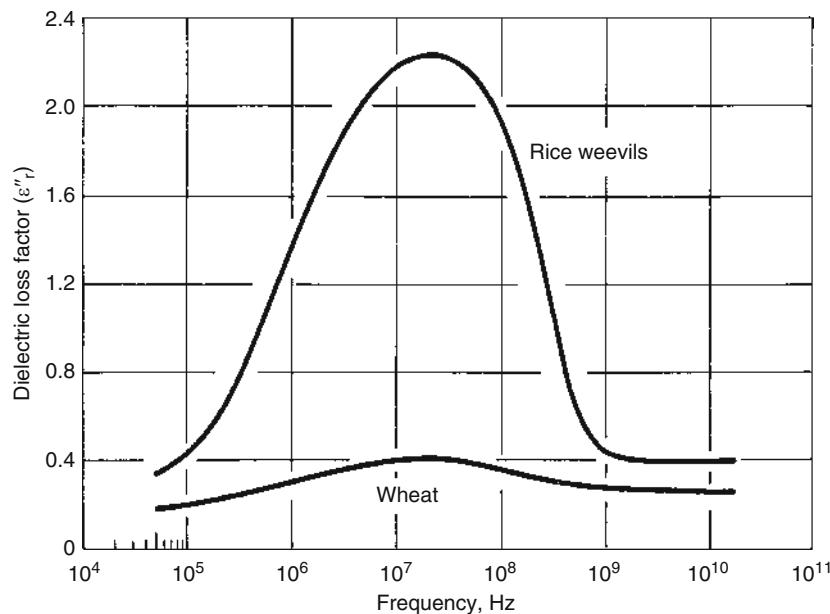

Because of the need for rapid nondestructive quality measurements for fresh fruits and vegetables, the dielectric properties of a few products were measured at microwave frequencies (Nelson, 1980; Nelson, 1983; Nelson, 1992). Although these studies provided background data on dielectric properties of several fruits and vegetables, the measurements did not show any promise for detecting peach maturity or hardcore condition in sweet potatoes by measurements at single frequencies (Nelson, 1980). Therefore, broadband permittivity measurements were initiated to study the dielectric properties of several fruits and vegetables over the frequency range from 200 MHz to 20 GHz (Nelson et al., 1994). Measurements over the same frequency range were obtained for tree-ripened peaches, *Prunus persica* (L.) Batsch., of different maturities (Nelson et al., 1995). Differences in the dielectric properties for different stages of maturity were noted at particular frequencies, and permittivity-based maturity indices, which combined the dielectric constant values at 200 MHz and the loss factor values at 10 GHz, were suggested, but it was noted that much more work was needed to establish their practicability.

Because the dielectric constants of peaches at different maturities diverged at the lower end of the frequency range, it appeared worthwhile to explore the dielectric

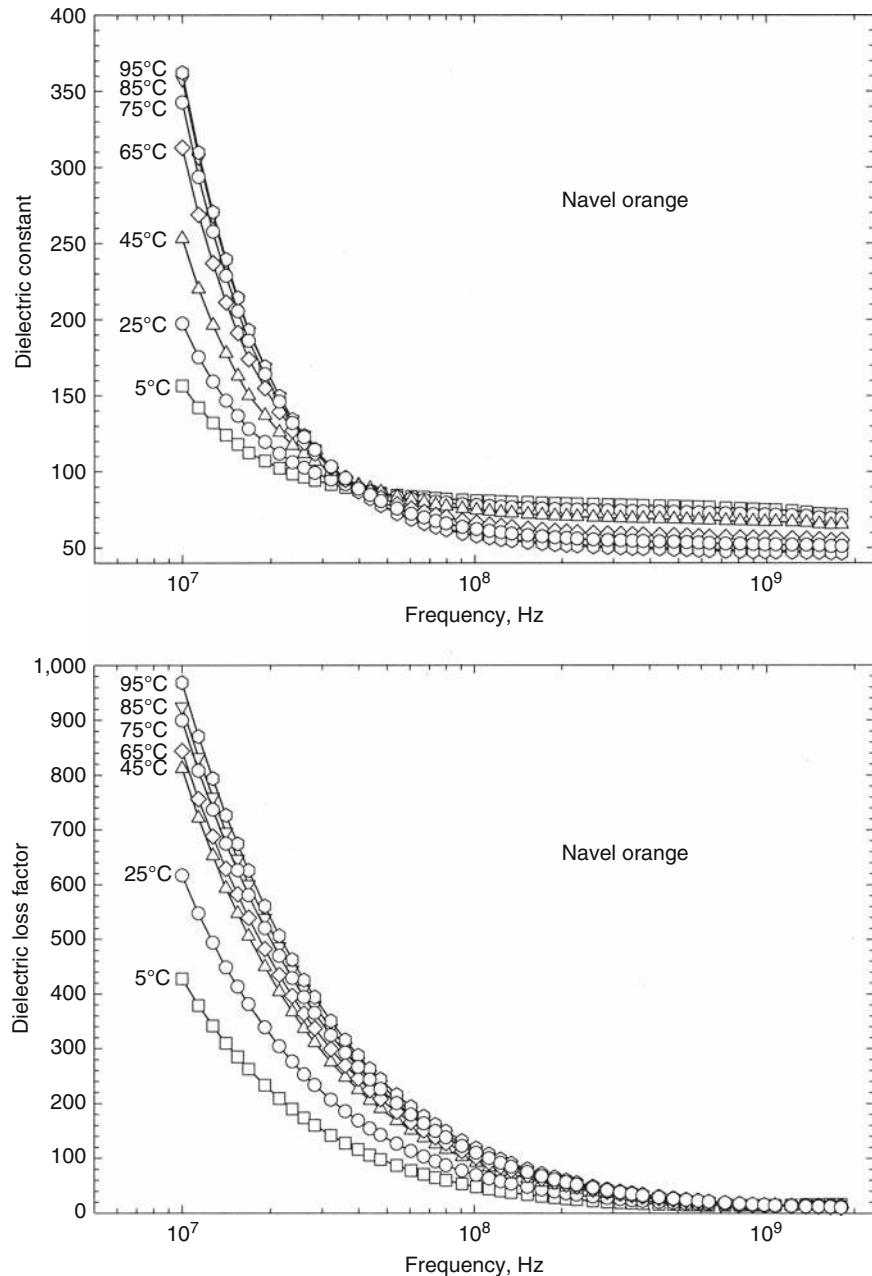

behavior of some fruits and vegetables at frequencies somewhat below this range (Nelson, 2003). Also, because changes in the dielectric properties of materials are important in RF and microwave heating, temperature-dependent data were obtained. An example of permittivity data obtained in the frequency range from 10 MHz to 1.8 GHz over the temperature range from 5°C to 95°C is shown in [Figure 3](#) for navel orange, *Citrus aurantium* subsp. *bergamia*, tissue (Nelson, 2006). In [Figure 3](#), the temperature dependence of the dielectric constant disappears at about 40 MHz. Above that frequency, the temperature coefficient for the dielectric constant is negative, but below that frequency the temperature coefficient is positive. This is most likely the frequency above which dipole relaxation accounts for most of the energy loss and below which ionic conduction is the dominant loss mechanism. That frequency varied for different fresh fruits and vegetables, but generally ranged between about 20 MHz and 120 MHz (Nelson, 2005).

Dielectric properties of freshly harvested melons have been studied to determine whether useful correlations exist between their dielectric properties and sweetness, as measured by soluble solids content (Nelson et al., 2006; Nelson et al., 2007). Although interesting correlations were obtained relating dielectric properties and soluble solids in complex-plane plots, correlations for predicting melon sweetness from the dielectric properties have so far not been successful (Nelson et al., 2007).

Dielectric properties of apples were recently measured and studied to determine whether they might be useful in sensing quality of stored apples (Guo et al., 2007a). Dielectric properties of the apples remained relatively constant during the 10-week refrigerated storage period.

Dielectric Properties of Agricultural Products, Figure 2 Variation with frequency of the dielectric loss factor of bulk samples of adult rice weevils and wheat at 24°C from 50 kHz to 12 Ghz (Nelson, 1996).

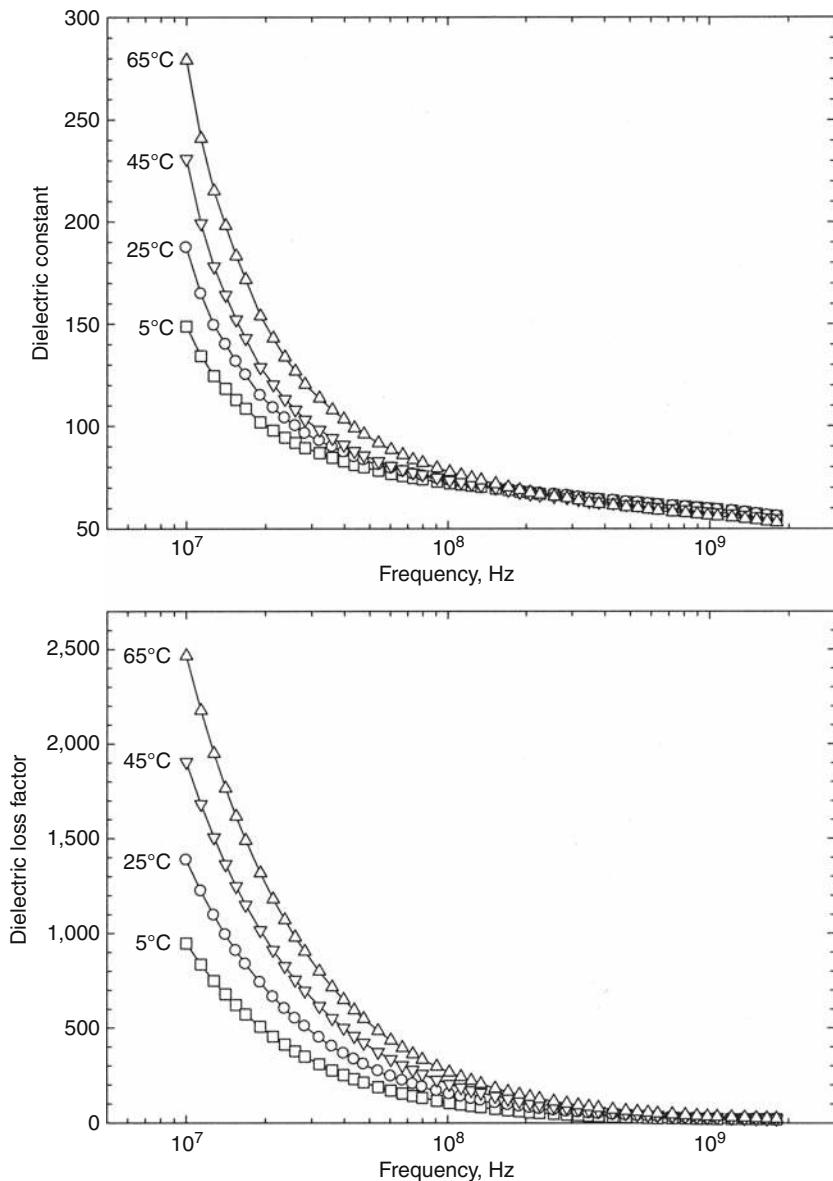

Dielectric Properties of Agricultural Products, Figure 3 Frequency and temperature dependence of the permittivity of navel orange, *Citrus aurantium* subsp. *bergamia*, at indicated temperatures (Nelson, 2003).

Dielectric properties of a commercial apple juice product were measured over the 200-MHz to 20-GHz frequency range (Nelson and Bartley, 2002). Because of the high water content of the apple juice, the dielectric relaxation of liquid water was clearly evident in resulting data. The temperature dependence of the dielectric properties of the apple juice is also very similar to that of pure liquid water, with the relaxation frequency for pure water shifting from below 20 GHz to higher frequencies as temperature increases (Hasted, 1973).

Poultry products

Some dielectric spectroscopy measurements have been taken recently on poultry products in exploratory work on quality sensing (Zhuang et al., 2007). Dielectric properties values for fresh chicken breast meat in the 10–1,800-MHz frequency range at temperatures from 5°C to 65°C are shown in Figure 4. These curves show frequency dependence of the dielectric properties similar to those for tissues of fruits and vegetables. Probable

Dielectric Properties of Agricultural Products, Figure 4 Frequency and temperature dependence of the dielectric properties of fresh chicken breast meat, *Pectoris major*, deboned at 2-h postmortem (Zhuang et al., 2007).

potential was indicated for using dielectric properties to assess meat quality characteristics.

Dielectric spectroscopy measurements were also taken on the albumen and yolk of fresh chicken eggs and at weekly intervals during 5 weeks of storage (Guo et al., 2007b). Dielectric properties changed during the storage period, but they did not correlate well with traditional quality factors for eggs.

Summary

Dielectric properties of materials are defined, and the importance and usefulness of the dielectric properties of agricultural products are discussed briefly, pointing out

their use in the rapid sensing and measurement of moisture content in grain and seed and in governing the behavior of materials subjected to RF and microwave electric fields for dielectric heating applications. Sources of information on the dielectric properties of such products are provided, and values of the dielectric constants and loss factors are presented graphically for a few products, including grain, fruit, and poultry products. These examples provide information not only on typical values of the dielectric properties, but also on their dependence on such variables as frequency of the alternating electric fields applied, moisture content, and temperature of the products.

DIFFUSE DOUBLE LAYER (DDL)

Md. Abdul Mojid

Irrigation and Water Management, Agricultural University, Mymensingh, Bangladesh

Synonyms

Electrical double layer (EDL); Electrical triple layer (ETL)

Definition

Diffuse double layer (DDL) is an ionic structure that describes the variation of electric potential near a charged surface, such as clay, and behaves as a capacitor.

Formation: Clays are aluminosilicates in which some of the aluminum and silicon ions are replaced by elements with different charge. For example, aluminum (Al^{3+}) may be replaced by iron (Fe^{2+}) or magnesium (Mg^{2+}), leading to a net negative charge. When suspended in an electrolyte, clay particles are surrounded by a hydrosphere of adsorbed water that contains a thin layer of adsorbed cations. Outside this layer, ions of opposite polarities form an electrically neutral diffuse layer. The adsorbed cations are influenced by electrostatic attraction, but those in the diffuse layer are influenced by two equal but opposing forces: electrostatic attraction and diffusive forces. This ionic structure consisting of the negative surface charges, adsorbed cations, and diffuse layer is known as the diffuse double layer, DDL. The thickness of the DDL is $<10^{-6}$ cm (Pamukcu, 1997).

Models: The Helmholtz, Gouy–Chapman, and Gouy–Chapman–Stern models describe the structure of a DDL. The first model states that the surface charge is neutralized by cations placed rigidly at an increment of their radius from the surface. The surface charge potential is dissipated linearly from the surface to the cations. The hypothesis of the rigid layers of cations is, however, questionable. The loosely held cations diffuse into the

liquid phase until the counter potential restricts this process – is the assumption of the second model. This assumption, also questionable, treats ions as point charges and physically limitless approach of the ions to the surface. The third model postulates that ions have finite size and the first layer of ions is at a distance equal to the radius of the ion from the surface. Also, some of the ions are adsorbed by the surface in the plane, and this layer is called the Stern layer.

Main features: Clay particles are surface-active materials and many of their properties depend on the activity of surface phenomena. The cations in the Stern layer can be replaced by other cations; thus, they are exchangeable and become available to plants. The capacity of a soil for exchange of cations between the soil and the surrounding solution is its cation exchange capacity, CEC. The cations in the DDL move along the clay–water surface under the influence of an electrical field (Revil and Glover, 1997) resulting in the surface electrical conduction. Increasing electrolyte concentration or decreasing water content reduces the thickness of DDLs and hence the mobility of cations within them. The cations in the Stern layer, although once assumed immobile, are now found mobile (Leroy and Revil, 2004) leading to the assumption of a dynamic Stern layer.

Definition

Diffusion is a process that causes the spread of a constituent mass within the medium under gradient of

concentration. It originates from the random motion of particles (molecular diffusion). Diffusion equation describes well various spread processes of water, gases, solutes, and heat in porous media. In case of a porous material, diffusion coefficient is interpreted as dispersion coefficient with the value dependent on porous material structure. Diffusion equation allows to describe, in a simple manner, the transfer of mass or heat in porous media by inclusion of various effects into one parameter – dispersion coefficient.

Introduction

In soil, various diffusion processes occur. They comprise diffusive transport of heat energy, of gases, of solutes, as well as of water under unsaturated conditions. These processes are important for plant biomass production and for the state of the environment.

Equation of motion based on Newton's Laws connects acceleration and force into simple equation:

$$\vec{F} = m\vec{a} \quad (1)$$

where \vec{F} is vector of force m is mass \vec{a} is vector of acceleration.

Analyzing transport processes in microscale, one should consider various forces acting on each part of the system and forces acting among particular parts of the system:

$$\frac{d(m\vec{v})}{dt} = \sum \vec{F}_i \quad (2)$$

where \vec{v} is vector of flow velocity t is time.

This in fact leads to a partial differential equation of the second order in three-dimensional space. In case of porous material, it gives complicated equations that are not tractable in a practical way.

While considering the porous medium such as soil in a macroscopic scale one should take into account a representative volume of the medium to perform homogenization of its properties.

All factors that influence flow can be combined into one parameter that governs water movement. Describing water flow in the soil medium, one should consider water interaction with solid phase, gravity forces influence on flux, water internal friction, etc. Instead, all those effects are lumped into one parameter called diffusivity function or diffusion coefficient.

Moisture diffusivity in soil

This kind of reasoning lead to the Darcy's equation (1856) giving connection between macroscopic, saturated water flow velocity v , and pressure drop Δh over the sample length Δx :

$$v = K_{sat} \frac{\Delta h}{\Delta x} \quad (3)$$

Coefficient K_{sat} , called today saturated hydraulic conductivity, is a parameter that depends on the soil type and bulk density.

For unsaturated conditions, this equation is applicable in a modified form:

$$f_w = -K \frac{\partial \Phi}{\partial x} \quad (4)$$

where f_w is water flux K is hydraulic conductivity function Φ is pressure potential in the samplex is spatial coordinate.

In this equation, hydraulic conductivity function K is highly moisture dependent and is specific for a soil sample.

Above equations are based on the assumption that water potential gradient is a driving force causing water flow in the sample. Often, it is useful to consider water content gradient as a factor causing water flow. In such a case, the previous equation reads:

$$f_w = -K \frac{d\Phi}{d\Theta} \frac{\partial \Theta}{\partial x} \quad (5)$$

where Θ is a volumetric moisture content of the soil sample.

In this picture, new characteristic of the flux can be introduced, namely, diffusivity function D_w :

$$f_w = -D_w \frac{\partial \Theta}{\partial x} \quad (6)$$

It is visible from the comparison of above equations that:

$$D_w = K \frac{d\Phi}{d\Theta} \quad (7)$$

what means that the diffusivity is equal to water permeability K multiplied by the slope of the water retention curve $d\Phi/d\Theta$.

Moisture potential is usually considered as consisting of two different parts:

$$\Phi = h + z. \quad (8)$$

In this equation, h is a pressure part of the potential and z is gravitational part of the potential, represented in the equation by the elevation z over a chosen reference level. Pressure potential is dependent on moisture content, soil type and structure, while gravitational potential depends on gravitational forces.

In three dimensions, the equation for flux of water reads as follows:

$$\bar{f}_w = -K \left(\vec{i} \frac{\partial \Phi}{\partial x} + \vec{j} \frac{\partial \Phi}{\partial y} + \vec{k} \frac{\partial \Phi}{\partial z} \right). \quad (9)$$

Flux \bar{f}_w is treated here as a vector in three-dimensional space. Application of the equation for moisture potential leads to the equation:

$$\bar{f}_w = -K \left(\vec{i} \frac{\partial h}{\partial x} + \vec{j} \frac{\partial h}{\partial y} + \vec{k} \left(\frac{\partial h}{\partial z} + 1 \right) \right). \quad (10)$$

which shows clearly the influence of gravity force on the flux in vertical (z) direction.

When applying change of the variables to the diffusivity, the above equation reads:

$$\bar{f}_w = -K \frac{dh}{d\Theta} \left(\vec{i} \frac{\partial \Theta}{\partial x} + \vec{j} \frac{\partial \Theta}{\partial y} + \vec{k} \left(\frac{\partial \Theta}{\partial z} + \frac{d\Theta}{dh} \right) \right) \quad (11)$$

and the coefficient D_w :

$$D_w = K \frac{dh}{d\Theta} \quad (12)$$

is a moisture diffusivity function.

Application of the mass conservation law:

$$\frac{\partial \Theta}{\partial t} = -\operatorname{div} \bar{q} \quad (13)$$

to the flux \bar{q} leads to the water diffusion equation:

$$\begin{aligned} \frac{\partial \Theta}{\partial t} &= \frac{\partial}{\partial x} \left(D_w \frac{\partial \Theta}{\partial x} \right) + \frac{\partial}{\partial y} \left(D_w \frac{\partial \Theta}{\partial y} \right) \\ &\quad + \frac{\partial}{\partial z} \left(D_w \frac{\partial \Theta}{\partial z} \right) + \frac{dK}{d\Theta} \frac{\partial \Theta}{\partial z} \end{aligned} \quad (14)$$

with gravitational term $\frac{dK}{d\Theta} \frac{\partial \Theta}{\partial z}$.

In practice, diffusion coefficient depends on the moisture content and often, due to the spatial variability of the soil, is position dependent. This causes certain problems in the application of this model to real conditions.

This equation together with initial and boundary conditions form a complete system that describes fate of moisture content in a certain volume. Initial condition function defines initial values of the moisture content in each point of the volume under consideration, while boundary conditions define values of moisture and/or flux of water at the boundaries of considered volume at the time when moisture movement is calculated.

To determine the moisture content distribution in a medium in a certain time, it is necessary to solve the water flow equation.

The solution depends on the actual moisture conditions existing at the boundaries of the considered region and, on initial moisture conditions inside the considered region. Moisture flow equation is the second-order equation in spatial coordinates. One has to provide the value of moisture content and of moisture gradient at the boundary.

The factor containing the water hydraulic conductivity K in the equation origins from the gravity forces and is present only in the equation where vertical flow is applicable.

Solution of the diffusion equations

Usually, when diffusion coefficient depends on the moisture content, one has to solve the diffusion equation numerically due to complicated form of this function. In some cases, for simple diffusivity functions analytical solution is known. This is the situation for constant diffusion coefficient and for various geometries of modeled volume.

Dependence of water diffusion on moisture content
Diffusion coefficient of water in the soil is specific for a given soil. It depends on the status and moisture content. In order to be able to model various shapes of diffusion functions, many mathematical functions presenting empirical models have been used ([Table 1](#)).

Importance of gravity forces

Gravity forces are especially important under the conditions close to saturation when pressure head gradient is low. When pressure head gradient has a large value in comparison to unity, the gravity forces do not play a significant role in water flow. In such a situation, water can easily flow against the gravity from the deeper layers of the soil to the surface.

Calculation of moisture diffusivity

Moisture diffusivity can be calculated from the measurement results of transient moisture profiles of isothermal, horizontal water flow. Inverse analysis with the application of Boltzmann–Matano transformation is possible (e.g., Pachepsky et al., [2003](#)). One dimensional diffusion equation for such a case has a form (e.g., Black et al., [1969](#); Lisle et al., [1987](#); Parlange et al., [1993](#)):

$$\frac{\partial \Theta}{\partial t} = \frac{\partial}{\partial x} \left(D_w(\Theta) \frac{\partial \Theta}{\partial x} \right), \quad (15)$$

where Θ is volumetric water content, t is time of water absorption, and x is distance of monitored moisture content from the water exposed surface of the sample. Boundary conditions are constant with a step at the beginning of the process:

Diffusion in Soils, Table 1 Empirical equations relating water diffusivity to volumetric water content

Equation	Symbols meaning	Source
$D_w = a \frac{\Theta^b}{(\Theta_s - \Theta)^a}$	D_w – diffusion coefficient Θ_s – saturated volumetric water content	Ahuja and Swartzendruber (1972)
$D_w = \frac{K_s}{\lambda z (\Theta_s - \Theta)} s^{3/2+1/\lambda}$	Θ – actual volumetric water content s – saturation of the soil K_s – saturated hydraulic conductivity	Mualem (1976)
$D_w = a \frac{\Theta^b}{(\Theta_s - \Theta)^a}$	α, a, b, λ – fitting parameters	van Genuchten (1980)

$$\Theta(0, t) = \Theta_1, \quad (16)$$

initial moisture in the sample is constant with a value:

$$\Theta(x, 0) = \Theta_2. \quad (17)$$

Application of Boltzmann transformation of variables that introduces variable:

$$\Theta(x, t) = \Theta(\eta) \quad (18)$$

with

$$\eta = \frac{x}{2\sqrt{t}}, \quad (19)$$

converts the partial differential equation into ordinary equation in a new variable:

$$\frac{d}{d\eta} \left(D_w(\Theta) \frac{d\Theta}{d\eta} \right) + 2\eta \frac{d\Theta}{d\eta} = 0 \quad (20)$$

with the boundary conditions

$$\omega(0) = \Theta_1, \quad (21)$$

$$\omega(\infty) = \Theta_2. \quad (22)$$

This equation can be solved by integration giving:

$$D_w(\Theta) = \frac{1}{2t_0(d\Theta/d\eta)\eta_0} \int_{\eta_0}^{\infty} \eta \frac{d\Theta}{d\eta} d\eta. \quad (23)$$

One should know the variability of moisture content in space and time $\Theta(x, t) = \Theta(\eta)$ from the experiment in order to apply this method.

Diffusion processes in soil, beyond the diffusion of water under unsaturated conditions, as described above, comprise diffusion of heat, of gases, and of solutes. The diffusion equations for these agents are in all the cases similar (cf. [Tables 2](#) and [3](#)). In each case, the flux of the agent under consideration is proportional to the driving force of the process and to a coefficient characterizing the transport properties of the given material.

The driving force of water movement is the gradient of water potential (Darcy's law). The heat flux is driven by the temperature gradient (Fourier's equation). In case of diffusion of gases and solutes, the driving forces are the concentration gradients of the gases or of the solutes (First Fick's equation).

Diffusion in Soils, Table 2 Equations for water movement under unsaturated conditions in soil and heat transfer both under saturated and unsaturated conditions (modified from Bolt et al., 1966)

General notion	Water	Heat	Symbols
Flux	$f_w = -K(\partial\Phi/\partial x)$, Darcy (1856)	$f_h = -\lambda(\partial T/\partial x)$, Fourier (1822)	f_w – unit flux of water
Conservation equation	$\partial\Theta/\partial t = -(\partial f_w/\partial x) \pm q_w$	$\partial(c_v T)/\partial t = -(\partial f_h/\partial x) \pm q_h$	f_h – unit heat flux K – water permeability
Movement equation for soil profile	$\partial\Theta/\partial t = (\partial/\partial x)(D_w(\partial\Phi/\partial x)) \pm q_w$	$\partial T/\partial t = (\partial/\partial x)(D_h(\partial T/\partial x)) \pm q_h$	λ – heat conductivity Φ – water potential T – temperature x – distance t – time Θ – volumetric water content c_v – heat capacity q_w, q_h – source/sink terms $D_w = K_h(\partial\Phi/\partial\Theta)$ $D_h = \lambda/c_v$

Diffusion in Soils, Table 3 Equations for gas and solute diffusion in soil (modified from Bolt et al., 1966)

General notion	Gas	Solute	Symbols
Flux	$f_g = -D_g(\partial C/\partial x)$, Fick (1855)	$f_s = -D_s(\partial C/\partial x)$, Fick (1855)	f_g – unit flux of gas
Conservation equation	$\partial[C(\varepsilon_g + B\Theta)]/\partial t = -(\partial f_g/\partial x) \pm q_g$	$\partial(\Theta C)/\partial t = -(\partial f_s/\partial x) \pm q_s$	f_s – unit solute flux B – Bunsen's coefficient of solubility
Movement equation for soil profile	$\partial C/\partial t = (\partial/\partial x)(D_g^*(\partial C/\partial x)) \pm q_g^*$	$\partial C/\partial t = (\partial/\partial x)(D_s^*(\partial C/\partial x)) \pm q_s^*$	C – concentration of the gas or solute Θ – volumetric water content x – distance t – time D_g – gas diffusion coefficient D_s – solute diffusion coefficient ε_g – air-filled porosity $D_{g*} = D_g/(\varepsilon_g + B\Theta)$ $D_{s*} = D_s/\Theta$ ΘC – amount of solute in a unit soil volume $[C(\varepsilon_g + B\Theta)]$ – amount of gas in unit soil volume q_g, q_g^*, q_s, q_s^* – source/sink terms

The properties of the diffusion medium are characterized by water permeability in case of water movement. In case of heat flux, it is the heat conductivity, while in case of gas and solute diffusion, it is the diffusion coefficient.

The similarities among the above processes become more evident after combination with the conservation equation. Then the equation gets the form of the second Fick's equation (Table 3) and material constant characterizing the properties of the medium acquires the dimension of square unit of length per unit of time (most often $m^2 s^{-1}$).

Thermal diffusivity in soil

The flow of heat in a soil is connected with many processes. Usually, it is not a simple heat conduction but involves also radiation heat transport, vapor transport with latent heat movement. In the simplest case, it is assumed that heat transfer undergoes conduction and can be

described with the diffusion equation. It is in fact the flow of thermal energy in the stable soil caused by temperature gradient.

Heat conduction equation comes out from the application of constitutive equation for the heat conduction in a matter, i.e., Fourier's law, $\vec{q}_h = -\lambda\nabla T$, that combines temperature gradient and heat flux in a linear manner with energy balance equation $dE/dt = \dot{Q} + \dot{W}$ that expresses energy conservation in the flow process, where \dot{Q} denotes heat flux term, \dot{W} represents work flux, and λ is the heat conductivity.

The application of both equations leads in the simplest case to (Hillel, 1982; Marshall and Holmes, 1988):

$$\frac{\partial T}{\partial t} = D_h \frac{\partial^2 T}{\partial x^2} \quad (24)$$

which has the form of diffusion equation for temperature distribution. The coefficient D_h is a thermal diffusivity

coefficient. One should keep in mind that despite of the form, this equation describes heat transport and not temperature transport.

Thermal diffusivity D_h can be calculated from the formula:

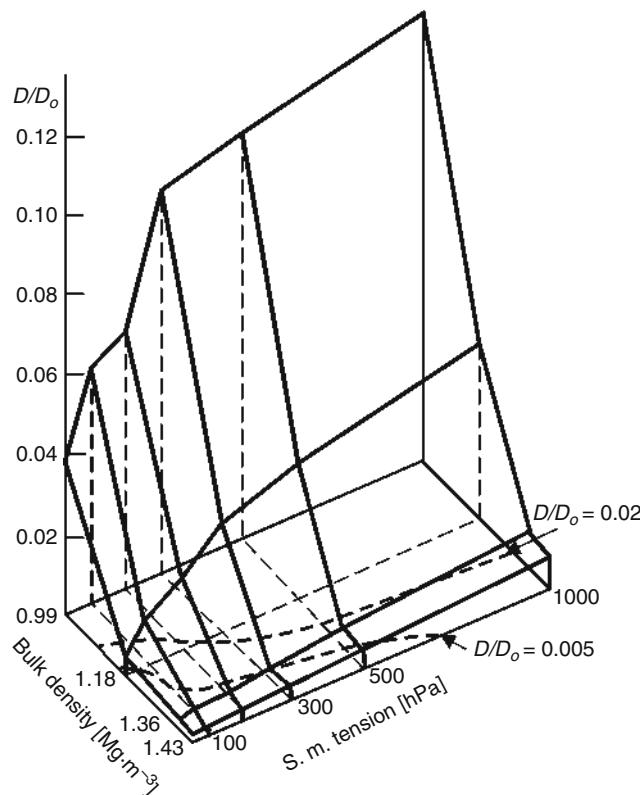

$$D_h = \frac{\lambda}{c_v} \quad (25)$$

where c_v is its heat capacity.

Thermal diffusivity of soils varies due to soil parameters variation. Moisture content is one of most important factors that change thermal diffusivity. Heat capacity of the soil is almost a linear function of moisture content, while thermal conductivity depends on moisture content nonlinearly (Figure 1). Thermal diffusivity has a maximum for certain moisture content, what is of high practical importance. Soil with the moisture content around this value will heat much quicker than soil with moisture far from that value. Optimal moisture allows to germinate seeds in spring significantly earlier.

Diffusion of gases

Concentration diffusion plays an essential role in the gas exchange within soil. The diffusive flow f_g of a gas within a porous medium is described by the first Fick's law.

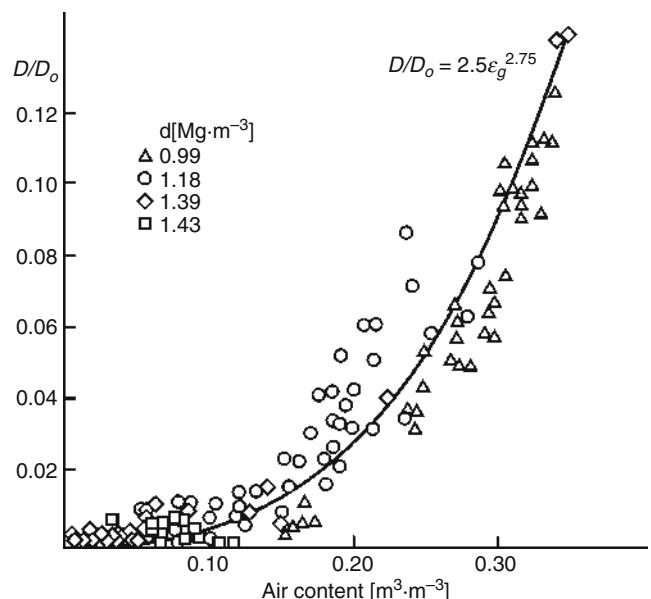

Diffusion in Soils, Figure 1 Dependence of relative gas diffusion coefficient in a loamy textured Chernozem Rendzina (Bezek, Poland) on soil moisture tension and bulk density (modified from Stępniewski, 1981).

$$f_g = -D_g \frac{\partial C}{\partial x} \quad (26)$$

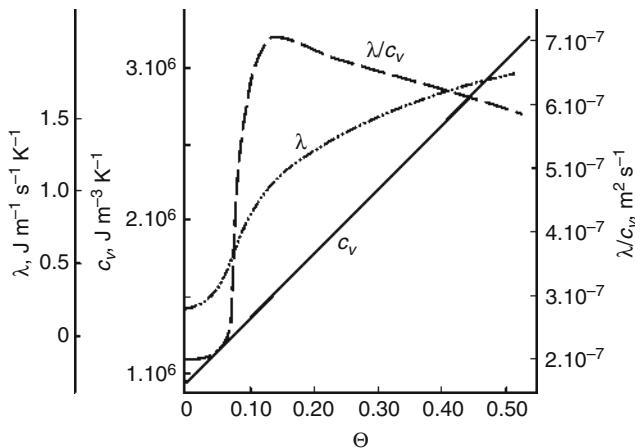

The change of the concentration of gases with time is described by the second Fick's law, containing also the sink/source term (Table 3).

Coefficient of gas diffusion in soil D_g depends on the kind of the diffusing gas, on the temperature and pressure, as well as on the content of air-filled pores, and their tortuosity, continuity, and shape. These, in turn, depend on the spatial arrangement of soil particles and distribution of water. The diffusive properties of soil medium usually are characterized by relative diffusion coefficient D_g/D_o , where D_o is the diffusion coefficient of the same gas in free atmospheric air under the same temperature and pressure conditions. The D_g/D_o value does not depend on the temperature, pressure, or the kind of the diffusing gas (e.g., Kristensen et al., 2010).

The dependence of relative gas diffusion coefficient on *soil bulk density* and on soil moisture tension is presented in Figure 2, and that on air-filled porosity ε_g – in Figure 3. The value of D_g/D_o in soil is usually below 0.2. As it can be noticed, it increases with soil moisture tension, and rapidly decreases with soil bulk density. It should be emphasized that gas diffusion coefficient in porous media does not depend on the size of the pores, as long as the pore diameters are greater than the mean free path of the molecules of the gas under consideration (Glinski and Stępniewski, 1985). This limit is the pore diameter of 0.10 µm. In the case of soil, pores of that size are emptied of water at soil moisture tension above 3 MPa ($pF > 4.5$),

Diffusion in Soils, Figure 2 Relationship of D/D_o to air-filled porosity ε_g , of the same as in Figure 1 loamy textured Chernozem Rendzina at different bulk densities d (modified from Stępniewski, 1981).

Diffusion in Soils, Figure 3 Thermal conductivity λ , heat capacity c_v , and thermal diffusivity $D_h = \lambda/c_v$ versus volumetric water content for a sandy soil of 50% total porosity and 3.5% organic matter content (modified from Van Duin, 1956).

i.e., at moisture contents below the permanent wilting point. It means that diffusion of gases within macropores ($>30\text{ }\mu\text{m}$) and mezopores ($30\text{--}0.2\text{ }\mu\text{m}$) usually containing plant available water does not depend on the pore size. It was demonstrated that the magnitude of gas diffusivity (as well as that of thermal diffusivity) is more sensitive to the porosity than to the scale dependency inherent in fractal structures (Anderson et al., 2000).

D_g/D_o usually shows a curvilinear relationship versus ε_g , as shown in Figure 3. It can be described by an empirical power model in the form:

$$\frac{D_g}{D_o} = \gamma \varepsilon_g^\mu \quad (27)$$

where γ and μ are empirical coefficients characterizing the diffusion medium.

It should be kept in mind that gas diffusion in soil comprises not only the macroscale diffusion within the entire soil profile, but also microscale and approximately spherical diffusion within particular aggregates, as well as longitudinal and radial diffusion within the plant root tissues (e.g., Gliński and Stępniewski, 1985; Cook and Knight, 2003). Due to soil heterogeneity and importance of microscale diffusion processes, the composition of air within the intra-aggregate pores may differ from that in the inter-aggregate pores. The former pores contain less oxygen and more carbon dioxide compared to the inter-aggregate pores (e.g., Zausig et al., 1993; Højberg et al., 1994; Horn, 1994; Horn and Smucker, 2005).

Diffusion of solutes

Diffusion of inert, nonreactive solutes in soil can be described by the first and the second Fick's equations presented in Table 3. Unlike the diffusion of gases, the diffusion of solutes takes place in the liquid phase of the soil.

Due to this, the diffusion coefficient depends on the continuity and tortuosity of the pores filled with water and increases with the degree of saturation with waters.

In case of reactive solutes which can undergo processes of adsorption, dissociation, ion exchange, and chemical reactions, these processes have to be taken into consideration within the sink/source term.

Summary

Diffusion processes in soil comprise transport of water under unsaturated conditions, transport of gases in liquid and gaseous phase, transport of heat in all the three phases, as well as transport of solutes within liquid phase. The flux per unit cross-sectional area and per unit time is proportional to driving forces of these processes which are the gradients of water content, of gas concentration, of temperature, and of solute concentration, respectively, as well as to the parameter called diffusion coefficient (dimension $\text{m}^2\text{ s}^{-1}$), characterizing properties of the medium in which the diffusion process takes place. Combination of these equations with the conservation law gives the formulas of the second Fick's equation type for all the fluxes with the source/sink term. It should be underlined that under field conditions diffusion processes are usually coupled one with other or with mass flow processes caused by infiltration and lateral flow of water as well as by gas movement due to pressure gradient.

DILATANCY

The tendency of a body under shearing stress to expand as it deforms. This property is typical of sandy soils and powders, as a result of the sliding and rolling of particles over one another along the shearing plane.

DISCHARGE

The volume of water flow through the stream or open channel past a point in a given time period.

Synonyms

Circadian rhythm in fluctuations of diameter; Daily plant organ radius variations; Diurnal changes in plant organ diameter; Diurnal fluctuations in size

Definition

Diurnal strains in plants:

- Diurnal – having a daily cycle
- Strain – a deformation produced by stress

Periodic reversible shrinkage and irreversible and/or reversible swelling of plant tissues. This process is a function of the changing levels of tissue hydration. Tissue hydration during natural day/night cycles in plants which have lost their leaves (late autumn, winter and early spring) depends on water accessibility and temperature, whereas in plants with leaf, tissue hydration additionally depends on the transpiration rate which is connected with air humidity, wind speed, CO₂ concentration, etc. Swelling of tissues is caused by hydrostatic pressure and mainly occurs at night. In contrast, during the day tissues shrink because of decrease in turgidity caused by transpiration. The measurable effect of this process is the decrease in the tangential strain. The strain is a response to the mechanical stress imposed on the plant cell walls by changing water pressure. The nature of the strain generated by changes in water pressure depends on the properties of the cell wall and it can be elastic, viscoelastic, and plastic. There are different phenomena which generate tangential strains in plant organs: variations in hydrostatic pressure, variations in osmotic pressure, variations in temperature, and growth of the tissues.

Historical perspective

Reversible shrinkage of plant organs was first reported during periods of temperatures below the freezing point (Hoffmann, 1857; Sachs, 1860). Wiegand (1906) described the swelling of tree branches during thawing and described a much bigger extension of the bark than of the xylem. This reversible seasonal deformation was attributed to the elastic properties of plant tissues. One of the first pieces of information concerning diurnal decrease in the size of a plant organ (orange fruit) was reported by (Bartholomew, 1923). However, initially the mainstream research in diurnal strains was connected with systematic observations of the radial growth of trees. Development of new tools and methods of observation helped to identify a daily rhythm of shrinkage and swelling of tree trunks (MacDougal, 1924; Reineke, 1932).

The first rapid increase in research on this phenomenon started in the late 1950s and lasted till the middle of the 1970s of the last century (Ninokata and Miyazato, 1959; Kozlowski and Winget, 1964; Klepper, 1968; Klepper et al., 1971; Molz and Klepper, 1973; Pereira and Kozlowski, 1976). During this time, the mechanism of diurnal variations in size of different plant organs was identified and described. However, the phenomenon was seen as a side effect of transpiration and water accessibility without any significant function. Since that time, both the recognition of the mechanism as well as the understanding of the role of diurnal strains in plant organs has expanded considerably.

Mechanism of diurnal strains fluctuation

During the early evolution of land plants, the problem of water loss due to direct exposure to dry air had to be solved (water stress). It was resolved on the physiological level by enhancement of osmotic adjustment and on the

structural level by the development of epidermis. However, evolution of a non-permeable epidermis would create new problem with gas exchange. The compromise which was achieved and enabled adaptive radiation of land plants was the evolution of stomata.

Although water is lost during the day, osmotic adaptation helps the plant to survive a short period of water stress. During the night, water is replenished in greater quantity than the amount lost, which generates a mechanical stress. The side effect of these two consecutive stresses is cyclic deformation of plant organs.

During the vegetative season when the sun is rising (1) stomata open (2) (Wronski et al., 1985; Herzog et al., 1995). Temperature steadily increases afterward (3), whereas the relative humidity of the air decreases (4). In this way, preferable conditions for high rate of water transpiration (5) are established (Lövdahl and Odin, 1992). Transpiration causes a decrease in water potential in water conduits (6) and eventually leads to water tension (7) in Soil-Plant-Atmosphere Continuum (SPAC). Water tension is a reason for the decrease in hydration of an apoplast (8), which actually means decrease in water potential of the apoplast and ultimately measurable shrinkage of the xylem (9). In this way, a steep gradient of water potential between apoplast and symplast (10) is created (Molz and Klepper, 1972) and in consequence, water flows from turgid cells (living cells of the symplast with high water potential) toward apoplast and water conduits (11) (with lower water potential). Cell-wall pressure (turgidity) pushes water outward in the living cells, effectively decreasing cells' water potential. Loss of water causes a decrease in turgidity (12) and stabilizes the water potential inside the cell at the apoplast water potential level. Loss of turgidity causes shrinkage of living tissues (13) (Yoshida et al., 2000; Tyree and Zimmerman, 2002; Alméras et al., 2006), and the below-threshold value is recognized by a living system as a water stress (14) (Molz and Klepper, 1973). During the day, the mechanism of restoration of the initial water status in cells leads to osmotic adjustment (15). This means that the water stress turns on an adaptational reaction, which decreases osmotic potential, lowering cell water potential (16), and thus preventing outward water movement. Osmotic adjustment allows for maintenance of relatively greater volume at low water potential and it helps to stop decline in turgidity.

As a rule, the process of adaptation toward water stress is overshoot (17) (Belousov and Grabovsky, 2006) – excessive decrease of water potential in the symplast causes water movement into living cells, though in plant conduits water tension has a very low water potential (refilling under water stress due to osmotic adaptation [18]). It happens when the day is very long and the osmotic adaptation passes through the constraints of water tension.

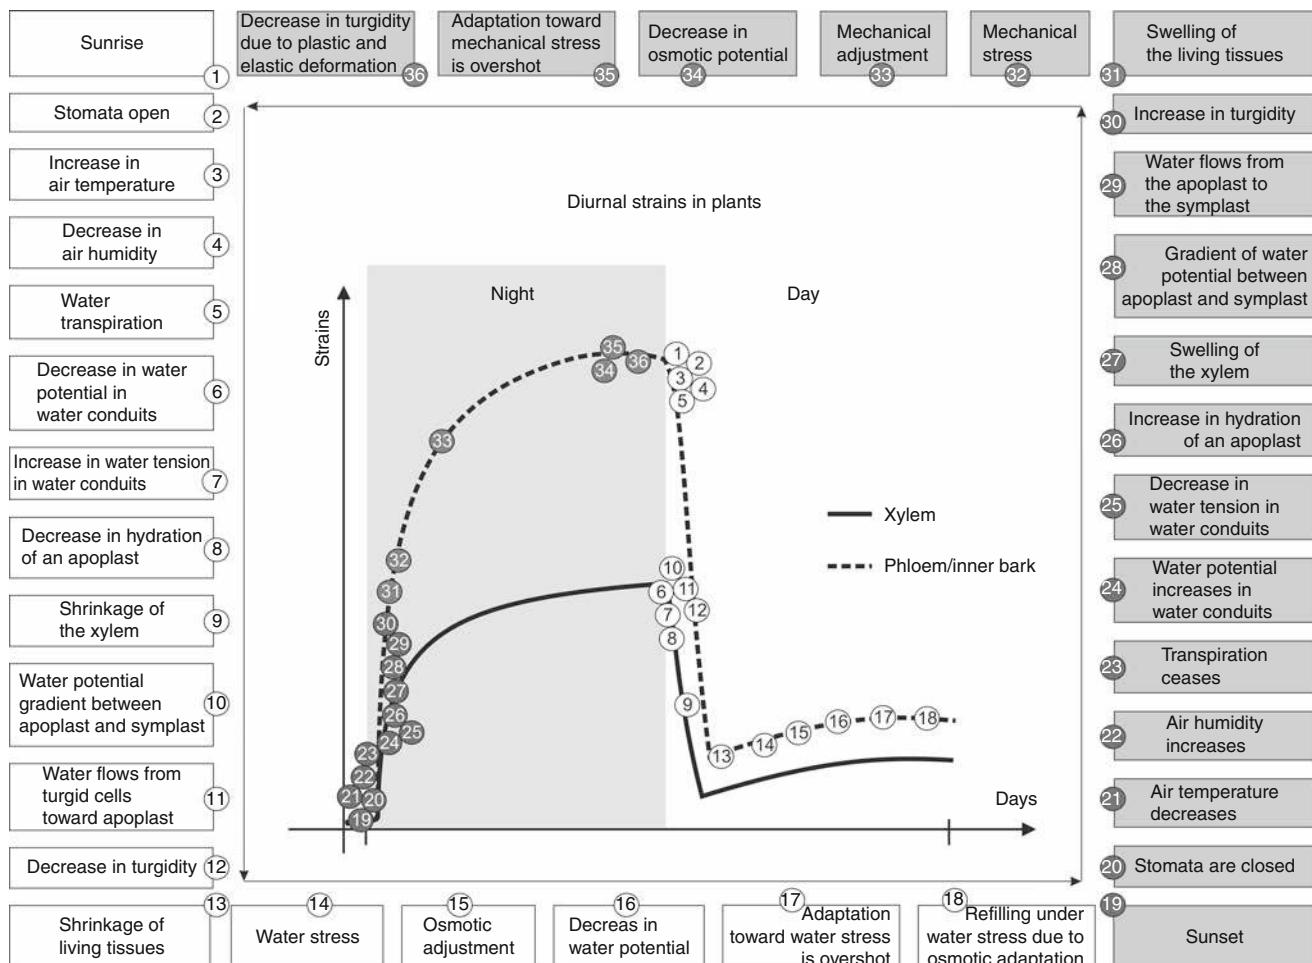

This adaptation to water stress is ended sharply at sunset (19) when stomata are closed (20) (Wang et al., 2008). During the night, air temperature decreases (21) and air humidity increases (22) (Lövdahl and Odin, 1992). In such circumstances transpiration ceases (23). In plant

water conduits water potential increases (24), causing a decrease in the water tension (25). This means rehydration of the apoplast (26). In consequence, swelling of the xylem elements (27) occurs (Mengel and Kirkby, 2001). Higher water potential in water conduits and lower water potential of living cells produce water potential gradient (28) and causes water flow from the apoplast to the symplast (29) (Molz and Klepper, 1972). Rehydration of living cells causes increase in turgidity (30), which at the tissue level is a basis for swelling (elastic and plastic deformation) of living tissues (31) (Yoshida et al., 2000; Tyree and Zimmermann, 2002; Alméras et al., 2006). The water recharging mainly occurs from sunset to midnight (Wang et al., 2008). In this way, during the first few hours of the night, mechanical stress inside the plant is generated (32) (Stankovic et al., 1998). One of the adaptive mechanisms to this stress is mechanical adjustment (33) (cell growth, cell-wall relaxation, schizogenous space formation, or schizolisisogenous space formation [Evert and Eichhorn, 2006]). The second adaptive mechanism to this stress is decrease in osmotic potential (34) (osmotic

adjustment). In consequence, adaptation to mechanical stress prevents an uptake of water into living cells, but again this adaptation process is overshoot (35) (Belousov and Grabovsky, 2006) at the end of the night and a small decrease in turgidity can be observed due to mechanical adaptation (i.e., plastic deformation) (36). This happens when the night is very long and mechanical adaptation relaxes tensile stress. Living tissues are vulnerable toward incoming daily water imbalance. On the next day, the whole process starts from the beginning (1) (Figure 1).

Measurements and applications

Diurnal strain measurements are nondestructive and can be monitored continuously with different types of dendrometers. The simplest technique is application of a caliper or one of the linear variable differential transformers (LVDT sensors) based on strain gauges (Ninokata and Miyazato, 1959; Klepper et al., 1971; Okuyama et al., 1995; Yoshida et al., 2000; Daudet et al., 2005). New noninvasive techniques are still developing. One of

Diurnal Strains in Plants, Figure 1 Mechanism of diurnal strains fluctuation. Numbers between 1 and 18 represent processes and events during the day and numbers from 19 to 36 symbolize processes and events during the night.

the most promising techniques which allows truly noninvasive measurements is digital image correlation (DIC) (Sutton et al., 2000). A second new technique is Electronic Speckle Pattern Interferometry (ESPI) (Jones and Wykes, 1989). Optical methods are inherently nonintrusive and noncontacting. They are highly also sensitive and provide full-field measurement data.

Diurnal strain measurements are potentially a powerful tool for studying (Alméras, 2008):

1. Tree physiology, i.e., helps to obtain information about:
 - (a) Tree water status (Klepper et al., 1971; So et al., 1979; Ueda and Shibata, 2001)
 - (b) Water transport (Zweifel et al., 2000; Sevanto et al., 2002)
 - (c) Transpiration rate (Herzog et al., 1995)
 - (d) Spatial and temporal patterns of physiological activity (Sevanto et al., 2002)
 - (e) Cambial growth dynamics (Kozlowski and Winget, 1964; Deslauriers et al., 2003)
 - (f) Wood morphogenesis (Okuyama et al., 1995; Abe and Nakai, 1999)
 - (g) The transport of sugar in phloem (Sevanto et al., 2003; Daudet et al., 2005)
 - (h) The rate of embolism in a stem (Hölttä et al., 2002)
 - (i) Embolism removal (Zwieniecki and Holbrook, 1998)
 - (j) The reduction in wood conductivity in senescent trees (Ueda and Shibata, 2002)
2. Practical applications, such as:
 - (a) Correcting continuously recorded dendrometric data (Kozlowski and Winget, 1964; Deslauriers et al., 2003)
 - (b) Estimating transpiration (Herzog et al., 1995)
 - (c) Establishing irrigation scheduling (Goldhammer and Fereres, 2001; Remorini and Massai, 2003)
 - (d) Detecting the effects of pathogens on plant water status (Cohen et al., 1997)

Summary

Daily shrinkage in plant organs is generally related to the variation in water potential. Plant organs shrink during the day because plants lose more water by transpiration than they can take up. The higher the water stress, the more the water lost during the day. At night, when there is little loss of water, plant organs will increase in diameter because of the uptake and storage of water. Since the living cells are much more elastic than wood cells, diurnal plant organ fluctuations are mainly influenced by changes of the thickness of living tissues. Therefore in stems of woody plants, the shrinking and swelling take place mainly in a ring of phloem outside the xylem. Both the shrinkage and swelling of the cells, tissues, or organs are the effects of stress. Shrinkage is caused by daily water stress, whereas swelling is caused by nocturnal mechanical stress. Whenever a change of local stress is applied to cells or tissue, they respond by actively generating forces

directed toward the restoration of the initial stress value (adaptation), but by overshooting it. This causes cyclic deformations which partly are irreversible. The irreversible part of deformation is called growth.

Definitions

DNA. Deoxyribonucleic acid that carries the genetic information in the cell and is capable of self-replication and synthesis of RNA (ribonucleic acid) in a process called transcription. DNA consists of two long chains of nucleotides twisted into a double helix and joined by hydrogen bonds between the complementary bases adenine and thymine or cytosine and guanine.

Soil. The top layer of the Earth's surface, consisting of rock and mineral particles mixed with organic matter. It plays an irreplaceable role in the biosphere because it governs plant productivity of terrestrial ecosystem and allows the completion of the biogeochemical cycles through its inhabiting microorganisms. The main characteristics are the domination of the solid phase, the presence of aqueous and gaseous phases, and its capacity of reactions by surface-active particles.

Vadose zone. Also termed the unsaturated zone, it is the portion of Earth between the land surface and the phreatic zone or zone of saturation ("vadose" is Latin for "shallow"). Water in the vadose zone has a pressure head less than atmospheric pressure, and is retained by a combination of adhesion (*funicular groundwater*) and capillary action (*capillary groundwater*).

Advection. A transport mechanism of a substance with a fluid in motion. An example of advection is the transport of solutes (DNA, pollutants) in the soil water flow.

Capillarity. The flow of liquids through porous media, such as the flow of water through soil. The capillary fringe is the subsurface layer in which groundwater seeps up from a water table by capillary action to fill pores. If pore size is small and relatively uniform, it is possible that soils can be completely saturated with water for several feet above the water table. Alternately, the saturated portion

will extend only a few inches above the water table when pore size is large. In smaller pores of the soil, water is held against the force of gravity by capillary forces and is called capillary water. This constitutes the only available source of water to plants.

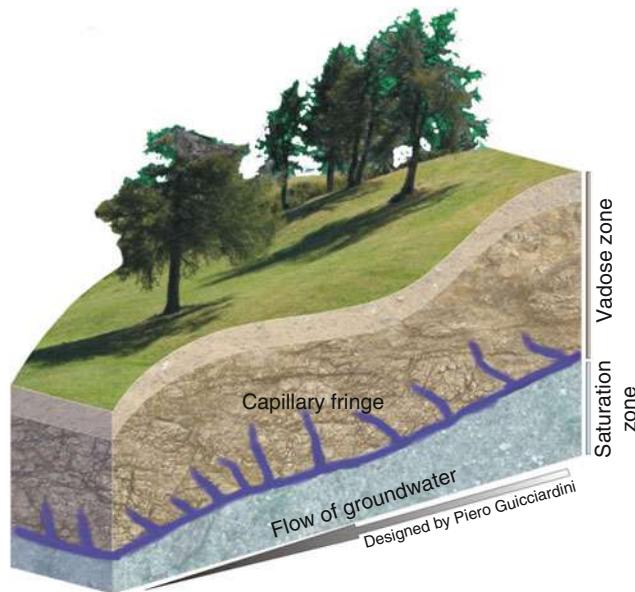

Real-time PCR. It allows for the detection of PCR (Polymerase chain reaction) amplification during the early phases of the reaction and this provides a distinct advantage over traditional PCR detection. Traditional methods use agarose gels for detection of amplicons at the final phase of the PCR reaction. Real-time PCR detects the accumulation of amplicons during the reaction and the data is measured at the exponential phase.

Introduction

The total soil DNA (tDNA) includes both intracellular (iDNA) and extracellular DNA (eDNA), with the latter originated from the former by active or passive extrusion mechanisms or by cell lysis. The eDNA can represent a relevant fraction of tDNA and thus a significant portion of the entire soil metagenome. Studies on the ecological relevance of eDNA in soils have concerned the gene transfer through transformation and interaction between eDNA molecules with the reactive surface of clay minerals, humic substances, and sand particles (Nielsen et al., 2006). Only recently has the attention been directed at the role of eDNA in the formation of bacterial biofilm in soil (Böckelmann et al., 2006) and at the possibility that eDNA can be transported by water through the soil profile (Agnelli et al., 2004). The key role of transformation in evolutionary terms justifies to continue the investigation on the fate of extracellular DNA in soil (Pietramellara et al., 2007). Extracellular DNA is also an important source of nitrogen and phosphorous, which are recycled by bacteria for the synthesis of new DNA; it might participate in gene transfer and, thus, in microbial evolution (de Vries and Wackernagel, 2004). Researches demonstrate that transgenes can move beyond the intended organism and into the surrounding environment, and it can be subjected to vertical advection if in the water solution (Dighton et al., 1997; Poté et al., 2003; Ceccherini et al., 2009b) that is in the vadose zone (Figure 1) of soil (Arias-Estévez et al., 2008). The extracellular DNA can be transported in the soil water flow also by horizontal movements, in fact, using soil column systems, the vertical and horizontal movements of a target sequence were monitored and quantified via real-time PCR in microcosm (Ascher et al., 2009) and *in field* experiments (Ceccherini et al., 2009a).

The extracellular DNA in soil

The release of DNA in soil is still poorly known and, for this reason, it is interesting to briefly discuss on what is known on the release of DNA from bacteria, fungal cells, and plant cells in soil. Conditions causing cell death are important for the release of DNA molecules; in prokaryotic and eukaryotic cells, the release can occur by physical

DNA in Soils: Mobility by Capillarity, Figure 1 Some different forms of soil water.

or spontaneous damage of the cell, by pathogen-induced cell lysis and necrosis or by active extrusion (Levy-Booth et al., 2007). Many genera of environmental bacteria, such as *Acinetobacter*, *Bacillus*, *Micrococcus*, release DNA during growth in liquid media (Lorenz and Wackernagel, 1994; Paget and Simonet, 1994), and this release can be stimulated by the presence of other organisms (Matsui et al., 2003). Here some examples are reported to give concise information to the readers. During biofilm formation by *Pseudomonas aeruginosa*, active DNA extrusion involved acylated homoserine lactone signaling molecules and was inhibited by halogenated furanone (HF). The DNA extrusion can also occur by membrane vesicle lysis, a process regulated by quorum sensing (Allesen-Holm et al., 2006). The breaking of bacterial cell walls and membranes can also occur by autolysis with release of DNA and RNA (Nishimura et al., 2003).

The release of DNA from fungal cells has been less investigated than that from bacterial cells despite 70% of the DNA in soil being of fungal origin (Borneman and Hartin, 2000).

Several studies have investigated the persistence of plant DNA in the terrestrial environments (Widmer et al., 1996; Lynch et al., 2004) but the release of DNA from plant roots and plant debris is still poorly understood. This release can occur after autolysis and decomposition of wilting tissues, by mechanical disruption of tissues or by enzymatic degradation of cell structures by plant pathogens. It is well known that chlorophyll, proteins, and RNA molecules are enzymatically degraded during leaf senescence (Green, 1994), and this probably also occurs for the DNA molecules.

Only few reports have studied the release of DNA from plastids or mitochondria. Probably, their DNA is more protected than the chromosomal one against degradation by cytoplasmic nuclelease activity, due to the presence of the organellar membranes (Nielsen et al., 2006). However, some authors (Ceccherini et al., 2003) reported a 98% loss of a chloroplast *aadA* gene in ground tobacco leaf material after 72 h as compared to a 56% loss of total DNA. Finally, during the decomposition of dead cells and tissues, conditions such as rapid desiccation, low temperatures, high salt concentrations, or low pH values, can affect the activity of the endoenzymes, increasing the persistence of both cells or tissues and their DNA (Hofreiter et al., 2001).

However, DNA released into the soil environment, both after cell death and by active extrusion, rarely is present as a pure molecule. Generally the DNA is released in the extracellular environment together with proteins, glucides, lipids, which could be considered as constitutional organic components (COC), and with RNA and cellular wall debris (CWD); this kind of DNA was termed “dirty eDNA” (Tamayo et al., 1999; Pietramellara et al., 2007).

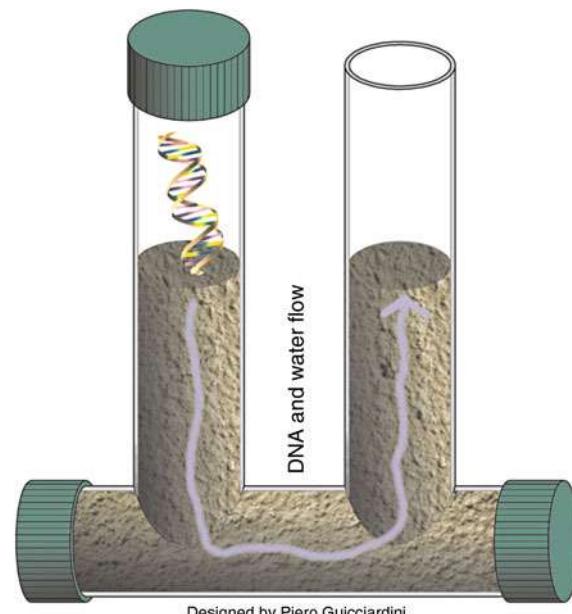

The capillarity

Soil capillaries are characterized by a rapid transport of water and solutes through the soil. These flows occur in macropores such as root and earthworm channels, mouse burrows, fissures, and cracks. Through preferential flow, there is transport of dissolved organic matter, like extracellular DNA, following vertical advection movements, and this soil area shows higher microbial biomass than the soil matrix, with an enhanced turnover of soil organic matter and nutrients (DiCarlo et al., 1999). A significant aspect of the majority of the studies on soil ecology is the lack of a dynamic soil system with water movement. Therefore, information on the transport of eDNA and on its potential transforming ability in subsurface soil is lacking. Moreover, plants get most of their water from capillary water retained in soil pores after gravitational water has drained and surface tension (suction) holds capillary water around the soil particles. As water is removed by plants or by evaporation from the soil surface, the films of water remaining around the soil particles become thinner and are held by the soil particles more tightly. This underlines the interest of some authors to monitor the movements and thus the fate of eDNA, using simulating or natural soil systems.

One of this kind of studies, addressing the possibility that DNA could move vertically in the capillary fringe, monitored the 35S-*nptII* sequence by PCR. DNA was added as a water solution at the bottom of the unsaturated soil column. After the addition, capillary water rose 4 cm within the soil column and the target DNA was detected up to that height. After a second wetting (12 h later), the target sequence was detected up to the top of the soil column (10 cm). However, after a third wetting

(24 h later), the marker sequence was only found at heights from 0.5 cm to 4 cm. Results clearly showed the vertical movement of DNA due the capillary rise and suggested the possibility of DNA degradation within the soil column (Ceccherini et al., 2007). Moreover, using simulating systems, the movements of a target sequence, belonging to *bt-maize MON810*, were quantified via real-time PCR. The genomic DNA was added at the top of unsaturated soil columns (Figure 2). The presence of the sequence in the eDNA fraction extracted from representative parts of the soil columns, demonstrated the DNA drifts in vertical and horizontal directions following the water solution motions. The high yields of the target sequence quantified in the eDNA also pointed out the efficiency of the eDNA extraction method (Ascher et al., 2009).

To complete this brief description, it is interesting to report some studies about solute movements by the gravitational pathway in soil. In a first case, unsaturated soil columns were used to examine the release and transport of DNA content of a tomato leaf, which was introduced into a column system after being dried at 35°C for 3 days. DNA from column leachate water was extracted and analyzed and tomato sequences detected by specific PCR amplification. Analysis using agarose gel electrophoresis showed degradation of DNA after its passage through unsaturated soil columns. The presence of tomato genes in the leachate water suggested a potential release of DNA from leaves and a potential transport of DNA over considerable distances in water-unsaturated soil. Consequently, transport of plant DNA in the vadose zone is

DNA in Soils: Mobility by Capillarity, Figure 2 Representation of a column system used to show the vertical and horizontal fluxes of a DNA solution in soil.

indicated, and also the risk that the DNA may reach the groundwater (Poté et al., 2007). In a second case, the study addressed the possibility that a target sequence of transgenic *bt*-maize could be detected *in field* where the crop was growing. The rhizosphere eDNA was extracted at different times, representative of maize growing stages and the target sequence was quantified via real-time PCR. This molecular approach revealed to be suitable for specific detection of target DNA, supporting the persistence of DNA *in field* (Ceccherini et al., 2009a).

Conclusions

The importance of natural transformation in evolutionary terms represents a valid reason to improve the investigation on the fate of extracellular DNA in soil. Several authors have demonstrated that there is a sharp discrepancy between its biological efficiency and its persistence; fragments of target DNA were detected after a long time in soil but no transformations were determined, probably because the genetic information originally present in the complete DNA molecule could be lost by degradation. Availability of water in soil is an important factor driving microbial activity. In bulk soil, bacterial cells occur mainly adsorbed to surfaces, refractory to movement, interacting only with partners in their immediate vicinity, unless they are transported by the soil water solution. Thus, water flow by capillarity induced by plant uptake and evaporation from soil surface, enhancing microbial and eDNA movements, can promote cellular activities with possibilities of horizontal gene transfer.

DROUGHT STRESS, EFFECT ON SOIL MECHANICAL IMPEDANCE AND ROOT (CROP) GROWTH

W. R. Whalley, L. J. Clark
 Department of Soil Science, Rothamsted Research,
 Harpenden, West Common, Hertfordshire, UK

Definition and introduction

While there is no doubt that limited water availability decreases root growth, it is often assumed that this is the main cause of decreased growth in drying soil. However, this may not always be the case. Many laboratory experiments on water stress use growth media where the mechanical impedance remains low and constant as its matric potential becomes more negative. For example, roots are often grown in vermiculite, where water content is adjusted to give a required matric potential, or in solutions such as PEG that are adjusted to a required osmotic potential (Whalley et al., 2000). However, as the water potential of the root environment becomes more negative, not only does the elongation rate decrease but also the pressure that roots are able to exert on their surroundings (Whalley et al., 1998). While this effect on root growth pressure may not be relevant to elongation through media with negligible impedance, it is relevant to elongation through strong soil. In fact, root growth pressure is far more sensitive than the rate of elongation (through low-impedance media) to water potential. As the matric potential of most soils becomes more negative, its strength increases greatly. There are relatively few studies that consider both soil strength and water potential, but those that do conclude that soil strength has a greater effect on root growth and penetration than soil water potential (e.g., Mirreh and Ketcheson, 1973; Yapa et al., 1988; Whalley et al., 1999). A difficulty of such experiments is that it is difficult to control soil water status and mechanical impedance independently (Whalley et al., 2000). To fully understand the effects of high soil strength on root elongation,

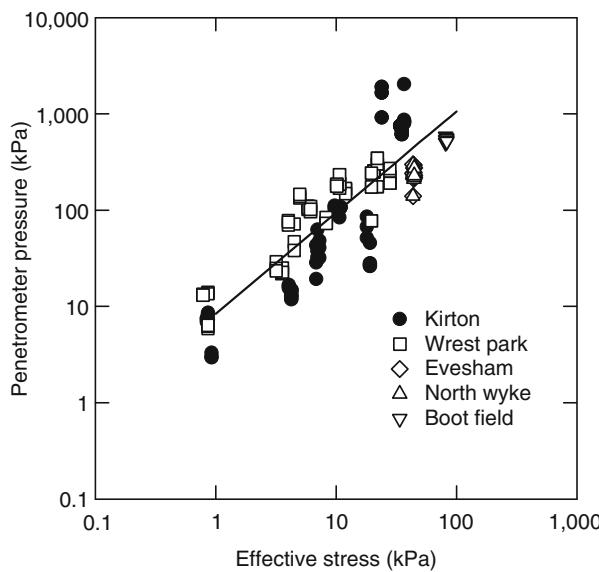

the relationship between soil water status and soil strength must be understood.

Soil strength and soil water status

For loose soil, with a bulk density less than about 1.4 g cm^{-3} , effective stress (product of degree of saturation and matric potential) gives a common relationship between penetrometer pressure and soil water status for a wide range of soils (Figure 1). Soil strength increases rapidly with soil drying, and even relatively wet soils are found to be strong even though they had not been compacted. In denser soils, however, empirical models that predict penetrometer resistance depend on soil type (e.g., Hernanz et al., 2000). Although good models to predict the penetration resistance of soil exist (Farrell and Greacen, 1966), in practice they are difficult to use because they need such extensive soil characterization. The following pedotransfer function to predict soil penetrometer resistance, Q , from soil density, ρ , degree of saturation, S , and matric potential Ψ

$$\log_{10}Q = 0.35\log_{10}(|\Psi S|) + 0.93\rho + 1.26 \quad (1)$$

was developed for a large number of Canadian soils (Whalley et al., 2007). This has the advantage that details of particle size distribution and organic matter content are not needed and data from moisture sensors can be used to predict penetrometer resistance, provided bulk density is known. An anomalous prediction of Equation 1 is that, as soil becomes increasingly dry and S approaches zero, the soil is predicted to become weaker, decreasing from

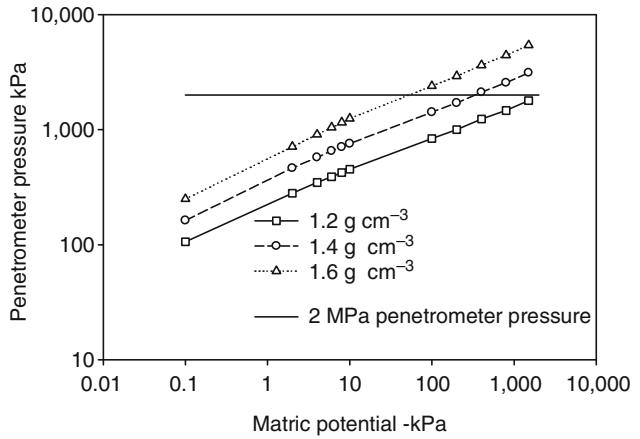

Drought Stress, Effect on Soil Mechanical Impedance and Root (Crop) Growth, Figure 1 Resistance to a rotating penetrometer plotted against effective stress for five different soils. (From Whalley et al., 2005). Resistance to a rotating penetrometer is considered to be a good approximation to the resistance to root penetration.

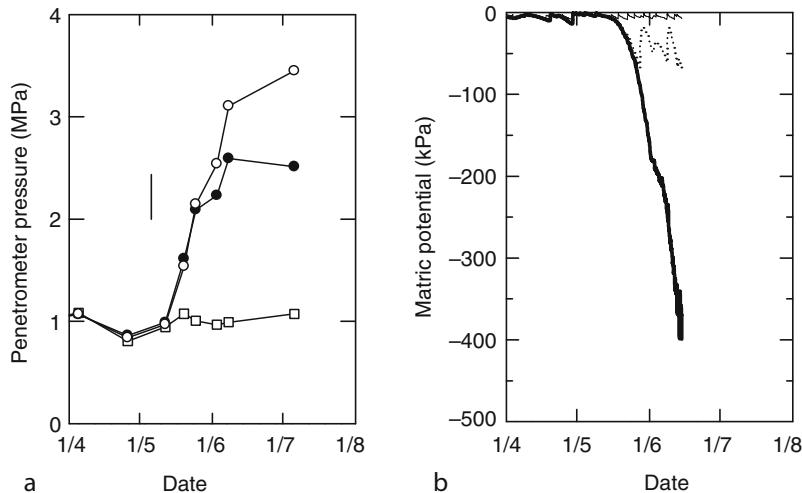

a maximum. For sand-kaolinite mixtures, this has been shown to be the case (Mullins and Panayiotopoulos, 1984) and beach sand also behaves in a similar manner. However, in agricultural soils strength does not decrease from the maximum, probably because of cementation by biological exudates and mineral precipitation as soil dries. Since Equation 1 was fitted to data from agricultural soils for $\Psi > -1.5 \text{ MPa}$, this anomalous behavior has been taken into account empirically. One of the implications of Equation 1 is that when soil is dense, high penetrometer pressures will be reached in much wetter soils than is the case for loose soil (Figure 2). Field data from Whalley et al. (2006) confirms that in the field, high soil strength occurs in relatively well-watered environments (see Figure 3). Penetrometer pressures in excess of 2 MPa were found in soil maintained at matric potentials of approximately -80 kPa .

Root elongation rate and soil strength

Penetrometer pressures between 2 and 3 MPa are commonly cited as a threshold to root elongation. However, root elongation rate decreases approximately linearly as soil strength increases (Bengough and Mullins, 1991). There has been a considerable research effort directed at understanding the elongation rate of roots growing in soils of various strengths. A seminal paper is that of Greacen and Oh (1972), who set out how the difference in pressure due to soil strength and cell turgor was accommodated by the cell wall. This model is appealing in its simplicity, but unfortunately it is inconsistent with physiological measurements. Passioura and Fry (1992) proposed a solution to allow ephemeral changes to elongation rate, due to set increases in turgor, as observed experimentally in algal

Drought Stress, Effect on Soil Mechanical Impedance and Root (Crop) Growth, Figure 2 Relationships between penetrometer pressure and matric potential calculated with Equation 1 using water release characteristic data for a silt soil. The horizontal line indicates a penetrometer resistance that is becoming too high for root elongation. As a dense soil dries, this penetrometer resistance is reached at a much higher value (i.e., in a wetter soil) in comparison with the loose soil. (Redrawn from Whitmore and Whalley, 2009.)

Drought Stress, Effect on Soil Mechanical Impedance and Root (Crop) Growth, Figure 3 The mean penetrometer resistance at a depth of 20 cm (a), the matric potential at a depth of 20 cm plotted against time (b) due to soil drying by wheat. The effects of three treatments are shown. These were well watered (open squares on the left panel and faint black line in right panel), drying limited to -80 kPa (closed circles on the left panel and dotted line in right panel), and finally rain fed (open circles on the left panel and heavy black line in right panel). The vertical line on the panel (a) is the SED (standard error for the difference). Note that when soil dries to -80 kPa, the penetrometer resistance exceeds 2 MPa. (Redrawn from Whalley et al., 2006.)

cells. To our knowledge this model has never been applied to root elongation which is probably because too much detailed information on cell-wall stiffening as a response to external stresses is needed.

Root penetration at boundaries

Roots can grow into rigid pores smaller than their nominal diameter (Bengough et al., 1997; Scholefield and Hall, 1985). In ryegrass, Scholefield and Hall (1985) found that this ability was limited by the size of the root cap and the stele, but Bengough et al. (1997) reported that the stele of maize roots did narrow in response to radial constriction. In soil, roots will often exploit cracks, voids, and large pores, or enlarge smaller pores by displacing soil particles. On encountering strong soil, root cell division and elongation are decreased (Eavis, 1967). Root diameter just behind the apex increases, and the production of lateral roots can be increased and also commences closer to the apex (Atwell, 1988). The increase in root diameter in response to impedance is caused by cortical cells enlarging radially rather than axially, with a corresponding change in the orientation of the cellulose microfibrils in the cell walls (Veen, 1982).

Thicker dicot roots have been observed to penetrate compacted subsoil in the field better than thinner monocot roots (Materechera et al., 1991, 1992). In both pea and lupin, 59% of the roots that reached the compacted layer were able to penetrate it, whereas in wheat and barley the root penetration was only 33% and 36%, respectively. The same authors found that species with thicker roots had better penetration of the subsoil, and particularly that the extent of thickening in the high-impedance treatment

Drought Stress, Effect on Soil Mechanical Impedance and Root (Crop) Growth, Table 1 Bending stiffness of roots of Azucena and Bala which had been grown either in strong (Impeded) or in weak (control) sand. The data was Log transformed before REML (analysis using the method of residual maximum likelihood) and the SED (standard error for the difference) is 0.1359. The back transformed bending stiffness in N mm $^{-1}$ is shown in brackets. (Taken from Clark et al., 2008a.)

	Control roots	Impeded roots
Azucena	-1.606 (0.2000)	-1.765 (0.1712)
Bala	-2.698 (0.0673)	-3.607 (0.0271)

relative to the control was important. It was also suggested that thicker roots gave better penetration because they would be more resistant to buckling (Barley and Greacen, 1967). In rice, genetic variability in root penetration into strong layers has been associated with genetic control of root diameter (Clark et al., 2008a). Although, greater bending stiffness in rice was associated with better penetration of strong layers, Clark et al. (2008a) noted that the process of penetration of a strong soil reduced bending stiffness (Table 1). This was thought to be due to cell-wall relaxation, which is implicated in the development of growth pressure (Clark et al., 1996).

An important observation by Clark et al. (2008b) is that the penetration of roots into a strong layer can be increased if there is a spatial gradient in soil strength. When there was a spatial gradient in strength, the penetration ability of Bala (a poor performing rice line) to penetrate a wax layer was similar to the better-performing Azucena in the absence spatial gradient in soil strength.

Summary

The most important message to take is that increases in soil strength sufficiently large to impede root elongation can occur after only a moderate degree of soil drying. In Figure 3, it can be seen that at matric potentials of around -80 kPa, which would normally be considered well watered for field-grown crops, penetrometer pressures in excess of 2 MPa were recorded. In such conditions root elongation is limited by high soil strength and not by the lack of water availability.

DRYING OF AGRICULTURAL PRODUCTS

Digvir S. Jayas, Chandra B. Singh
 Department of Biosystems Engineering, University of Manitoba, Winnipeg, MB, Canada

Definition

Drying is the process of the removal of water (moisture) from hygroscopic materials at low to medium moisture contents (normally $<30\%$ wet basis) by means of evaporation. When the moisture content of the agricultural products is high (usually $>50\%$ wet basis) the process of

removal of moisture is referred to as dehydration. The examples of the products that are dried include cereals, oilseeds, legumes, and some processed foods; and examples of the products that are dehydrated include fruits, meats, and vegetables (Pabis et al., 1998; Sokhansanj and Jayas, 2006).

Process

Drying/dehydration is one of the most important postharvest treatments being adopted worldwide to reduce the spoilage and increase the shelf life or storage durability of agricultural products. Removal of moisture is a complex simultaneous heat and mass transfer process but treating it as such is not sufficient because end use characteristics or quality of the product cannot be handled this way. Moisture from inside the hygroscopic materials moves to the surface and then it evaporates to the surrounding atmosphere. This movement in moisture is caused by the gradient of water vapor pressure being high inside the materials to being low outside the materials. The movement of moisture could be by liquid diffusion, vapor diffusion, capillary flow, or a combination of these features. Usually the moisture gradient is established by application of heat from external sources. The process can be done at atmospheric pressures but can also be done under vacuum, and similarly the process can be done at a range of temperatures. The selection of the process temperature and pressure depends on the end use quality of the dried/dehydrated products. Heat is transferred to the product by a heating medium usually hot air or superheated steam, this heating medium also carries the moisture away from the product. Sometimes heat can be applied by contact such as by mixing hot sand with granular material or by coating a liquid product on a rotating drum whereas at other times heat could be applied through radiation, for example, in infrared dryers or through volumetric heating, for example, in microwave dryers. Drying of products using solar radiation (sun drying) is the simplest and oldest form of drying; however, sun drying is weather dependent and is slow, therefore other sources of heat are used. Depending on the heat source, operating pressure, and operating mechanism, dryers are classified as hot air, infrared, microwave, vacuum, freeze, flash, superheated steam, spouted bed, fluidized bed, and spray. The dryers are also classified based on the relative flow of material and the heating medium as concurrent flow, counter flow, cross flow, or mixed flow.

Challenges in drying agricultural products

Most dehydrated products are rehydrated prior to consumption; therefore, the texture and taste of the product

after rehydration are important quality parameters. Since agricultural products are sensitive to the heat (temperature), improper drying may cause the thermal damage to the product and the product may be spoiled or quality of end product may be poor. Under-drying will reduce the shelf life and over-drying will result in loss of mass, more power consumption, and thus economical losses. Drying characteristics of various agricultural and biomaterials are different and are also influenced by growing region, growing season, and weather conditions; therefore, it becomes necessary to study drying characteristics of the specific product for design of proper and efficient dryers.

E

EARTHWORMS AS ECOSYSTEM ENGINEERS

Patrick Lavelle
IRD/UPMC Université Paris 6, CIAT, Cali, Colombia

Definition

Earthworms probably are the most common animals on Earth. Appeared some 10 M years ago, they have coevolved with their environment and developed intimate mutualistic relationships with microorganisms and other soil inhabitants through ecosystem engineering.

What does an earthworm life look like? Adaptive strategies

Organisms that live in soils have adapted to three major limitations: moving in a compact environment, respiring in a porous space that is alternatively filled of water or air, and feeding on generally poor quality resources.

Earthworms can move in the soil thanks to a hydrostatic skeleton that allows to concentrate strength at the fore part of the animal and drill into the soil compact structure, or pull soil particles and detach them from the soil matrix before ingesting them. Their gut is a simple elongated tube in which the greatest part of digestion is performed by ingested microflora in a rather elaborated digestion partnership.

Respiration is cutaneous, which requires a constantly humid skin. High molecular weight hemoglobin in blood allows earthworms to make use of low concentrations of oxygen in the environment.

Earthworms feed on and live in leaf litter (epigeic functional category), live in subvertical galleries and feed on a mixture of litter and soil (anecics), or live and feed in soil (endogeics).

Active soil and litter movers and conductors of most soil organisms activities, earthworms are both dominant biological and physical engineers.

The earthworm engine: what makes earthworms such powerful bioturbators?

How to find energy to move each day 1–20 times its own weight of soil. An energy balance on the razor edge

Microbial communities that are mostly dormant in soil are selectively activated in earthworm guts through the addition of intestinal mucus (6–40% of ingested soil dry weight) and water (1 v/v soil). Although little is known of which functions are activated, we know that this mostly concerns bacterial communities as opposed to fungal, and that most enzymatic activities developed in earthworm guts actually come from these activated bacteria. Especially remarkable, as regards soil function are the occurrence of N fixing bacteria, P and N mineralization, and occasional Ca excretion.

Mutualist relationships with microflora allow earthworms to assimilate large amounts of energy, estimated at 5–10% of the energetic value of digested litter and organic matter, a rather high proportion considering the relatively low quality of the food that is, in the case of soil organic matter, dispersed in a rather compact mineral matrix.

The very scarce examples of energy budget available for earthworms show a very large investment in mechanical activities. In case of the endogeic tropical earthworm *Reginaldia omodeoi* (formerly known as *Millsonia anomala*), they represent over 96% of assimilated energy and allow the worms to ingest and egest daily from 10 to 25 times their own weight of soil depending on the age and general soil conditions (moisture, temperature, and

organic matter content). At the scale of a population and landscape scale, several 100 t ha⁻¹ (up to 1,250 t in moist savannas of Ivory Coast) casts may be deposited each year, mainly concentrated in the 20 upper cm of soil.

The value of earthworm-made habitats for soil inhabitants

Earthworms build three kinds of biogenic structures: galleries, middens, and casts.

Galleries may represent rather extended and connected networks of tubular pores that develop mainly in the upper 20 cm of soil, although they may occasionally reach several meters in depth. Total length of galleries may reach 890 m m⁻², which represents a total volume of 9.2 l.

Middens are specific structures made by anecic earthworms when they collect litter close to the mouth of their gallery and favor its preliminary decomposition by micro-organisms (mainly bacteria) and smaller fauna before ingesting it.

Casts may be rather diverse in their shapes, sizes, and compositions depending on soil quality and the feeding regime of the worm.

They are in any case very special microsites in soils, with high organic contents resulting from selective ingestion of organic particles and high concentrations in mineral N (20 to >200 ppm NH₄⁺ depending on the initial soil N content) and P (2–43.3 µg g⁻¹).

Earthworm structures are thus suitable habitats for a wide range of microorganisms (mainly bacteria), micro- and meso-fauna that take advantage of the generally improved conditions, and shelter provided. Earthworms may, however, sometimes have adverse effects on some litter arthropods affected by surface litter removal. Nematodes communities, especially of plant parasitic nematodes, have also been reported to be depressed in the presence of earthworms. Several mechanisms seem to be involved, such as provoked hatching of larvae that further die trapped into compact cast structures, or destruction of chemo receptors by specific proteolytic enzymes produced by bacteria in the earthworm gut.

Earthworms and ecosystem services: the landscape scale

For their intense effects as biological engineers that shape and regulate activities of microorganisms and smaller invertebrates, and physical engineers that construct porosity and soil macro aggregation, earthworms have significant effects on the provision of ecosystem services by soils.

Earthworms and climate regulation: C sequestration and green house gasses

Earthworms participate in climate regulation effects of soil through C sequestration and green house gasses

emissions. The overall effect of earthworms is not yet fully understood, since they have highly contrasted effects depending on the scale of measurement: great enhancement of C mineralization and greenhouse gas (GHG) emissions at small scales of time and space (gut content and freshly deposited casts) followed by inhibition in the compact structure of casts where microbial activity is progressively reduced to zero. It seems that a key element to determine whether the long-term effect of earthworms on soil C sequestration is positive or negative is the life span of earthworm casts. Very scarce experimental work show that casts once stabilized by a drying cycle, may resist for very long periods of time (several years) unless they are broken down by other ecosystem engineers or natural physical processes.

Earthworms and water supply: infiltration, storage, and transfer

Bioturbation and tunneling effected by earthworms significantly influence soil hydraulic properties. The result is mostly an enhanced water infiltration and transfer toward deeper soil strata although the overall effect of an earthworm community may greatly depend on the relative proportion of functional groups with contrasted effects. The so-called compacting species accumulate in soil large amounts of compact casts that form the stable macro aggregates that provide soils with structural stability and favorable hydraulic properties. However, when alone, these worms rapidly compact the soil, and in extreme cases create an impermeable crust of coalescent casts that may have catastrophic effects on plant communities. De-compacting species are much smaller worms that may feed on casts of compacting species thus regulating their impact on soil hydraulic properties; an adequate balance between effects of both types seems to be necessary to maintain optimal hydraulic conditions in the upper centimeters of soil where earthworm activity is mainly concentrated.

Earthworms and primary production: the five processes

The most spectacular effect of earthworms is observed on plants. Five different mechanisms are known to alternate or add their effects to stimulate plant growth and vigor: (1) nutrient release in the plant rhizosphere, (2) stimulation of microbial mutualists (especially mycorrhizae), (3) organization of soil structure that improves water supply, (4) control of pests and diseases, and (5) pseudo hormonal effects with a stimulation of Plant Growth promoters in the rhizosphere. Although the relative contribution of each single process is not known in most cases, there is some evidence that pseudo hormonal effects may be a rather constant effect while nutrient release and pest control occasionally have determinant impacts.

Do earthworms benefit from their own activities?

Are earthworms accidental engineers or do the structures that they create represent an extension of their phenotype improving their adaptive value? Since earthworms from a given species do not reingest their own casts, they have been said to be accidental engineers. However, at a larger scale, there is some evidence that soils comprise mosaics of functional domains with different species of soil engineers, earthworms, roots, termites, or ants. Most engineers affect soil structure, the composition of communities of smaller organisms, and soil processes in different ways; there is some evidence that each such activity is limited in time and the mosaic represented by the physical domains of all these ecosystem engineers might represent the spatial consequence of a process of ecosystem succession at their respective scales of dm^2 to m^2 . If this is true, each species would be part of an auto organized system in which species engineering activities are part of an auto organized system that ultimately has positive feedback on their fitness. The community composed by the different ecosystem engineers as a whole may thus be considered having an extended phenotype strategy.

Earthworm management

Earthworms are rather sensitive to ecosystem changes associated with most land use strategies. They are especially vulnerable to tillage, pesticides, and bare soil conditions. In most cases, active communities may be maintained even in relatively intensive practices provided (1) soil is covered all the time and fertilizer inputs comprise a minimum proportion of organic elements; (2) tillage is limited at a minimum or simply avoided; and (3) if pesticides are to be used, their inotoxicity toward earthworms must have been demonstrated in field conditions.

ECOHYDROLOGY

Maciej Zalewski

International Institute of Polish Academy of Sciences,
 European Regional Centre for Ecohydrology under the
 auspices of UNESCO, Łódź, Poland
 Department of Applied Ecology, University of Łódź,
 Łódź, Poland

Definition

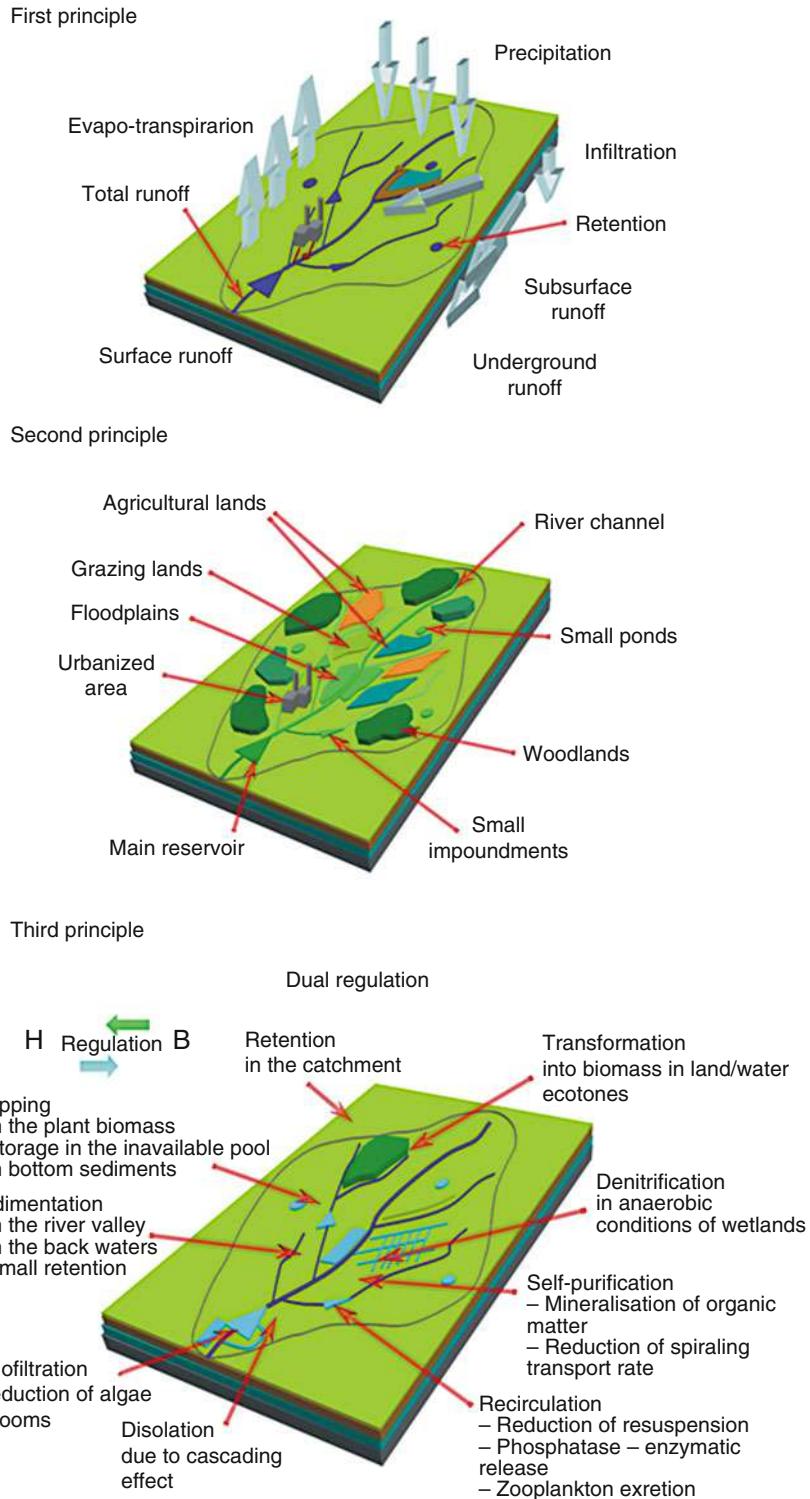

Ecohydrology (EH) a subdiscipline of hydrology that focuses on ecological processes occurring within the hydrological cycle and strives to utilize such processes for enhancing environmental sustainability. Has been developed under the International Hydrological Programme of UNESCO.

The general assumption of EH is to reverse degradation and achieve sustainable water and ecosystems in anthropogenically modified basins. In addition to the reduction of erosion, nutrients, and pollutant emissions there is a necessity to regulate ecological processes based on understanding “water – biota interactions,” from molecular (e.g., microbial loop) to ecosystem (biomanipulation) and to landscape scales (reforestation, creation land/water ecotone zones).

Two halves of ecohydrology can be distinguished: (1) Terrestrial (EHT), where the major question is how plant cover in given geomorphology and soil conditions changes the dynamic water balance and nutrients/pollutants transfer in to aquatic ecosystems and (2) Aquatic (EHA), where hydrology–biota interactions may change nutrients/pollutants allocation from dynamic to non-available pools, such as changing the intensity of eutrophication (up to an order of magnitude).

The following principles of EH provide a framework for its implementation ([Figure 1](#)):

1. Hydrological: The quantification of the hydrological cycle of a basin, should be the template for functional integration of hydrological and biological processes.
2. Ecological: Integrated processes at a river basin scale can be steered in such a way as to enhance the basin's carrying capacity (resilience, biodiversity, and ecosystem services).
3. Ecological engineering: The “key element of EH as a new tool for Integrated Water Resources Management (IWRM) is “dual regulation” – use of the understanding of terrestrial and aquatic organisms’ adaptation to water quality and dynamics. It can be expressed by testable hypotheses, as follows (1) Hydrological processes generally regulate biota; (2) Biota can be shaped as a tool to regulate hydrological processes; (3) These two types of regulations can be harmonized with hydrotechnical infrastructure to achieve sustainable water and ecosystem services.

Ecohydrology, Figure 1 Three ecological principles. Hydrological (upper), ecological (middle), and ecotechnological (lower).

Methodology of science – EH is integrative – a transdisciplinary, problem-solving science based upon the deductive concept, formulated from the general theory of physics, hydrology, and ecology. As a transdisciplinary science, the implicit goal of which is to achieve sustainability, EH integrates not only hydrology and ecology but also considers geophysics, geology, molecular biology, genetics, geo-information techniques, mathematical modeling with socioeconomic (e.g., foresight) and legal aspects.

EH goals as a problem-solving science

1. Slowing down the transfer of water from the atmosphere to the sea (considering flood and drought control as priorities)
2. Reduce input and regulate the allocation of excess nutrients and pollutants in aquatic ecosystems to improve water quality, biodiversity, and human health
3. Enhancement of ecosystem carrying capacity (resilience, biodiversity, ecosystem services for society) in harmonization with the societal needs within the framework of Integrated Water Resources Management (IWRM)

ECOSYSTEM

ELASTICITY

The property of a body to deform instantaneously under an applied stress and in proportion to it, to retain the new form as long as the stress is maintained, then to regain the original dimensions when the stress is released.

Bibliography

Introduction to Environmental Soil Physics (First Edition) 2003 Elsevier Inc. Daniel Hillel (ed.) <http://www.sciencedirect.com/science/book/9780123486554>

ELASTOPLASTICITY

State of a matter (e.g., soil, grains, fruits) subjected to a stress greater than its elastic limit but not so great as to cause it to rupture, in which it exhibits both elastic and plastic properties.

ELECTRICAL CONDUCTIVITY

The ability of a body (e.g., soil, grains, fruits) to conduct electricity.

ELECTRICAL DOUBLE LAYER (DIFFUSE LAYER, DOUBLE LAYER)

An idealized model to describe the electrical state of a surface, and commonly used to describe the physical behaviour of clay particles in soil. The clay surface and its surface charge constitute one layer, while aqueous solution in contact with the solid is a second (Stern) layer. The latter is held in place by counterions to the ions on the charged surface, the two together forming a kind of molecular capacitor. Ions further from the surface, and less strongly held, form a more diffuse (or Gouy) layer.

ELECTRICAL PROPERTIES OF AGRICULTURAL PRODUCTS

Zuzana Hlaváčová
 Department of Physics, Slovak University of Agriculture in Nitra, Nitra, Slovakia

Synonyms

Dielectric properties; Electric characteristics; Electrical properties

Definition

Electric properties – electric conductance, conductivity, electric resistance, resistivity, impedance, admittance, permittivity, relative permittivity, complex permittivity with the components – real part that is equal to permittivity and imaginary part characterizing dielectric losses in material, further we can mention dielectric loss angle, loss tangent, Maxwell relaxation constant.

Electric properties are the properties that characterize transport of charge carriers in the material or propagation of electromagnetic waves in material. Conductance – G (siemens – S) is an ability of the material to conduct the electric current. Four types of conduction can be mentioned. The charge carriers are electrons related to the electron conductance. Ions are charge carriers related to the ionic conductance. If the charge carriers are positively charged particles, it is called hole conductance (P-type), and in the case of macromolecules or particles aggregation it is electroforetic conductance.

Resistance – R (ohm – Ω) is the reciprocal value of the conductance. Conductivity – σ (S m^{-1}) is the conductance of material related to its proportions. Resistivity – ρ (Ωm) is reciprocal value of the conductivity. Impedance – Z (Ω) is material resistance at the alternate current. Admittance – Y (S) is reciprocal value of the impedance.

Introduction

It is necessary to consider the change of the electric conductivity type at transition of the electric current through the biological material. The inside of the cell has the ionic conductivity. The electric current in a cellular membrane (insulator) passes as displacement current. The density of the electric current i is defined as

$$i = \frac{1}{S} \frac{dQ}{d\tau} \quad (1)$$

where: Q – charge (coulomb – C), τ – time (s), S – surface (m^2).

The relationship between the density of the current and electric field intensity is

$$\vec{i} = \sigma \vec{E} = -\sigma \text{grad} U \quad (2)$$

where: σ – electric conductivity (S m^{-1}), $\text{grad } U$ – gradient of the electric voltage (V m^{-1}), \vec{E} – intensity of the electric field (V m^{-1}). This equation is also valid for electrolyte at low values of electric field intensity. Wien has shown in 1927 that some anomalies occur from the presented equation at intensity of 10^7 V m^{-1} .

Berliner (1973) declared that it is necessary to consider three components of direct electric current, when it is transiting through the material: conduction component, which is invariable in the time; absorption component i_a due to polarization effects and it can be described as follows

$$i_a = A\tau^{-k} \quad (3)$$

where: A – constant (amper – A), k – constant (1), and if the time τ is equal 0, then i_a is equal 0 too; and finally, the charging component i_n , which can be described as a flow passing through the capacitor with a capacity C by relation

$$i_n = \frac{U}{R} e^{-\frac{\tau}{RC}} \quad (4)$$

where: R – resistance of the circuit (Ω), U – source voltage (V). If the time τ is approaching to 0, charging component is approaching to ratio $\frac{U}{R}$. The line current decreases with the time and its value is approaching to the conduction component. Electric measurements by direct current are strongly influenced by the polarization effects at high moisture content of the material.

If the current passing through the material is unsteady, for the electric current density is valid

$$i = \sigma E + \frac{d(\varepsilon E)}{d\tau} \quad (5)$$

where: ε – permittivity of material (F m^{-1}) (*Dielectric Properties of Agricultural Products*). Complex value of current density is valid in the case of alternating electric field in the form

$$\hat{i} = (\sigma + j\omega \varepsilon) \hat{E} \quad (6)$$

where: \hat{E} – complex value of electric field intensity, j – imaginary unit (1), ω – angular frequency (s^{-1}).

Permittivity of moist material must be considered to be complex. It has a real part ε' and an imaginary part ε''

$$\hat{\varepsilon} = \varepsilon' - j\varepsilon'' = \varepsilon - j\frac{\sigma}{\omega} = \varepsilon (1 - j \operatorname{tg} \delta_\varepsilon) \quad (7)$$

where δ_ε is the loss angle (1) of the dielectric and

$$\operatorname{tg} \delta_\varepsilon = \frac{\sigma}{\omega \varepsilon} \quad (8)$$

where: $\operatorname{tg} \delta_\varepsilon$ – loss tangent (1).

ε'' is interpreted to include the energy losses in the dielectric arising from all dielectric relaxation mechanisms and ionic conduction. Materials, such as agricultural products and foods, generally show significant loss factors, and the dielectric properties are therefore dependent on both temperature and frequency, as well as the chemical and physical characteristics of the material including composition and density (Topp and Ferré, 2001).

Electric current passes as a displacement current in the nonconductors. Maxwell named the quantity

$$\vec{i} = \varepsilon \frac{\partial \vec{E}}{\partial \tau} \quad (9)$$

as the displacement current density. If the alternating currents are used at the measurements, then the Maxwell relaxation constant places an important role. It is defined by the equation

$$\tau_M = \frac{\varepsilon}{\sigma} \quad (10)$$

τ_M presents the time (s), after which the space charge density falls e -times in the material. Maxwell relaxation constant is the criterion of material return to equilibrium state, that is, to state without space charge. This time with values for conductor from 10^{-15} to 10^{-13} s and for non-conductors achieves up to 10^6 s (Hlaváčová, 2003).

Electrical properties of agricultural products

Electric properties of the agricultural products of biological origin have been of interest for many years. When studying the physical properties of tissue, it is necessary to consider its non-homogeneity from the macroscopic and microscopic points of view. When testing the electric properties from the microscopic point of view, it is evident that the inside of the cell is conductive because there is a conductivity of ion type in the content of the organic and inorganic matter solutions. The cell membranes are not conductors. From the macroscopic point of view, the agricultural products can be regarded as non-homogeneous semiconductors or dielectrics. The density and structural arrangement of the cells as well as the properties of each type of tissue can influence the electrical properties of these materials. The characteristics of loose and porous materials are also influenced by the properties of air, which is trapped between the parts or in the pores, especially by its relative humidity and temperature. The deployment of the parts in the pack, the size of parts, gappiness, contact surface, and bulk density also influence the electric properties of loose materials. Among the influential factors for porous materials, the following can be involved: size and distribution of pores, porosity, and bulk density. A further factor is the temperature of the material, but the most significant is the influence of the presence of water (see *Water in Forming Agricultural Products*), its uneven deployment in the material, different binding energy in each water bond in the material (see *Adsorption Energy of Water on Biological Materials*), and sorption properties (Hlaváčová, 2003).

The resistivity of some materials at temperature of 20°C is given in Table 1 (Physical properties of food – http://www.tf.uniag.sk/e_sources/katfyz/fvp/uvod.htm; Blahovec, 2008; See also *Physical Properties as Indicators of Food Quality*).

The influence of water presence in agricultural products on electric properties is shown for example on Figure 1.

The resistivity is decreased from value 10^8 to $10^4 \Omega\text{m}$. The dependency of agricultural products resistivity has the decreasing power function character whose regression equation is

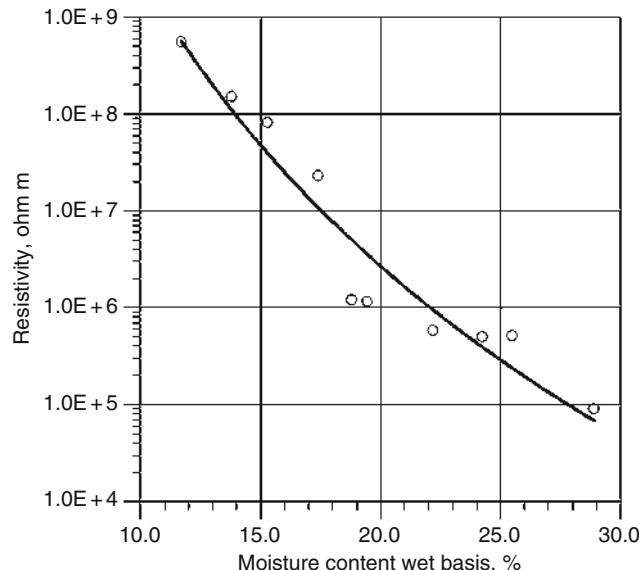

$$\rho = \rho_o \omega^{-d} \quad (11)$$

where ρ is resistivity, ρ_o is resistivity at the reference moisture content, ω – moisture content wet basis, and d a constant.

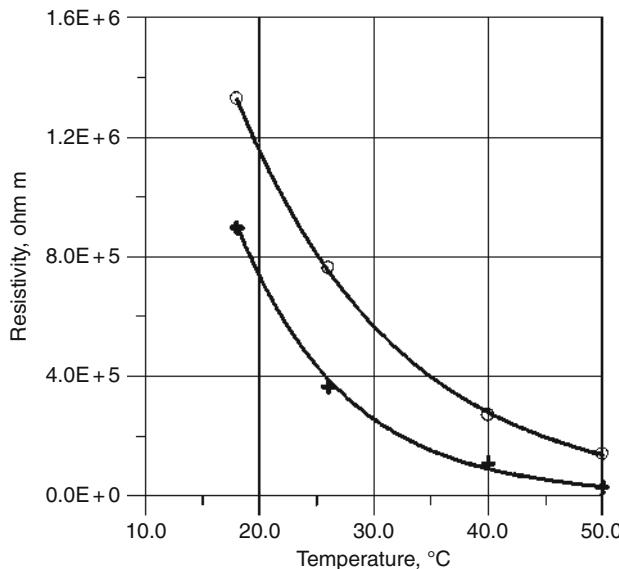

Electrical Properties of Agricultural Products, Table 1 Resistivity of some materials

Material	$\rho (\Omega\text{m})$
Gold	2.04×10^{-8}
Silver	1.505×10^{-8}
Copper	1.555×10^{-8}
Silicon	3×10^3
NaCl solution concentration $\leq 0.5 \text{ kg m}^{-3}$	13.3
Concentration (2–5) kg m^{-3}	1.33–3.33
Saturated solution	0.15
Milk, milk products	1.67–2.75
Sour milk	1.25–1.6
Beer	5.56–7.7
Juice	2.63–2.86
Syrups	16.7–25
Mineral water	1.25–7.7
Fresh fruit juice	2.5–5
Water	39
Tomatoes ($\omega = 95\%$)	35.7
Cucumbers ($\omega = 95\%$)	43.5
Potatoes ($\omega = 75\%$)	26.3–27
Root vegetables	24.4–66.7
Pears	37–71.4
Apples	17.9–26.3
Wheat ($\omega = 24\%$) ($\omega = 10\%$)	$\sim 10^4$ $\sim 10^8$
Butter	~ 12.5

ω – moisture content wet basis

Electrical Properties of Agricultural Products, Figure 1 The dependency of the resistivity on moisture content wet basis for *Amaranthus hypochondriacus* at an average bulk density of 760.4 kg m^{-3} (Hlaváčová, 2003).

Electrical Properties of Agricultural Products, Figure 2 The temperature dependencies of resistivity for corn (*Zea Mays*) grain hybrids of *Fabullis* (○) at the moisture content wet basis of 16.9% and of *Raissa* (+) at 17.34%.

On Figure 2, temperature dependencies of the resistivity of two hybrids of corn are presented to illustrate the influence of temperature on electric properties.

Information on the temperature distributions and electric properties dependency on temperature of a treated material are necessary in the case of thermal treatment (e.g., ohmic heating). We found out that the conductivity of seeds or grains increases and the resistivity decreases with temperature exponentially for all samples at all moisture contents (Hlaváčová, 2003). Displacement of the curves on Figure 2 can be caused by various properties of two hybrids.

The regression equation for resistivity has the form

$$\rho = \rho_o e^{-k\frac{t}{t_o}} \quad (12)$$

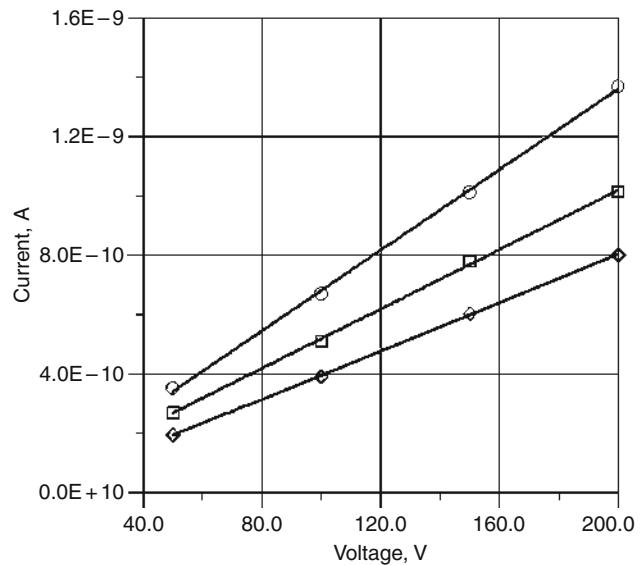

where: ρ_o – resistivity at the reference temperature, t – temperature, k – constant, $t_o = 1^\circ\text{C}$.

This equation is in a good relation with Arrhenius formula for the conductivity in the case of agricultural products

$$\sigma = \sigma_o e^{\frac{E_a}{kT}} \quad (13)$$

where: E_a – activation energy for conductivity, k – Boltzman constant, T – thermodynamic temperature.

Other influence on electric properties is shown on Figure 3. The measurements were made with variously treated seeds (rubbed, coated, and encrusted) of nine sugar beet cultivars (Hlaváčová, 2003). It was found that the electrical conductivity of seeds is affected by their surface treatment. The current passing through the pack of seeds

Electrical Properties of Agricultural Products, Figure 3 Voltage dependencies of the current passing through the sample of sugar beet (*Beta vulgaris L.*) seeds, cultivars *Intera* (rubbed seeds, ○), *Polina* (coated seeds, □) and *Remona* (encrusted seeds, ◇) at average moisture content of 9.39%.

was measured. The current increases linearly with the voltage (in the measured voltage range to 200 V). The current was highest when flowing through a sample of rubbed seeds and lowest when passing through a sample of encrusted seeds.

Average conductivity at the moisture content of 9.39% for cultivar *Remona* (encrusted seeds) was $1.741 \times 10^{-10} \text{ S m}^{-1}$, for cultivar *Polina* (coated seeds) $2.285 \times 10^{-10} \text{ S m}^{-1}$, and for *Intera* (rubbed seeds) $3.006 \times 10^{-10} \text{ S m}^{-1}$. It results that coating and encrusting of seeds decrease their conductivity. The mode of sugar beet seeds surface treatment could be estimated by the measurements of their electric properties.

Kuang and Nelson (1998) described low-frequency dielectric properties (see *Dielectric Properties of Agricultural Products*) of biological tissues, characterized by α - and β -dispersions. There are included ion activities, tissue microstructure, electrode polarization, which always cause problems at the measurement.

Electrical properties utilization

Electrical properties are utilized in many areas of human activities. They have the biggest application at moisture content measurements. The material investigation and moisture measuring using electromagnetic waves in wide spectrum serve for quality control and improvement in many branches like industry, forest and wood-working industry, civil engineering, agriculture, and commerce (Nelson, 2005).

Agricultural products properties are determined from their leachates too. Couto et al. (1998) utilized conductivity measurement of leachates for quantitative mechanical damage evaluation in soybeans. For example, Maezawa and Akimoto (1996) utilized electrical conductivity to determine the characteristics of low-temperature sensitive vegetables. Other types of electric properties utilization were collected in the paper of Kuang and Nelson (1998), as well as in the paper of Hlaváčová (2003). We can use electrical properties on microscopic levels, for instance for the cell turgor pressure determination. On the macroscopic level, electric properties are exploited at the determination of agricultural products' moisture content (seeds, grains, vegetables, cotton lint, etc.), at determination of seeds or grain deterioration, of seeds germination (see *Electromagnetic Fields, Impact on Seed Germination and Plant Growth*), of frost sensitivity or chilling and freezing tolerance, at determination of seeds vigor, of soybean seed coat lignin content, and for selection of seeds with high viability. The electrical measurements are utilized in many works to determine the properties of the fruit; the electrical conductivity of intact fruits was utilized for finding the relationship between the electrical parameters of the tissue and quality indices, including the probability of occurrence of sound, diseased, and damaged fruit for different storage periods (*Nondestructive Measurements in Fruits*). The electric conductivity or resistivity measurement can be used at the quality of food indication (*Physical Properties as Indicators of Food Quality*), for example, determination of chloride in milk or clinical mastitis detection, the inactivation of *Escherichia coli* in skim milk or meat by high intensity pulsed electric fields. Electrical heating is utilized for the food treatment, for instance the direct ohmic heating, sterilization, or pasteurization.

Electromagnetic heating, such as microwave and radiofrequency heating, is used in many processes such as reheating, precooking, tempering, baking, drying, together with pasteurization, and sterilization in industry and at home, as well as including electromagnetic heating processes related to dielectric properties (see *Dielectric Properties of Agricultural Products*) of the material. Since microwave heating is common in many food processes, determination of dielectric properties becomes significant to understand the heating profiles of foods in a microwave oven, and to develop equipment and microwaveable foods (Sahin and Sumnu, 2006).

Conclusions

Electric properties of the agricultural products are influenced by the internal structure and from the macroscopic point of view by the properties of air, which is trapped between the parts or in the pores in the case of loose and porous materials, most especially its relative humidity and temperature. The deployment of the parts

in the pack, the size of parts, gappiness, contact surface, and bulk density also influence the electrical properties of loose materials. Among the influential factors related to porous materials, the following can be involved: size and distribution of pores, porosity, and bulk density. A further factor is the temperature of the material, but the most significant is the influence of presence of water (see *Water in Forming Agricultural Products*), its uneven deployment in the material, different binding energy in each water bond in the material (see *Adsorption Energy of Water on Biological Materials*), and sorption properties. Electric properties are utilized in many areas of human activities. They have the biggest application at moisture content measurements.

Electric properties data on agricultural products and foods have been compiled for reference in several publications. However, these materials are so complex in their composition and in their electric behavior that it is necessary to measure the electric properties under the particular conditions of interest to obtain reliable data.

ELECTRICAL PROPERTIES OF SOILS

Shmulik P. Friedman

Environmental Physics and Irrigation, Institute of Soil, Water and Environmental Sciences, The Volcani Center, Agricultural Research Organization, Bet Dagan, Israel

Definitions and terminology

Electrical conductivity (σ) [$\text{Q}^2\text{T}^1\text{M}^{-1}\text{L}^{-3}$, Sm^{-1}] is defined as the ratio of the electrical current density (J) [$\text{QT}^{-1}\text{L}^{-2}$] to the electric field strength (E) [$\text{MLQ}^{-1}\text{T}^{-2}$]:

$$J = \sigma E \quad (1)$$

and describes a material's ability to conduct an electrical current. The *dielectric permittivity* (ϵ) [$\text{Q}^2\text{T}^2\text{M}^{-1}\text{L}^{-3}$, Fm^{-1}] is the ratio of the electrical flux density, D [QL^{-2}] (electrical displacement) to the electrical field strength:

$$D = \epsilon E \quad (2)$$

and as such it is a macroscopic measure of the ability of the medium to polarize in response to an applied electrical field. In other words, the permittivity relates to a material's ability to transmit (or "permit") an electrical field. In terms of a parallel-plate capacitor, the electrical flux density (D) relates to the total (true) charge density on its surfaces, to the electrical field (E), to the free charge density, and to the bound (neutralized by the medium's polarization) surface charge density that represents a new defined vector of the same physical dimensions as D named polarization (P) [QL^{-2}] (von Hippel, 1954). In vacuum, D and E are related through $D = \epsilon_0 E$, where ϵ_0 is the permittivity of vacuum, equal to $8.854 \times 10^{-12} \text{ F m}^{-1}$. In the general case, Equation 2 holds and the interrelation between the three field vectors is:

$$D = \epsilon E = \epsilon_0 E + P \quad (3)$$

The ratio, $P/\epsilon_0 E$, namely, the bound to free charge density ratio, is termed *dielectric susceptibility* ($\chi \equiv \epsilon/\epsilon_0 - 1$), and it can be alternatively used for relating the polarization (of an isotropic, linear dielectric material) to the electrical field: $P = \chi \epsilon_0 E$.

The conductive and capacitive properties of soils can be represented by either a *complex conductivity* (σ^*) (/its reciprocal *complex resistivity*, ρ^*) or a *complex permittivity* (ϵ^*), related through

$$\sigma^* = \frac{1}{\rho^*} = i2\pi f \epsilon^* \quad (4)$$

where f is the frequency and $i = \sqrt{-1}$. The complex conductivity is expressed by its *real* (σ') and *imaginary* (σ'') components:

$$\sigma^* = \sigma' + i\sigma'' \quad (5)$$

and the common terminology is to express the complex permittivity with two positive permittivity entities. The

real part (ϵ') represents energy storage and the imaginary part (ϵ'') represents energy dissipation, assumed to stem from two contributions: dielectric relaxation (ϵ_d'') and low-frequency ("direct current," DC) conductivity ($\sigma_{DC}/2\pi\epsilon_0 f$)

$$\epsilon^* = \epsilon' - i\epsilon''; \epsilon''(f) = \epsilon_d''(f) + \sigma_{DC}/2\pi\epsilon_0 f \quad (6)$$

The ratio between the dissipative and conservative permittivities is called the *loss tangent*: $\tan \delta = \epsilon''/\epsilon'$.

The *dielectric constant*, also termed *relative permittivity* (ϵ_r), is the ratio of the real permittivity of the material (ϵ') to the permittivity of vacuum (ϵ_0), and it is proportional to the imaginary component of the complex conductivity

$$\epsilon_r = \frac{\epsilon'}{\epsilon_0} = \frac{\sigma''}{2\pi f \epsilon_0} \quad (7)$$

In the following we will refer to only the dimensionless, real high-frequency relative permittivity (ϵ_r), denoting it as ϵ (omitting the r and ∞ subscripts and the ' r ' superscript), and to only the low-frequency real conductivity (σ_{DC}) denoting it as σ (omitting the DC subscript and the ' r ' superscript).

The *effective* (also termed *apparent* (σ_a) or *bulk* (σ_b)) *electrical conductivity* of the soil (σ_{eff} , Sm^{-1}) can be defined in more than one way: Torquato (2002, p. 359), for example, defines it as the relation between the volume-averaged electrical field ($\langle E \rangle$, Vm^{-1}) and the volume-averaged electrical current density ($\langle J \rangle$, Am^{-2})

$$\langle J \rangle = \sigma_{eff} \langle E \rangle \quad (8)$$

Here we will adopt a more general and practical approach to defining σ_{eff} (and similarly the *effective permittivity*, ϵ_{eff}): the conductivity (/permittivity) of a homogeneous, single-phase material that elicits the same response in a measuring device.

Introduction

Measurements of electrical properties of soils began at the end of nineteenth century (e.g., Briggs, 1899; Wenner, 1915; Smith-Rose, 1933; Archie, 1942). The low-frequency (Hz to kHz) electrical conductivities of soils (σ_{DC}) are in the range of $0.001\text{--}2 \text{ dSm}^{-1}$ and their high-frequency (MHz to GHz) dielectric constants (ϵ_∞) possess values of $3\text{--}50$. As such, soils can be classified as good conductors ($\sigma/(2\pi f\epsilon) >> 1$), inhibiting the propagation of electromagnetic (EM) waves at low frequencies (adequately described mathematically by the diffusion equation), and as low-loss dielectrics ($\sigma/(2\pi f\epsilon) << 1$) at high frequencies (where EM wave propagation is adequately described by the wave equation). The low-frequency (LF) electrical conductivity (σ_{DC}) and the high-frequency (HF) dielectric constant (ϵ_∞) are the more commonly measured and modelled electrical properties, as they serve for evaluating the soil water content and soil solution salinity. Thus, the scope of this entry is limited to the "static" (frequency-invariant) features of these two properties. The reader interested in the

frequency response (dispersion, relaxation) of the soil conductivity and permittivity is referred to other manuscripts (Dukhin, 1971; Santamarina et al., 2001). The following entries list the common methods for measuring the soil's LF σ_{eff} and HF ϵ_{eff} , discuss in brief their dependence on the various compositional, geometrical, and interfacial soil attributes, and review major empirical and physical models for describing σ_{eff} and ϵ_{eff} .

Electrical conductivity (EC)

Methods of measurement of low-frequency σ_{eff}

The three common methods for measuring the soil LF (Hz to kHz) electrical conductivity are: (1) Direct (contact) electrical resistivity, ER, based on injecting current through two electrodes and measuring the voltage drop in two other electrodes via four-probe arrays (Rhoades and van Schilfgaarde, 1976; Binley and Kemna, 2005); (2) Electromagnetic induction (EMI) based on inducing a magnetic field in the soil via a transmitter and measuring the secondary magnetic field via a receiver antenna (Everett and Meju, 2005); and (3) Time Domain Reflectometry (TDR) based on measuring the attenuation of an electromagnetic wave travelling through a waveguide inserted in the soil (Dalton et al., 1984; Robinson et al., 2003). ER operates at various modes, for example, shaft-mounted four-electrode inserted after pre-augering and surface arrays and between boreholes, and in a broad range of spatial scales from millimeters to kilometers, EMI devices usually measure to depths from 1 m to tens of meters and the TDR probes are usually about 10 cm long. The commonly used frequency range for the soil σ_{DC} determination in the field is about 100 Hz to several kHz, because at lower frequencies electrode polarization interferes with the readings and at higher frequencies (kilo- to megahertz) the EC is no longer constant at the DC value, but increases with frequency.

Soil attributes affecting σ_{eff} and its modelling

An unsaturated soil is considered to be a three-phase, solid–water–air system. The minerals constituting the solid phase of soils are nonconducting ($\sigma_s = 0$), as, of course, is the air ($\sigma_A = 0$), so that the only conducting phase is the aqueous solution, which has an intrinsic specific electrical conductivity of σ_W (Sm^{-1}). For these reasons, in certain circumstances, especially when σ_W can be reliably evaluated, measurements of the soil effective EC (σ_{eff}) can be used for evaluating volumetric water contents (θ) and, as a special, two-phase case, the porosity (n) of water-saturated soils.

The *major factors that affect σ_{eff}* can be grouped into three categories: Those in the first category describe the *bulk soil* and define the respective volumetric fractions occupied by the three phases and possible secondary structural configurations (aggregation): porosity (n), water content (θ), and structure. Factors in the second category are the important *solid particle* quantifiers, which are relatively time invariable: particle shape and orientation, particle-size

distribution, cation-exchange capacity, and wettability. Factors in the third category are the relevant *soil solution* attributes, and as these change quickly in response to alterations in management and environmental conditions, we may also call them *environmental* factors: ionic strength (σ_W), cation composition (SAR, Sodium Adsorption Ratio $\equiv (\text{Na}^+)/((\text{Ca}^{2+} + \text{Mg}^{2+})/2)^{1/2}$), and temperature. As stated above, the soil solution is the only conducting phase, which is why its volumetric fraction (n in a water-saturated soil and θ in unsaturated soils) and conductivity (σ_W) are the two dominant factors in determining σ_{eff} . Nevertheless, the geometry and topology of the aqueous phase is determined by the solid-phase attributes. Furthermore, the contribution of the adsorbed cations to the overall soil σ_{eff} , significant for medium- and fine-textured soils, is also determined mostly by the soil's cation-exchange capacity, which is a solid-phase attribute.

Archie's empirical law (Archie, 1942) is the most widely used relationship to relate σ_{eff} of water-saturated rocks and soils to their porosity (n) and solution EC (σ_W):

$$\sigma_{eff} = \frac{\sigma_W}{F} = \sigma_W n^m \quad (9)$$

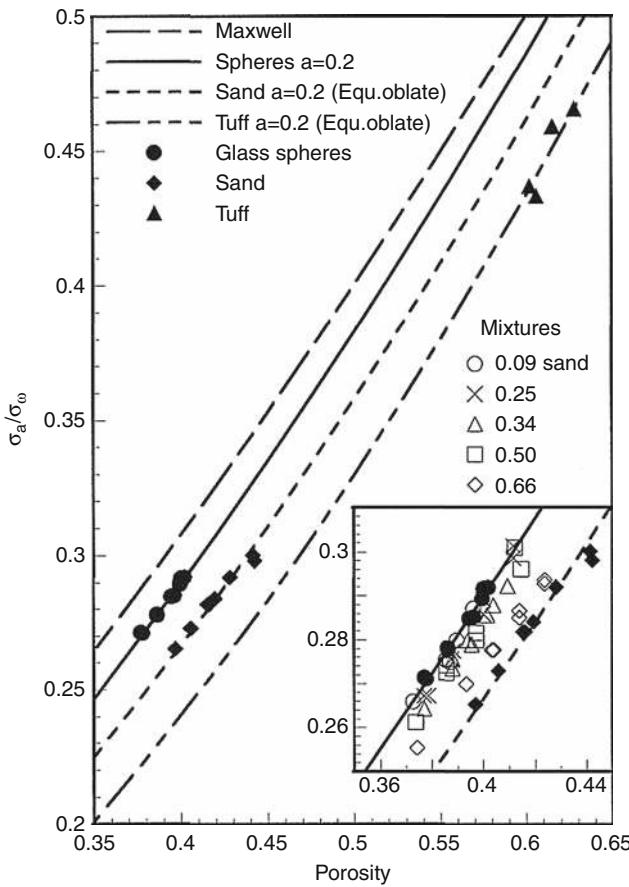

The electrical formation factor $F (= n^{-m})$ is an intrinsic measure of the microgeometry of the soil. Archie found that the exponent m ranged from 1.3 for unconsolidated sands to approximately 2.0 for consolidated sandstones, and a broader range from 1.2 to 4.4 for other granular materials is tabulated elsewhere (Lesmes and Friedman, 2005). As m increases with cementation, Archie termed it the cementation index. For granular, unconsolidated media such soils m increases as the grains become less spherical while variations in grain size and sorting has little effect on m (Jackson et al., 1978). For packings of mono-size glass spheres, sand particles, and tuff particles, characterized as oblate particles of aspect ratios of 1, 0.48, and 0.33, for example, the best-fitted m values were 1.35, 1.45, and 1.66 (Friedman and Robinson, 2002).

One possible constructive physical approach for describing the $\sigma_{eff}/\sigma_W(n)$ relationship of coarse-textured soils is to adopt *mean field theories* (also termed "mixing laws" or "mixing models") (Sihvola, 1999; Torquato, 2002; Wang and Pan, 2008). These theories deal with the actual three-dimensional structure of the multiphase medium or with its idealized geometrical description, referring to one phase as inclusions immersed in a host material representing the second phase. The universal expression of Sihvola and Kong (1988) for the effective conductivity (σ_{eff}) of spherical, nonconducting ($\sigma_s = 0$) particles, for example, is

$$\sigma_{eff} = \sigma_W + \left\{ \left[\frac{(n-1)\sigma_W [\sigma_W + v(\sigma_{eff} - \sigma_W)]}{\frac{2}{3}\sigma_W + v(\sigma_{eff} - \sigma_W)} \right] \cdot \left[1 - \frac{\frac{1}{3}(n-1)\sigma_W}{\frac{2}{3}\sigma_W + v(\sigma_{eff} - \sigma_W)} \right]^{-1} \right\} \quad (10)$$

which contains a heuristic parameter, v , that accepts values between 0 and 1 and accounts for the effect of neighboring particles on the internal electrical field of a reference particle. Best-fitting the heuristic mixing parameter v of [Equation 10](#) to the measured $\sigma_{\text{eff}}/\sigma_W(n)$ relationship for packings of glass spheres ([Figure 1](#)) resulted in $v = 0.2$ ([Friedman and Robinson, 2002](#)).

[Equation 10](#) applies to spherical particles, but the most important geometrical soil attribute with regard to its $\sigma_{\text{eff}}/\sigma_W(n)$ relationship is probably *particle shape*, which varies from almost spherical sand grains to flat, disklike and long, needlelike clay tactoids. It is practically impossible to calculate the effective conductivity of packings of angular and rough-surfaced particles, but these features were found to be of secondary importance in their effects on σ_{eff} ([Friedman and Robinson, 2002](#)). Representing the

Electrical Properties of Soils, Figure 1 Ratio of the effective (apparent) electrical conductivity (σ_{eff}) to that of the solution (σ_W) as a function of the porosity. Lines represent [Equation 28](#) with the value of $v = 0.2$ (denoted a in the legend) fitted to the glass spheres data. The main graph shows the glass spheres, sand (aspect ratio of $a/b = 0.46$), and tuff ($a/b = 0.35$) particles, where the aspect ratios have been adjusted to fit the data. The inset graph shows data for sand mixed in glass spheres ([From Friedman and Robinson \(2002\)](#). Reproduced by permission of the American Geophysical Union, Copyright (2002) AGU).

particle geometry as an ellipsoid of revolution (spheroid) provides both convenient analytical expressions and sufficient flexibility for transformation into a variety of shapes by altering the aspect ratio ([Sihvola and Kong, 1988](#); [Sareni et al., 1997](#); [Jones and Friedman, 2000](#)). By extending or contracting the b and c axes while keeping a constant, one can transform a sphere into either a disklike (oblate) or needle-shaped (prolate) particle, such as are often encountered in the natural environment. Particle shape is then incorporated in σ_{eff} modelling through a parameter named the depolarization factor (N^i), which describes the extent to which the inclusion polarization is reduced according to its shape and orientation with respect to the applied electrical field. For the special cases of ellipsoids of revolution ($a \neq b = c$), [Jones and Friedman \(2000\)](#) found that $N^a(a/b)$ can be satisfactorily approximated ($r^2 = 0.9999$) by a single empirical expression,

$$N^a = \frac{1}{1 + 1.6(a/b) + 0.4(a/b)^2}; \quad (11)$$

$$N^b = N^c = \frac{1}{2}(1 - N^a)$$

through the whole range of aspect ratios, a/b , from thin disks to long needles. The depolarization factors are: for a sphere, in which a , b , and c are all equal in length $N^{a,b,c} = 1/3, 1/3, 1/3$; for a thin disk (extreme oblate), 1, 0, 0, respectively; and for a long needle (extreme prolate), 0, $1/2$, $1/2$, respectively. The particle aspect ratio, a/b , of coarse-textured soils can be retrieved from databases, evaluated directly by visual inspection under magnification, or determined indirectly by the simple angle of repose measurement ([Friedman and Robinson, 2002](#)).

Nonspherical particles can form either *anisotropic* or *isotropic* packings, depending on whether they are preferentially aligned in the same direction or are randomly oriented. The effective conductivity of nonspherical particles, aligned to form a uniaxial–anisotropic medium, is no longer a scalar, but is a second-order tensor, defined by its diagonal components $\sigma_{\text{eff}}^a \neq \sigma_{\text{eff}}^b = \sigma_{\text{eff}}^c$ ([Sihvola and Kong, 1988](#)), and horizontal σ_{eff} (parallel to bedding planes) are usually larger than vertical σ_{eff} (perpendicular bedding planes) for both water-saturated and unsaturated media ([Friedman and Jones, 2001](#)). However, slightly nonspherical particles can be oriented almost randomly and form an approximately isotropic medium with a scalar σ_{eff} modelled as ([Sihvola and Kong, 1988](#)):

$$\sigma_{\text{eff}} = \sigma_W + \left\{ \left[\sum_{i=a,b,c} \frac{(n-1)[\sigma_W + v(\sigma_{\text{eff}} - \sigma_W)]\sigma_W}{3[\sigma_W + v(\sigma_{\text{eff}} - \sigma_W) - N^i \sigma_W]} \right] \cdot \left[1 - \sum_{i=a,b,c} \frac{(n-1)N^i \sigma_W}{3[\sigma_W + v(\sigma_{\text{eff}} - \sigma_W) - N^i \sigma_W]} \right]^{-1} \right\} \quad (12)$$

Friedman and Robinson (2002) measured the $\sigma_{eff}/\sigma_W(n)$ relationships of also packings of sand and tuff particles (and sand–glass spheres mixtures) (Figure 1). Keeping $v = 0.2$ (fitted for the spherical glass spheres), and adjusting the aspect ratios of the sand and tuff particles to provide a best fit to their $\sigma_{eff}/\sigma_W(n)$ measurements gave a/b values of 0.46 and 0.35 (oblate shaped: $a < b = c$), respectively, which are remarkably similar to those determined from the repose angle measurements (i.e., 0.48 and 0.33, and also to particle shape factors, $4\pi Area/Perimeter^2$, determined by image analysis of two-dimensional particle micrographs) and to those predicting the $\varepsilon_{eff}(n)$ relationships of these packings (Figure 5).

The effect of the soil's *particle-size distribution (PSD)* on its σ_{eff} is expected to be less pronounced than those of particle shape and orientation (similarly to its effect on ε_{eff} , discussed below), slightly decreasing the $\sigma_{eff}/\sigma_W(n)$ relationships as the width of the PSD increases (Robinson and Friedman, 2005).

Archie's (1942) law for describing the dependence of σ_{eff} of *unsaturated* soils and rocks on their saturation degree ($S \equiv \theta/n$) is

$$\sigma_{eff}(S) = \sigma_{sat} S^d \quad (13)$$

where σ_{sat} is the effective conductivity of the fully saturated soil. The saturation index (d) was observed to be about 2 for consolidated rocks and to range from 1.3 to 2 for unconsolidated sands (e.g., Schön, 1996). This power law was observed to hold down to saturations of about 0.15–0.20. At lower saturations, the power law breaks down, especially in fine-textured soils, as surface effects become dominant. In the absence of surface conductivity, the extended form of Archie's law can be used to predict the effective conductivity of partially saturated soils:

$$\sigma_{eff} = \sigma_W n^m S^d \quad (14)$$

The saturation index is usually larger than the cementation index ($d > m$), because as saturation decreases, the water films surrounding the grains become thinner and the conducting paths become more tortuous. Gorman and Kelly (1990), for example, obtained average best-fitted values of $m = 1.30$ and $d = 1.53$ for various Ottawa sand mixtures. Ament et al. (2000) assumed for simplicity that $m = d$ in Archie's model, and obtained an average, best-fitted exponent of $m = 1.58$ for sandy loam soils. The commonly used semiempirical model of Mualem and Friedman (1991) relating σ_{eff} to the soil pore-size distribution (as inferred from its water retention characteristics, $\psi(S_e)$, ψ (m) being the matric head), and a tortuosity factor, θ^λ

$$\sigma_{eff}/\sigma_W = \theta^\lambda \left[\int_0^{S_e} \frac{dS_e}{\psi} \right]^2 / \int_0^{S_e} \frac{dS_e}{\psi^2} \quad (15)$$

predicts that $m = 1 + \lambda$ and $d = 2 + \lambda$, where λ is a tortuosity exponent that for coarse-textured soils can be taken as 0.5,

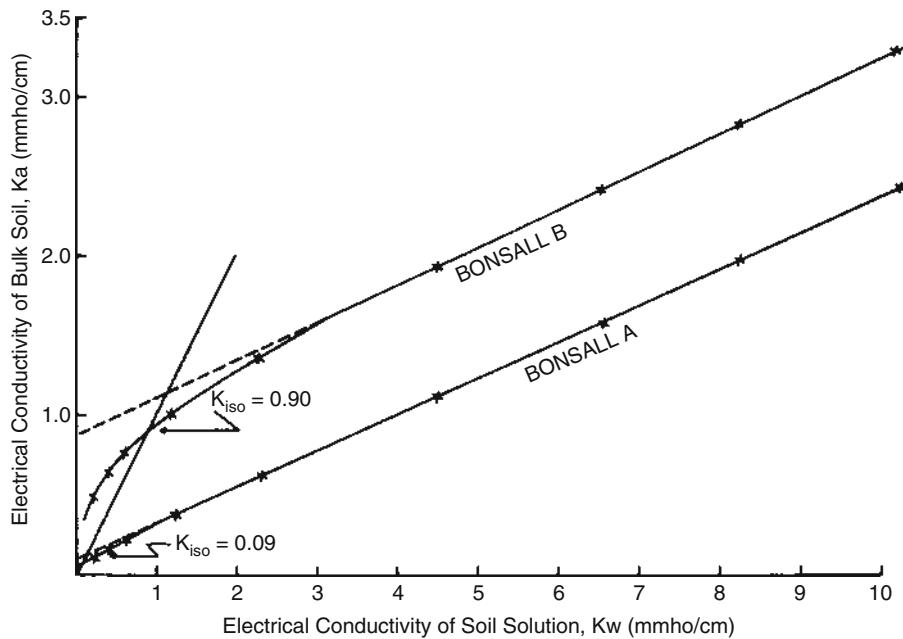

making $m = 1.5$ and $d = 2.5$. In general, λ can be best-fitted to the $\sigma_{eff}/\sigma_W(\theta)$ and $\psi(S_e)$ measurements (Weerts et al., 1999). Mualem and Friedman's (1991) model does not refer to the whole liquid phase volume but subtracts from both n and θ a noncontributing volume (θ_0) close to the solid surfaces, which they proposed to estimate as the water content at wilting point (matric pressure of -1.5 MPa) that correlates well with the specific surface area and clay fraction of the soil. The effective degree of saturation in Equation 15 is then defined as $S_e \equiv (\theta - \theta_0)/(n - \theta_0)$. Equation 15 can also be written as $\sigma_{eff}/\sigma_W = \theta^{2+\lambda}/n$, and Persson (1997), for example, best-fitted a λ value of about 0.2 to $\sigma_{eff}/\sigma_W(\theta)$ measurements in a sand ($n = 0.38$), homogeneously packed into short ($\lambda = 0.25$) or long ($\lambda = 0.16$) columns. An earlier attempt to relate the $\sigma_{eff}/\sigma_W(\theta)$ relationship to the soil's pore-size distribution was made by Nadler (1982) who noticed that the formation factor–water content function, $F(\theta)$, resembles the shape of the soil water retention curve, $\psi(\theta)$. Therefore, he suggested the use of an expression of the form $F(\theta) = a\psi$ in which a is an empirically determined proportionality constant for the relatively dry region, while for the relatively wet region he suggested using Burger's (1919) two-phase mixing law, arbitrarily extended to an unsaturated soil: $F(\theta) = 1 + k(1-\theta)/(\theta)$ in which k is an empirically determined, S -independent particle shape factor.

In fine-grained soils or in nonsaline (low σ_W) conditions, the *contribution of adsorbed ions (surface conduction)* to σ_{eff} can be significant and the $\sigma_{eff}(\sigma_W)$ relationship is nonlinear (Figure 3). The most frequently applied simplifying assumption is that σ_{eff} can be regarded as being replaced by two conductors in parallel, one representing the free-solution ions (σ_W/F) and the other the adsorbed ones ($\sigma_{surface}$) (Waxman and Smits, 1968; Rhoades et al., 1976; Shainberg et al., 1980; Nadler, 1982; Mualem and Friedman, 1991):

$$\sigma_{eff} = \frac{\sigma_W}{F} + \sigma_{surface} \quad (16)$$

The solution and surface conduction mechanisms do not strictly act in parallel in the macroscopic, soil sample scale, but only in the single-pore scale.

The decoupling assumption embedded in Equation 16 is thus physically inappropriate for application to a locally heterogeneous medium and its use can lead to a significant overestimation of σ_W/F , especially for media of high cation-exchange capacity, broad pore-size distribution, and low connectivity (Friedman, 1998b). Yet, this simple parallel-conduction model has several practical advantages. One major advantage is that F and $\sigma_{surface}$ (if assumed to be σ_W -independent) can be easily estimated by plotting on a linear scale σ_{eff} versus σ_W (Figure 2). The formation factor can be then estimated from the slope of the linear portion of the $\sigma_{eff}(\sigma_W)$ plot at high σ_W , and the σ_W -independent assumed $\sigma_{surface}$ (for high enough σ_W ; e.g., $\sigma_W > 4$ dSm $^{-1}$ in Figure 2) can be estimated from the extrapolated y -intercept at $\sigma_W = 0$. At relatively saline solutions, both $\sigma_{eff}(\sigma_W)$ functions are linear with similar

Electrical Properties of Soils, Figure 2 The effective electrical conductivity, σ_{eff} (denoted here K_a) of water-saturated Bonsall soil from the A and B horizons as a function of the electrical conductivity of the soil solution, σ_w (denoted here K_w). K_{iso} is the isoconductivity point where $\sigma_{eff} = \sigma_w$ (From Shainberg et al., 1980. Reproduced by permission of the Soil Science Society of America).

slopes (0.225 and 0.235 for the A and B horizons, respectively) regardless of the different clay percentage of the two soil horizons. At low σ_w , the two $\sigma_{eff}(\sigma_w)$ relationships are nonlinear, especially that of the clayey B horizon (35% clay versus 8% of the A horizon). Shainberg et al. (1980) studied the effects of CEC (*cation-exchange capacity*) and ESP (*exchangeable sodium percentage*) in conditions of nonlinear $\sigma_{eff}(\sigma_w)$ relationships and found that the contribution of the surface conductance to σ_{eff} (as indicated by the intercept of the tangent line at $\sigma_w=0$) increases with increasing CEC (/clay content). Although less conclusive, the surface conductivity was also found to increase with the ESP (or corresponding SAR) levels, probably because of the higher electrical mobility of the adsorbed sodium ions as compared to calcium. Based on other studies, Rhoades et al. (1999) concluded that the $\sigma_{eff}(\sigma_w)$ relationship does not depend on the soil ESP(SAR), provided soil structure and porosity have not been seriously degraded by the sodicity.

Among *empirical functions* proposed by soil scientists for describing the $\sigma_{eff}(\sigma_w, \theta)$ relationship, the most commonly used is that of Rhoades et al. (1976) who referred to $\sigma_{surface}$ as essentially independent of θ and σ_w and wrote Equation 16 as:

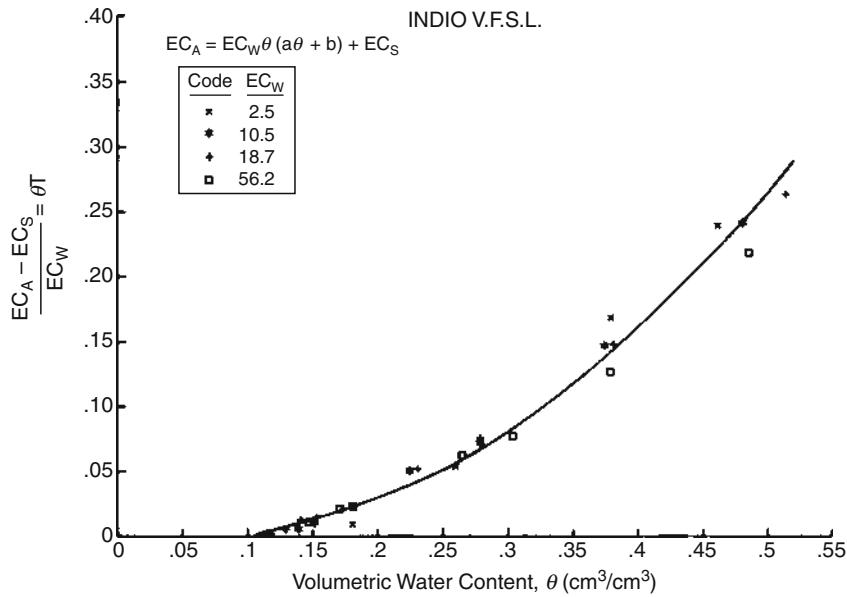

$$\sigma_{eff} = T(\theta)\theta\sigma_w + \sigma_{surface}; T(\theta) = a\theta + b \quad (17)$$

The transmission coefficient (T) is assumed to be a linear function of θ . The empirical parameters a and b

varied among different soils: $a = 2.1, b = -0.25$ for clay soils; and $a = 1.3-1.4, b = -0.11 - , -0.06$ for the other three loam soils discussed in their 1976 article. An example of a transmission coefficient best-fitted to $\sigma_{eff}(\sigma_w, \theta)$ measurements at 4 σ_w levels in a very fine sandy loam (6% clay, 52% silt) is presented in Figure 3 with $T(\theta)\theta = 1.2867\theta^2 - 0.1158\theta$ plotted. It is seen that $T(\theta)\theta$ is indeed a parabolic function of θ , virtually independent of σ_w , validating the applicability of the simplified, two-conductor model (Equations 16 and 17) for saline conditions.

The surface conductivity term should increase with the solution EC which was addressed by various empirical expressions, with parameters accounting for the cation-exchange capacity (surface charge density) and electrical mobility of exchangeable cations (Waxman and Smits, 1968; Nadler et al., 1984; Sen et al., 1988), that were also correlated to easily measured textural characteristics, for example, the hygroscopic water content (Nadler et al., 1984) or Archie's cementation exponent (Sen et al., 1988).

The effects of soil microgeometry, mineralogy, and solution chemistry on the *surface conductivity term* ($\sigma_{surface}, \text{Sm}^{-1}$) of Equations 16 and 17 should reflect the interfacial electrical charge density, the equivalent counterions mobility, and the tortuosity of the surface paths, which is similar to, but not necessarily equal to, the tortuosity of the pore paths. Toward this end, it is required to model the electrical double layer (EDL) that forms on the surface of the mineral grains and to evaluate the intrinsic (specific) surface conductance, $Z_{surface}$ (S), which usually possesses values in the range of

Electrical Properties of Soils, Figure 3 Plot of $(\sigma_{eff} - \sigma_{surface})/\sigma_W = T(\theta)\theta$ according to Equation 17 of measured $\sigma_{eff}(\sigma_W, \theta)$ data for Indio very fine sandy loam equilibrated with solutions of different σ_W (given in $dS m^{-1}$). The solid line represents Equation 17 with the best-fitted transmission coefficient: $T(\theta) = 1.2867\theta - 0.1158$ (From Rhoades et al., 1976. Reproduced by permission of the Soil Science Society of America).

10^{-9} – 10^{-8} S. The specific surface conductance represents the conduction in the fixed (Stern), usually assumed negligible for σ_{DC} , and diffuse parts of the EDL.

A comprehensive, rigorous discussion of the effect of surface conductance on $\sigma_{eff}(\sigma_W, \theta)$ would be too long for this entry and is also not relevant for most practical applications because there are too many unknown parameters involved. The interested reader is, therefore, referred to other publications using single-grain σ_{eff} models for incorporating the contribution of $Z_{surface}$ (e.g., Kan and Sen, 1987; Johnson and Sen, 1988; Schwartz et al., 1989; Lyklema, 1995; Revil and Glover, 1997, 1998; Revil et al., 1998). Also three-dimensional networks of conductors can be used to model the interactions between the bulk and surface conduction mechanisms (e.g., Bernabe and Revil, 1995; Friedman, 1998b). However, these network models are not very applicable in practical applications. From the practical point of view, it should be noted that measuring methods such as induced polarization (Lesmes and Frye, 2001) can be applied in the field and have the potential merit of assisting in differentiating the contributions of surface and bulk fluid conductivities to the measured σ_{eff} .

The electrical conductivity of free solution (σ_w) increases by about 2% per $1^\circ C$ (around $25^\circ C$, corresponding to the decrease of the free water viscosity) and a similar $temperature(T)$ -dependence effect is to be expected for σ_{eff} of coarse-textured soils so that the reduced conductivity, σ_{eff}/σ_w , is temperature independent. However, in clayey soils that exhibit significant surface

conduction, the counterion mobility increases more sharply with temperature and the $\sigma_{eff}(T)$ relationship is more complex (Clavier et al., 1984; Sen and Goode, 1992; Wraith and Or, 1999). Sen and Goode (1992), for example, present slopes from 0.02, corresponding to the slope of free solution, to 0.12 of $\sigma_{eff}(T)$ measurements at high σ_w for shaly sands containing varying amounts of clay.

Dielectric permittivity

Methods of measurement of high-frequency ϵ_{eff}

The common methods for measuring the soil high-frequency (MHz to GHz) permittivity are (in order of increasing frequencies with some overlaps): (1) Capacitance probes, based on measuring the operating frequency in an oscillator circuit (Blonquist et al., 2005; Skierucha and Wilczek, 2010); (2) Impedance probes, based on measuring the reflection coefficient of a standing wave (Gaskin and Miller, 1996; Blonquist et al., 2005); (3) Ground Penetrating Radar (GPR) based on measuring the propagation velocity of transmitted, free electromagnetic (EM) waves (Annan, 2005); and (4) TDR based on measuring the propagation velocity of EM waves travelling through waveguides (Topp et al., 1980; Robinson et al., 2003). The in situ capacitance, impedance, and TDR probes are all few centimeters long, and GPR can operate in resolutions of few centimeters to tens of meters for GHz to MHz frequencies, from either above the soil surface or between boreholes.

Soil attributes affecting ε_{eff} and its modelling

The problems of determining the effective electrical conductivity and the effective dielectric permittivity, based on the volumetric fractions and geometrical attributes of the three soil phases, $\sigma_{eff}(\sigma_S, \sigma_W, \sigma_A, n, \theta)$ and $\varepsilon_{eff}(\varepsilon_S, \varepsilon_W, \varepsilon_A, n, \theta)$, are mathematically analogous: Both involve solving the Laplace equation for the potential while preserving the continuity of the potentials and normal fluxes at the interfaces between the phases. The major difference is that while for EC only one phase is conducting ($\sigma_W > 0, \sigma_S = \sigma_A = 0$), for the permittivity all three solid, water, and air phases are “conductive” (in the mathematical sense) and possess intrinsic, single-phase, 100 MHz-GHz permittivities of approximately 5, 80, and 1, respectively. Although the *permittivity contrasts* are finite (as opposed to $\sigma_W/\sigma_S = \sigma_W/\sigma_A = \infty$), as the permittivity of water, stemming from orientation polarization, is much higher than those of the other two phases ($\varepsilon_W/\varepsilon_S \approx 16; \varepsilon_W/\varepsilon_A \approx 80$), the soil’s ε_{eff} is very sensitive to its volumetric water content, which explains the merit of the dielectric methods for determining the volumetric water content (θ) of partially saturated and the porosity (n) of water-saturated soils and rocks. The large enough contrast between the permittivities of earth minerals and air ($\varepsilon_S/\varepsilon_A \approx 5$) is also usually sufficient for determining the porosity of dry soils and rocks, but the measured ε_{eff} is less sensitive to n than that of water-saturated media. For real multiphase media such as wet soils, the Laplace equation can be solved by numerical methods if their complex geometry can be reliably characterized and discretized. Another option is to refer to a simplified geometry of some common representative quantifiers and to solve the electrostatic problem for the transformed medium. An exact analytical solution to the Laplace equation does not exist even for the most simplified mixture geometry one can conceive (Robinson and Friedman, 2005; Doyle et al., 2007). Therefore, the common practice is to apply some approximating assumptions regarding the spatial structure of the electrical fields in the different phases, a concept which we term here mean field theories.

The *major factors determining the effective permittivity of soils* are volumetric water content, porosity, particle shape and orientation, particle-size distribution, mineralogy, and temperature.

The three components version of the refractive index (RI) model (Birchak et al., 1974), which accounts for only the *volumetric fractions of the three phases*, is (Alharthi and Lange, 1987; Whalley, 1993; Robinson et al., 1999)

$$\varepsilon_{eff}^{\frac{1}{2}} = \theta \varepsilon_W^{\frac{1}{2}} + (n - \theta) \varepsilon_A^{\frac{1}{2}} + (1 - n) \varepsilon_S^{\frac{1}{2}} \quad (18)$$

The physical assumption behind Equation 18 (sometimes referred to as time propagation equation (Wharton et al., 1980) or ray theory (Chan and Knight, 2001)) is that the travel time of an EM wave in a two-phase medium is a summation of three travel times: in the solids, water, and air, as if propagating in a direction perpendicular to the layering of these phases. Each single-phase travel

time is proportional to the layer thickness, namely, to the volumetric fraction of the phase, and to its propagation velocity, which is proportional to $1/\sqrt{\varepsilon_i}$ of that phase. This three-phase layers arrangement is, of course, a very poor description of the real geometry of the soil’s mineral skeleton, and the water-phase configuration in the compliant pore system. In addition, when the wavelength (centimeters for GHz frequencies) is much larger than the solid particles (usually from micrometers to fractions of millimeters), the EM wave “does not see” the solid inclusions, but rather a single homogeneous mixture of a given permittivity, which we term here effective permittivity. The ε_{eff} depends on the single-phase permittivities and volumetric fractions according to a different physics, which allows for the concentration of the conducting paths in the more conducting phases and for the circumventing of the isolating objects.

The most commonly used *empirical $\varepsilon_{eff}(\theta)$ relationship* nowadays, rightly, is the “universal” formula of Topp et al. (1980):

$$\varepsilon_{eff} = 3.03 + 9.3\theta + 146\theta^2 - 76.7\theta^3 \quad (19)$$

which was best-fitted to careful measurements made on four soil types and was suggested to hold approximately for all types of mineral soils. This relationship was found to give good predictions, mostly for coarse- and medium-textured soils (Dirksen and Dasberg, 1993; Friedman, 1998a), and was also found close to relationships resulting from different theoretical approaches (Van Loon et al., 1991; Friedman, 1997, 1998a). Comparing the $\varepsilon_{eff}(\theta)$ relationships of various soils to the functional water content dependencies of other transport properties (electrical and thermal conductivities, solute and gas molecules diffusivities, and hydraulic conductivity) reveals that the $\varepsilon_{eff}(\theta)$ relationship is indeed less strongly dependent on soil type as compared to the other transport parameters. Yet, as expected on physical grounds and observed in many experimental studies, the $\varepsilon_{eff}(\theta)$ relationship does depend on the soil textural and mineralogical properties (Hoekstra and Delaney, 1974; Wang and Schmugge, 1980; Dobson et al., 1984; Dirksen and Dasberg, 1993; Heimovaara et al., 1994; Friedman, 1998a) in a complicated manner and in some cases to a significant extent.

Various other empirical equations have been suggested for the relationship between the MHz-GHz ε_{eff} and θ (Wang and Schmugge, 1980; Hallikainen et al., 1985; Roth et al., 1992; Malicki et al., 1996), mostly polynomial functions, in some cases describing the relationships reliability by allowing their coefficients to be dependent on, for example, the clay and sand percentage (Dobson et al., 1984) or on the bulk density and clay and organic matter contents (Jacobsen and Schjønning, 1993). Another empirical approach is to replace the $1/2$ exponent of the RI model with a free parameter, which is supposed to account for some of the determining factors. Roth et al. (1990), for example, found an optimal exponent of 0.46, which is another support for the empirical merit of the RI model.

Replacing the $\frac{1}{2}$ exponent of [Equation 18](#) with $\frac{1}{3}$ results in the Loyenga's ([1965](#)) mixing model, which is not superior to the RI model from both theoretical and empirical aspects ([Robinson and Friedman, 2003](#)). The only explainable exponents of the RI-type model are the two extreme values of 1 (arithmetic mean) and -1 (harmonic mean), which refer to the three phases arranged unrealistically in parallel layers with the applied electrical field directed parallel (1) or perpendicular (-1) to the layering. These two relationships constitute the most extreme theoretical upper and lower bounds (known as Wiener bounds, [Sihvola, 1999](#)) to the $\epsilon_{eff}(\theta)$ relationship, and any outside measurements or theoretical results should be doubted.

Most of the theoretical approaches for relating ϵ_{eff} of dielectric mixtures to their constituents volumetric fractions and single-phase permittivities fall into one of the two major conceptual categories of discrete capacitor network models ([Ansoult et al., 1985](#); [Friedman, 1997](#); [Tabbagh et al., 2000](#)), which will not be discussed here and continuum *mean field theories* or “*mixing models*” ([Sihvola, 1999](#)). One example is the Maxwell–De Loor mixing model, which assumes the solid phase to be a host medium for randomly distributed and oriented disk-shaped inclusions of the other phases ([De Loor, 1968](#)). The assumption of a continuous solid phase may be adequate for some low-porosity rocks, but not for soils. A more realistic description of the soil aqueous phase, at least at intermediate and high water contents, is probably not that of disconnected inclusions, but of a continuous background phase. [Friedman \(1998a\)](#) studied the role of the configuration of the three soil phases by extending the two-phase Maxwell-Garnett ([1904](#)) formula (MG) to two-phase composite spherical inclusions (a core of ϵ_2 surrounded by a concentric shell of ϵ_1) immersed in the third phase (of ϵ_0) serving as the background. The resulting MG-type mixing model for the effective permittivity of a three-phase mixture, $\epsilon_{eff}(\epsilon_0, \epsilon_1, \epsilon_2, f_1, f_2)$, of volumetric fractions f_1, f_2 , and $f_0 (= 1 - (f_1 + f_2))$ is ([Tinga et al., 1973](#); [Friedman, 1998a](#)):

$$\epsilon_{eff} = \epsilon_0 + \frac{3[(f_2 + f_1)(\epsilon_1 - \epsilon_0)(2\epsilon_1 - \epsilon_2) - f_2(\epsilon_1 - \epsilon_2)(2\epsilon_1 + \epsilon_0)]\epsilon_0}{\left[(2\epsilon_0 + \epsilon_1)(2\epsilon_1 + \epsilon_2) - 2\frac{f_2}{f_2 + f_1}(\epsilon_1 - \epsilon_0)(\epsilon_1 - \epsilon_2) \right]} \\ - \frac{[(f_2 + f_1)(\epsilon_1 - \epsilon_0)(2\epsilon_1 + \epsilon_2) + f_1(\epsilon_1 - \epsilon_2)(2\epsilon_1 + \epsilon_0)]}{(f_2 + f_1)} \quad (20)$$

There are six possible concentric arrangements of the three phases (attributing ϵ_S , ϵ_W , and ϵ_A to either ϵ_0 , ϵ_1 , or ϵ_2), and as the permittivity of water is much higher than that of the other components, it is especially the location of the water phase which dictates the resulting ϵ_{eff} . The minimal $\epsilon_{eff}(\theta)$ relationships correspond to configurations in which the water, with its significantly higher dielectric constant is encapsulated within the solid and gaseous phases (*WSA*). The maximal ϵ_{eff} values stem from an arrangement with permittivities increasing radially outward (*ASW*). The real configuration of the solid, water, and gaseous phases in soil is not a constant one, but varies

with the saturation degree. For low water contents, it is reasonable to assume that the gaseous phase is continuous and surrounding the solid and liquid phases. As the water content increases, the gaseous phase develops discontinuities and a better description is that of a continuous liquid phase surrounding the solid and gaseous phases. Thus, [Friedman \(1998a\)](#) proposed saturation-degree-dependent weight functions for two chosen dry (*SWA*) and wet (*ASW*) configurations:

$$f_w^{SWA} = 1 - S; f_w^{ASW} = S; S = \frac{\theta}{n} \quad (21)$$

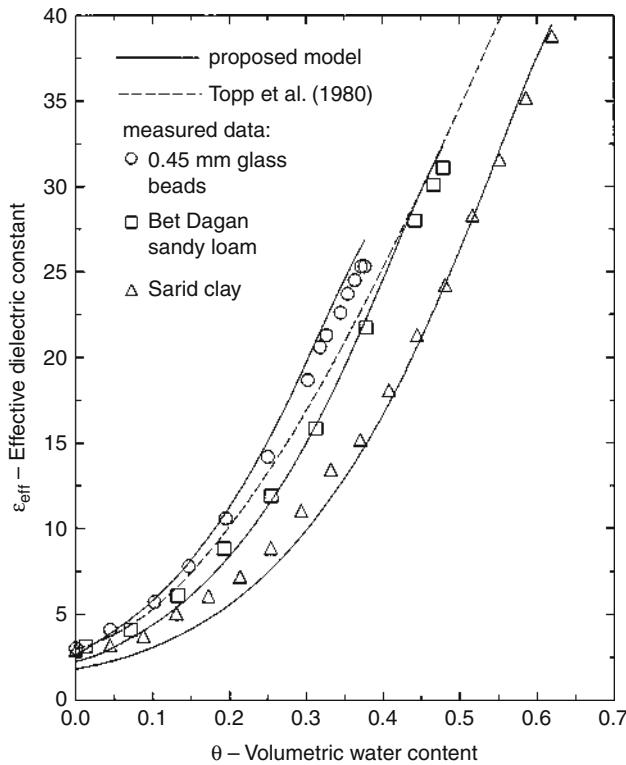

and representing their mutual contribution by the Effective Medium Approximation (EMA) ([Bruggeman, 1935](#)), which treats both components symmetrically. Applying the EMA equation to the dual *SWA-ASW* system (with $f_w^{SWA} + f_w^{ASW} = 1$) results in the following quadratic equation for ϵ_{eff} :

$$\epsilon_{eff} = \left\{ \frac{[f_w^{SWA}(\epsilon_{ASW} - 2\epsilon_{SWA}) + f_w^{ASW}(\epsilon_{SWA} - 2\epsilon_{ASW})]^2}{16} \right. \\ \left. + \frac{\epsilon_{SWA}\epsilon_{ASW}}{2} \right\}^{1/2} \\ - \frac{[f_w^{SWA}(\epsilon_{ASW} - 2\epsilon_{SWA}) + f_w^{ASW}(\epsilon_{SWA} - 2\epsilon_{ASW})]}{4} \quad (22)$$

This approach of macroscopic mixing of “percolating” (*ASW*, continuous water phase) and “non-percolating” (*SWA*, discontinuous water phase) configurations resembles (in this sense) the local porosity theory of [Hilfer \(1991\)](#), which refers to the local, microscopic porosities and percolation probabilities of the real, detailed structure of the porous medium. Replacing [Equation 20](#) with the corresponding expressions for confocal composite ellipsoidal inclusions ([Sihvola and Lindell, 1990](#)) applies it to nonspherical particles.

[Jones and Friedman \(2000\)](#) extended this approach to nonspherical particles and demonstrated reasonable agreements with directional ϵ_{eff} and ϵ_{eff} measurements in partially saturated anisotropic packings of mica particles. Extension of this approach for aggregated media, characterized by a bimodal pore-size distribution is provided in [Miyamoto et al. \(2005\)](#) and [Blonquist et al. \(2006\)](#).

The composite sphere model presented above ([Equations 20–22, Figure 4](#)) with $\epsilon_W \approx 80$ generally gives higher ϵ_{eff} values than the measured ones, especially for fine-textured soils of high specific surface area (usually associated with high porosity) and at low- and mid-range water contents. One main reason for this discrepancy is the inadequate attribution of an $\epsilon_W \approx 80$ value to the whole aqueous phase volumetric fraction. There is much experimental evidence ([Hoekstra and Delaney, 1974](#); [Dobson et al., 1985](#); [Dirksen and Dasberg, 1993](#); [Heimovaara et al., 1994](#); [Wraith and Or, 1999](#)), as well as theoretical arguments

Electrical Properties of Soils, Figure 4 Measured effective permittivities as a function of volumetric water content for three granular media (symbols), and their prediction according Friedman (1998a) composite sphere model (solid lines, Equations 20–22 and 24–26). Also shown is the universal function of Topp et al. (1980) (dashed line) (From Friedman (1998a). Reproduced by permission of the American Geophysical Union, Copyright (1998) AGU).

(Or and Wraith, 1999) to indicate that the GHz permittivities of the thin water films surrounding the soil particles are much lower than that of free water at the same temperature, frequency, and ionic strength (Kaatze, 1996). The presence of soil minerals affects the dielectric properties of the water molecules adjacent to their surfaces by restricting their rotational movements, thus reducing their polarizability and permittivity. This phenomenon can be very significant in fine-textured soils and is usually incorporated in $\epsilon_{eff}(\theta)$ modelling by adding a fourth, *bound water* phase of a lower permittivity (Dobson et al., 1985; Dirksen and Dasberg, 1993; Robinson et al., 2002). Dobson et al. (1985) added it as a fourth component, having volumetric fraction θ_{BW} and permittivity ϵ_{BW} , while extending the Maxwell–De Loor mixing model (De Loor, 1968) giving:

$$\epsilon_{eff} = \frac{3\epsilon_S + 2(\theta - \theta_{BW})(\epsilon_W - \epsilon_{BW}) + 2\theta_{BW}(\epsilon_{BW} - \epsilon_S) + 2(n - \theta)(\epsilon_A - \epsilon_S)}{3 + (\epsilon_S/\epsilon_{BW} - 1) + \theta_{BW}(\epsilon_S/\epsilon_{BW} - 1) + (n - \theta)(\epsilon_S/\epsilon_A - 1)} \quad (23)$$

Dirksen and Dasberg (1993) adopted this model and assumed that the soil minerals are surrounded by a single monomolecular layer of bound water of a GHz permittivity of 3.2, as that of ice, and that the rest of water are free water. One severe limitation of this approach is that the free and “bound” water are treated as two separate phases, randomly dispersed in the mixture and without any spatial correlation. This limitation can be overcome within, for example, the framework of the above-presented composite sphere model, by treating the neighboring free and “bound” water phases as two adjacent spherical shells. Robinson et al. (2002) suggested to evaluate the amount of bound water by the easily measurable hygroscopic water content of the soil, in agreement with the high correlation between the amount of hygroscopic water at 50% relative humidity and a single monomolecular layer found by Dirksen and Dasberg (1993), and to add a fourth, bound water phase to the RI model (Equation 18). Dobson et al. (1985) also tested the four-phase RI mixing model (with high bound water permittivities of 20–40) and found an optimal exponent of 0.65 for a variety of soil textures and several GHz frequencies.

A more physical treatment of the bound water phenomena was provided by Or and Wraith (1999) relating the dielectric relaxation frequency of the bound water to their viscosity according to the Debye (1929) model and incorporating the dependence of the water viscosity on its distance from clay surfaces according to Low's (1976) findings. For practical purposes, Or and Wraith (1999) proposed to characterize the bound water as a single layer with a temperature-independent permittivity of 12 and thickness determined by letting the relaxation frequencies of its water molecules be lower than a cutoff frequency of the measuring device (e.g., 1 GHz for a Tektronix 1502B Time Domain Reflectometer).

An alternative approach to incorporate bound water effects is to refer to a single water phase, its permittivity being dependent on the soil texture and water content. Friedman (1998a) suggested a pragmatic approach, assuming that the GHz permittivities of the soil solution grow in an exponential mode with the distance from the solid surface, x , from their minimal value at $x = 0$ (ϵ_{min}) to a maximum value corresponding to that of free water (at the given temperature, frequency, and solutes concentration, ϵ_{max}) according to a general scaling length, $1/\lambda$, common to all soil minerals:

$$\epsilon(x) = \epsilon_{min} + (\epsilon_{max} - \epsilon_{min})(1 - e^{-\lambda x}); \quad (24)$$

$$\epsilon_{min} = 5.5; \lambda = 10^8 \text{ cm}^{-1}$$

For evaluating the average, single-phase water permittivity (ϵ_W), Friedman (1998a) proposed to take the harmonic mean of $\epsilon(x)$ (Equation 24) resulting in

$$\epsilon_W(d_W) = \frac{d_W \epsilon_{max}}{d_W + \frac{1}{\lambda} \ln \left[\frac{\epsilon_{max} - (\epsilon_{max} - \epsilon_{min})e^{-\lambda d_W}}{\epsilon_{min}} \right]} \quad (25)$$

where the average thickness of the water shell (d_w) is calculated by dividing the volume of water contained in a volume of the bulk soil by the wettable surface areas of its solid phase, which for a unit soil volume means dividing the volumetric water content by the product of the soil bulk density (ρ_b , ML^{-3}) and specific surface area (S_{SA} , L^2M^{-1})

$$d_w = \frac{\theta}{\rho_b S_{SA}} \quad (26)$$

Figure 4 presents a test of the Friedman's (1998a) $\epsilon_{eff}(\theta)$ model against measurements with three granular materials, together with the Topp et al.'s universal function (Equation 19). It seems that the composite sphere model prediction is reasonable for all three media – coarse, medium, and fine textured – whereas Topp et al.'s function adequately describes only the $\epsilon_{eff}(\theta)$ curve of the medium-textured Bet Dagan sandy loam. The predictability of the Friedman's (1998a) composite sphere model, a capacitor-network model (Friedman, 1997), and other three empirical models (Topp et al., 1980; Dobson et al., 1984; Roth et al., 1992) was further tested against 19 additional measured $\epsilon_{eff}(\theta)$ curves of mineral porous media of a broad textural range, taken from published reports of measurements under controlled conditions (n , temperature) and which provide information on the ρ_b (/n) of the packed samples, on the S_{SA} or on the soil texture, from which S_{SA} can be estimated. Based on a root-mean-square-deviation test, it can be generally stated that the performance of all those five models is quite similar, with the composite-sphere model yielding the best predictability for the whole set of 22 media as well as for just the 18 natural soils. Therefore, if the soil porosity and specific surface area can be reasonably evaluated, and there is readiness to perform the simple spreadsheet calculations (Equations 20–22 and 24–26), it is recommended to use this physical model, bearing in mind its main strengths and weaknesses: it takes into account the saturation degree-dependent phase configurations and bound water (soil texture) effects, but it ignores *particle shape* effects, which are probably responsible for some of the differences among the $\epsilon_{eff}(\theta)$ relationships of the three media presented in **Figure 4**, which we are going to discuss next, referring to the two extremes of water-saturated and oven-dry media.

Firstly, we present the universal mixing law for the two-phase effective permittivity, $\epsilon_{eff}(n, \epsilon_s, \epsilon_0)$, of spherical inclusions (the solid particles with permittivity ϵ_s) immersed in a background of permittivity ϵ_0 (either ϵ_w for water-saturated soils or ϵ_a for oven-dry soils) (Sihvola and Kong, 1988)

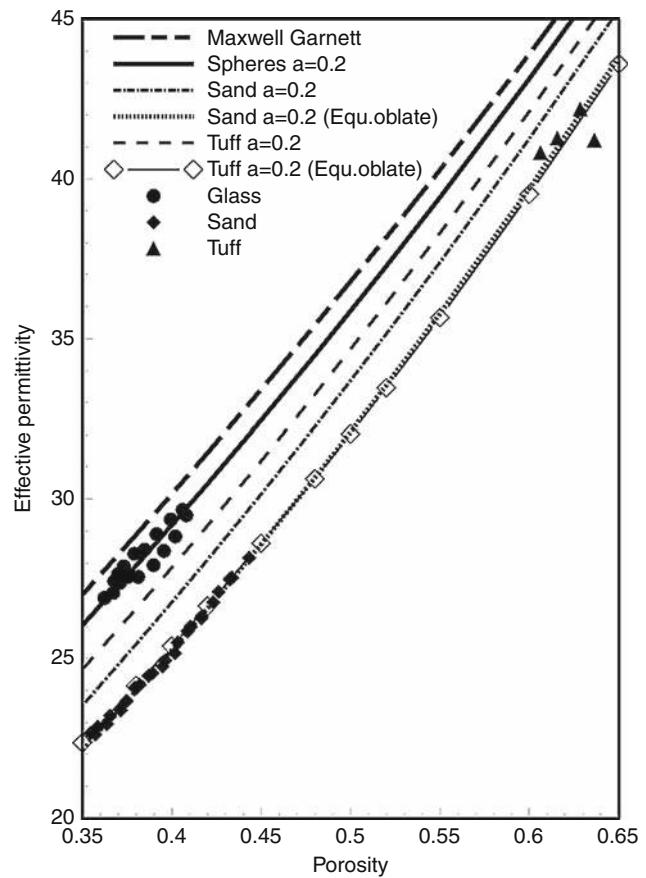

$$\epsilon_{eff} = \epsilon_0 + \left\{ \left[\frac{(1-n)(\epsilon_s - \epsilon_0)[\epsilon_0 + v(\epsilon_{eff} - \epsilon_0)]}{3[\epsilon_0 + v(\epsilon_{eff} - \epsilon_0) + (\epsilon_s - \epsilon_0)]} \right] \cdot \left[1 - \frac{(1-n)(\epsilon_s - \epsilon_0)}{3[\epsilon_0 + v(\epsilon_{eff} - \epsilon_0) + (\epsilon_s - \epsilon_0)]} \right]^{-1} \right\} \quad (27)$$

which is the analogue to the effective conductivity, $\sigma_{eff}(n, \sigma_w, \sigma_s = 0)$ expression (Equation 12), except for the solid phase being “conductive” ($\epsilon_s > 0$) for the $\epsilon_{eff}(n, \epsilon_s, \epsilon_0)$ problem. Keeping $v = 0.2$ (as for the $\sigma_{eff}(n)$ of glass spheres packings, **Figure 1**) results in a good prediction of the $\epsilon_{eff}(n)$ of water-saturated packings of glass spheres (**Figure 5**; Friedman and Robinson, 2002).

The extension of Equation 27 to randomly oriented spheroidal particles (the analogue to Equation 12) is (Sihvola and Kong, 1988).

$$\epsilon_{eff} = \epsilon_0 + \frac{\sum_{i=a,b,c} \frac{(1-n)[\epsilon_0 + v(\epsilon_{eff} - \epsilon_0)][\epsilon_s - \epsilon_0]}{3[\epsilon_0 + v(\epsilon_{eff} - \epsilon_0) + N^i(\epsilon_s - \epsilon_0)]}}{1 - \sum_{i=a,b,c} \frac{(1-n)N^i(\epsilon_s - \epsilon_0)}{3[\epsilon_0 + v(\epsilon_{eff} - \epsilon_0) + N^i(\epsilon_s - \epsilon_0)]}} \quad (28)$$

Measured $\epsilon_{eff}(n)$ relationships of the water-saturated glass spheres, sand particles, and tuff particles along with

Electrical Properties of Soils, Figure 5 Effective permittivity as a function of porosity for glass spheres ($\epsilon_s = 7.6$), quartz sand ($\epsilon_s = 4.7$), and tuff grains ($\epsilon_s = 6.0$). Predictions of permittivity are presented for equivalent oblates of $a/b = 0.465$ for sand and 0.364 for tuff. Note that the sand and tuff lie on lines close together due to the difference in the permittivity of the solid grains (From Friedman and Robinson, 2002. Reproduced by permission of the American Geophysical Union, Copyright (2002) (AGU)).

those evaluated by [Equation 28](#) are presented in [Figure 5](#), demonstrating remarkable prediction capability of the mixing model. This closure is also indicative of the merits and physical significance of the empirical relationship between the slope angle and the shape factor, of the choice of an oblate-spheroid geometry to represent the particle shape, and of the heuristic mixing models ([Equations 12](#) and [28](#)) with $v = 0.2$ for predicting the $\epsilon_{eff}(n)$ and $\sigma_{eff}(n)$ relationships of isotropic granular media made of nonspherical particles. Here, as opposed to $\sigma_{eff}(n)$ ([Figure 1](#)), the relationships vary not only because of particle shape, but also due to different solid (independently determined) permittivities of $\epsilon_S = 7.6$, 4.7, and 6.0 for the glass spheres, sand, and tuff, respectively. The significance of the particle shape effects is demonstrated by the $\epsilon_{eff}(n)$ lines for spherical particles ([Equation 27](#), or assuming an aspect ratio of $a/b/c = 1$ for the polarization factors of [Equation 28](#)), which are higher than the corresponding $\epsilon_{eff}(n)$ relationships for the actual oblate ($a < b = c$) particles.

As to the effect of the soil's *particle-size distribution* (*PSD*) on its ϵ_{eff} : Similarly to σ_{eff} , the mean particle size does not affect ϵ_{eff} and it is only the broadness (variance) of the PSD which is expected to affect the $\epsilon_{eff}(n, \theta)$ relationship. The MG model (two-phase version of [27](#)) formed the basis of a self-similar model derived by Sen et al. ([1981](#)), its main modification was of sequential additions of the inclusion solid phase into the host water phase, while the background pore system remains intact to low values of porosity. The resulting formula is impressively simple (Sen et al., [1981](#)):

$$\left(\frac{\epsilon_S - \epsilon_{eff}}{\epsilon_S - \epsilon_0}\right) \left(\frac{\epsilon_0}{\epsilon_{eff}}\right)^{1/3} = n \quad (29)$$

Nevertheless, this model should apply, in principle, to a fractal medium of infinitely wide PSD and should therefore form a lower (/upper) bound for the estimate of ϵ_{eff} of real water-saturated ($\epsilon_0 = \sigma_W$) (/oven-dry, $\epsilon_0 = \sigma_A$) granular media made of spherical particles of bounded particle-size distribution, as indeed proven by Robinson and Friedman ([2001](#)). Using mixtures of mono-size fractions of glass spheres and mixture of mono-size sand grains, Robinson and Friedman ([2001](#)) demonstrated how an increased broadness of the PSD reduces the ϵ_{eff} of water-saturated packings (and how it is expected to increase the ϵ_{eff} of oven-dry soil, thus, practically not affecting it for wet soils). It should be noted that the increasing width of PSD and particle asphericity tend to reduce the medium porosity. However, the effects on ϵ_{eff} and σ_{eff} discussed here are beyond this indirect effect, namely, referring to how these geometrical attributes affect ϵ_{eff} for a given porosity.

Knowing nothing on the soil mineralogy it is recommended to use a value of $\epsilon_S = 5$ for the *solid phase permittivity* when evaluating ϵ_{eff} (Dirksen and Dasberg, [1993](#); Friedman, [1998a](#)). A value of $\epsilon_S = 5.1$, for example, was determined for a sandy loam soil by Robinson and

Friedman ([2003](#)). If the mineralogical composition (and the corresponding mineral permittivities) is known then the appropriate modelling approach would be to extend the summations in, for example, [Equation 27](#) or [28](#) to several kinds of solid inclusions. Nevertheless, referring to a single type of solid inclusion with a permittivity equal to the arithmetic mean of the known composition introduces a negligible error, as demonstrated by Robinson and Friedman ([2002](#)) using mixtures of glass spheres ($\epsilon_S = 7.6$) and quartz sand grains ($\epsilon_S = 4.7$). Therefore, using a single mean ϵ_S value is satisfactory. ϵ_S of soil minerals range in general in 4–9 (Olhoeft, [1981](#); Robinson and Friedman, [2003](#); Robinson, [2004](#)) and that of soil organic matter is slightly lower. ϵ_S can be measured by the immersion method (Robinson and Friedman, [2003](#)), namely, by measuring the effective permittivity of packings of the same porosity, $\epsilon_{eff}(\epsilon_S, \epsilon_0, n = \text{const.})$, immersed in background fluids of different permittivities, ϵ_0 (higher and lower than ϵ_S), interpolating $\epsilon_{eff}(\epsilon_0)$ with a mixing model, and determining ϵ_S by the interception of $\epsilon_{eff}(\epsilon_0)$ and the 1:1 line.

The data and modelling (using $\epsilon_S = 5$) in this entry refers to only mineral soils. For the $\epsilon_{eff}(\theta)$ relationships of peat or soils of *high organic matter contents*, it is recommended to use different empirical equations best-fitted to these organic soils (Topp et al., [1980](#); Roth et al., [1992](#); Pepin et al., [1992](#)).

The permittivity of free water decreases by about $^{1/3}\%$ per 1°C increase due to random thermal motion enhancement and diminished directional polarization. Thus, ϵ_{eff} of coarse-textured soils slightly decrease with increasing *temperature* (T). However, in clayey soils with appreciable bound water increasing temperature causes release of low-permittivity bound water, which results in an overall increase of ϵ_{eff} (Hoekstra and Delaney, [1974](#); Wraith and Or, [1999](#); Or and Wraith, [1999](#)), a phenomenon Or and Wraith ([1999](#)) termed "thermo-dielectric effect," and proposed to utilize for evaluating the soil-specific surface area from $\epsilon_{eff}(T)$ measurements.

The MG ([Equation 27](#), assuming $v = 0$) prediction of, for example, $\epsilon_{eff} = 35.6$ for $n = 0.5$, $\epsilon_S = 5$, and $\epsilon_W = 80$ is close to the value of $\epsilon_{eff} = 34.6$ resulting from the frequently used empirical relationship of Topp et al. ([1980](#)) for a volumetric water content of 0.5. As opposed to it, the refractive index model ([Equation 18](#)) results in a much lower value of $\epsilon_{eff} = 31.25$. Robinson et al. ([2005](#)) demonstrated good predictability and proposed to use for practical purposes of water content determinations in coarse-textured soils the following hybrid, RI – two-phase mixing model

$$\epsilon_{eff}^{\frac{1}{2}} = \left(\frac{\theta}{n}\right) \epsilon_{sat}^{\frac{1}{2}} + \left(1 - \frac{\theta}{n}\right) \epsilon_{dry}^{\frac{1}{2}} \quad (30)$$

with the effective permittivities of the water-saturated (ϵ_{sat}) and oven-dry (ϵ_{dry}) soil determined by measurements or by the more reliable (compared to three-phase) two-phase mixing models (e.g., [Equation 27](#) or [28](#)).

Summary

The soil's electrical conductivity (σ_{eff}) and dielectric permittivity (ϵ_{eff}) are two macroscopic properties determined by the volumetric fractions and by the intrinsic properties of the soil's solid, liquid, and gaseous phases and their geometrical and interfacial features. Measurements of high-frequency ϵ_{eff} serve for the evaluation of the soil's porosity and volumetric water contents, and additional, simultaneous measurements of the low-frequency σ_{eff} allow evaluating the salinity of the soil's solution. Thus, measurements of σ_{eff} and ϵ_{eff} are useful for monitoring the flow and retention of water and electrolytes in the soil profile.

Definitions

Soil electrical resistivity. Resistance of soils to electrical current flow for a given electrical potential across the soil material. The SI unit is ohm meter (Ωm).

Soil structure. Spatial arrangement of soil particles at various scales, typically from clay particles (μm) to soil profile (m).

Introduction

Soil structure, that is, the arrangement of soil particles in space (Guérif, 1987; Dexter, 1988) is one of the factors of physical quality of soils. In the agricultural context, this structure is modified at several space and time scales by different factors: plants growth, earthworm's activity, traffic, tillage, and climate. Because the mechanical stresses applied to the soil by these factors do not affect the whole soil volume, soil structure of agricultural fields is generally very heterogeneous. Several methods for the characterization of soil structure at the profile scale (i.e., the macrostructure) already exist. These are based on the visual description of a soil pit (Roger-Estrade et al., 2004), on measurements of soil properties such as bulk density, porosity, water retention, and penetration resistance, or on characterization of the water infiltration.

One of the main problems of these methods for soil structure analysis in field conditions is that they are destructive and cannot easily be used to obtain a spatial and temporal monitoring of the soil structural heterogeneity. Geophysical nondestructive methods such as electrical resistivity have already been demonstrated as useful quantitative methods for soil mapping at farmer scale (Bourennane et al., 1998), monitoring of water content or solute transfer (Michot et al., 2003), and description of porosity evolution (Dannowski and Yaramancı, 1999). Electrical resistivity of soils depends on volumetric clay and water contents because the electrical flow occurs within the pores filled in water and at the surface of clayed particles. Consequently, electrical resistivity would depend on soil bulk density and more generally on soil structure.

The aim of the study conducted from several years at INRA in France is to examine the feasibility of using electrical resistivity in describing the structure of tilled layers in agricultural fields, that is, the change in soil macrostructure due to traffic (compaction), tillage (fragmentation), and climate (crack formation).

Electrical resistivity measurements

The electrical resistivity of a soil volume is calculated from the potential difference due to the continuous and low frequency artificial current injected by electrodes into the soil. There are different electrode configurations, called electrodes arrays where the electrical current (I) is injected by two electrodes conventionally named A and B and the potential difference (ΔV) is measured by two other electrodes M and N. The measured electrical resistivity of the prospected medium is called apparent resistivity (ρ_a) and is calculated by Eq. 1:

$$\rho_a = \left[\frac{2\pi}{(1/AM) - (1/BM) - (1/AN) + (1/BN)} \right] \frac{\Delta V}{I} \quad (1)$$

where AM (resp. BM , AN , BN) represents the distance between electrodes A and M (resp. B and M, A and N, B and N).

The electrode configuration used in our experiments is the Wenner array. Four electrodes are arranged in line, with A and B electrodes at the external positions and M and N electrodes in between. The distances AM , MN , NB are equal (0.10 m in our case). We measured soil electrical resistivity and analyzed its spatial distribution in 2D from the tomography technique (ERT). For that, the Wenner array is moved on a line from one point to another to measure the electrical resistivity of adjacent locations. By increasing the distance between all the four electrodes, the depth of investigation increases and deeper zones in the soil profile can be characterized. The measured resistivities can thus be quickly obtained. They are called "apparent resistivities" because each value corresponds to an integrated volume.

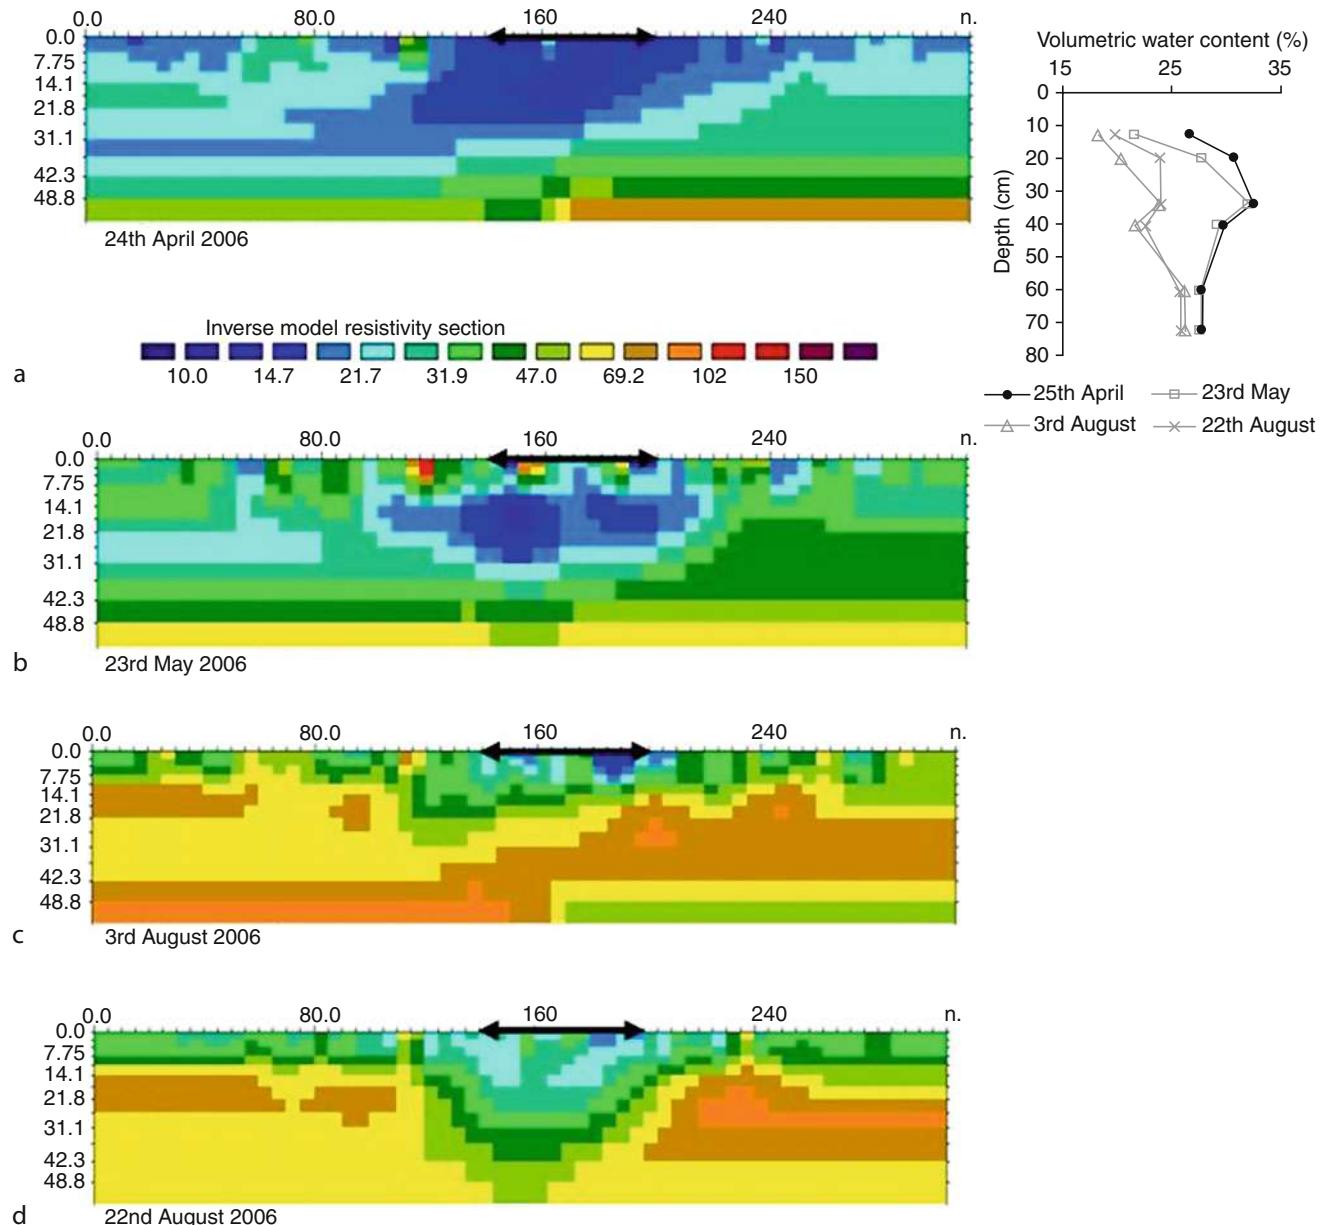

Raw resistivity data are so-called "bulk or volume" resistivity for which a soil volume is measured. To be accurately analyzed in space, the spatial distribution of bulk resistivity is determined by inverse modeling. Resulting resistivity, that is, resistivity forward solution, is then called "inverted resistivity," calculated at each block of structured grid. The inverse resistivity problem is nonlinear, nonunique, and ill-posed with respect to data errors and incomplete data sets. It is usually solved in an iterative process that applies a forward modeling routine for nearly arbitrary resistivity distributions in every inversion step. For a thorough presentation of goelectrical inverse process, the reader could refer to books on the subject, such as those by Aster et al. (2005) or Tarantola (2005).

We used the Res2Dinv program with the smoothness-constrained least-squares method based on the quasi-Newton optimization technique (Loke and Barker, 1996). An estimation of the difference between measured and inverted resistivity is given by the Root Mean Square error (RMS). Because of the solution nonuniqueness, we assumed that the most reliable and realistic inverted resistivity distribution was obtained for a RMS lower than 10% (Delapierre, 1998).

Inverted data were then represented on a regular and refined grid with an increasing cell size toward the spatial boundaries (e.g., see Figure 1).

Temperature influences electrical resistivity values and it is very important to correct the temperature effect (Besson et al., 2008). The Campbell equation is the most commonly used (Campbell et al., 1948):

$$\frac{1}{\rho_T} = \frac{1}{\rho_{ref}} [1 + \alpha(T - T_{ref})] \quad (2)$$

Electrical Resistivity to Assess Soil Properties, Figure 1 2D electrical resistivity profiles (depth and width in centimeters) in Villamblain immediately at compaction (a) 1 month; (b) 3 months; (c) and 4 months; (d) after compaction. The *black arrow* represents the position of the wheel (tire with a 65 cm width).

where T represents the temperature of the measurement, T_{ref} the electrical resistivity measured at the reference temperature (usually taken equal to 25°C), ρ the electrical resistivity at T , ρ_{ref} the electrical resistivity at T_{ref} , and α a correction factor equal to 0.02.

Field experiments

Field experiments were performed in two plots with a loamy soil – typical Luvisol (FAO, 2006) in Estrées-Mons, Picardie Region – and a loamy-clay soil – haplic

Cambisol (FAO, 2006) in Villamblain, Beauce Region. For both sites, we created a compacted band by wheeling at field capacity with a heavy tractor.

For the Estrées-Mons site, a sub-plot was tilled with a mouldboard plow (in the direction of wheeling). The objective was to fragment the compacted band and to create a complex arrangement of compacted blocks, loose material, and large voids. For the Villamblain site, the compacted band was not disturbed, subject only in time to the climate and biological activities.

Soil structure was characterized from the visual observation of a soil pit dug perpendicularly to the tillage direction. Macroscopic features were classified with a particular attention to zones with massive structure and no visible macroporosity. These zones, called Δ zones (Manichon, 1982), resulted from the maximum intensity of soil

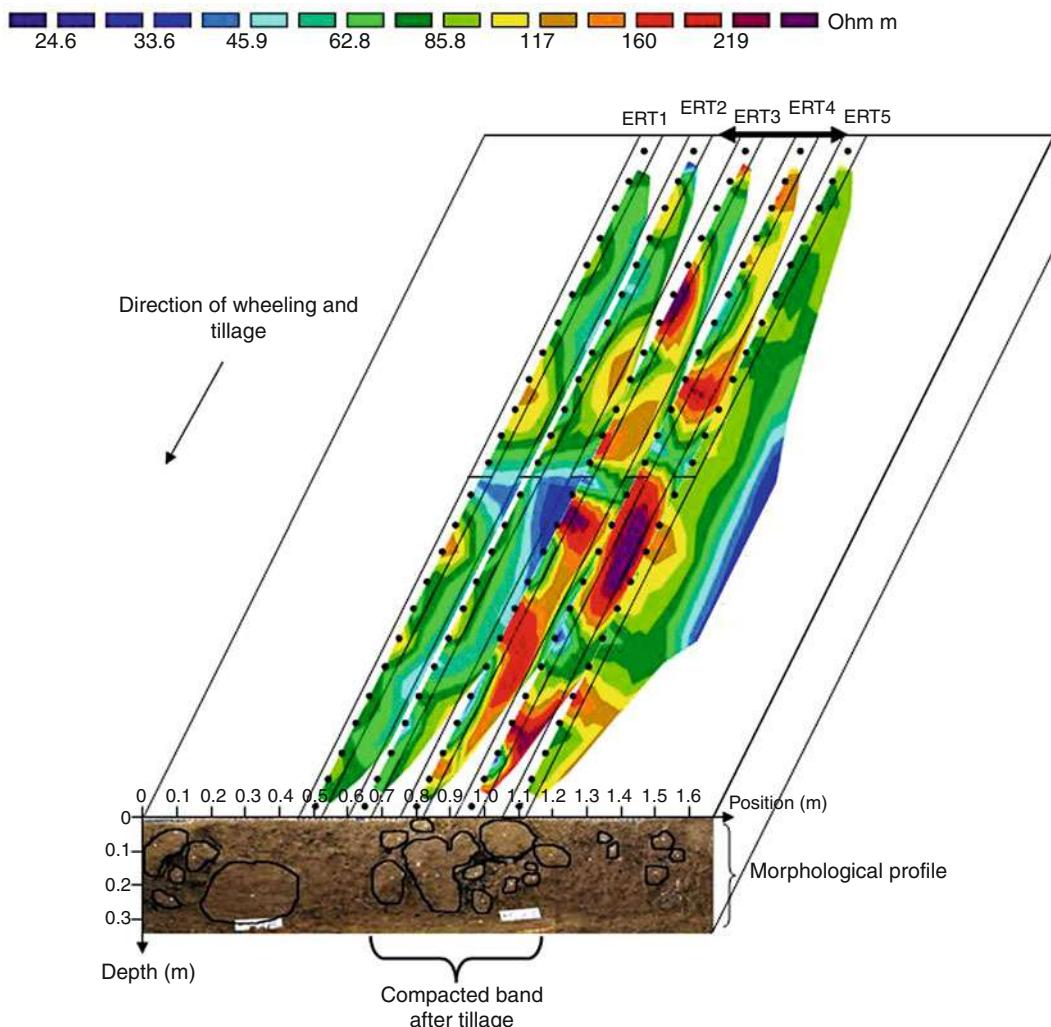

compaction in field conditions. The Δ zones had a massive structure, no visible macropore, high cohesion, and a clean breaking surface. Bulk densities were also measured on undisturbed soil cores sampled in both soil profiles.

ERT measurements were measured as described above before each dug pit. Multielectrode lines were perpendicular (Villamblain) or parallel (Estrées-Mons) to the traffic direction. We used resistivimeter (Syscal R1) from the Iris technology (Iris Instrument, France).

Results

Compaction after traffic (Estrées-Mons and Villamblain sites)

Soil compaction was characterized by an increase in bulk density of the topsoil from 1.36 to 1.47 Mg m^{-3} in the haplic Cambisol soil (Villamblain site) and from 1.39 to

Electrical Resistivity to Assess Soil Properties, Figure 2 2D electrical resistivity profiles in Estrées-Mons after tillage. The five electrical profiles (ERT1 to ERT5) were performed in the direction of the wheeling and tillage and the distance between the profiles was 15 cm. The black lines on the morphological profile correspond to the contours of the compacted blocks and the black arrow corresponds to the position of the wheel.

1.59 Mg m^{-3} in the loamy soil (Estrées-Mons site). The structure of bands under wheel tracks was Δ type, that is, cohesive and massive. For non-trafficked zones, the soil structure was more porous and aggregated, which is consistent with less compaction and disturbance.

Results of ERT are illustrated on Figure 1a (Villamblain site). For the soil layer 0–30 cm depth, resistivity was approximately equal to $10 \Omega\text{m}$ under the wheel tracks and $25 \Omega\text{m}$ outside the wheel tracks. The smallest value of resistivity was attributed to compaction. Besson et al. (2004) observed similar results in Estrées-Mons site, with a decrease in resistivity of $15 \Omega\text{m}$ (i.e., from 40 to $25 \Omega\text{m}$) due to compaction. This effect on resistivity was measured just after traffic and when the soil was wet, that is, close to field capacity. Indeed, resistivity variation due to compaction is generally exacerbated for dry soils.

Fragmentation after tillage (Estrées-Mons site)

Five electrical profiles called ERT1 to ERT5 were performed from the top of the plot, parallel to the traffic direction (Figure 2). The fragmentation of compacted band by tillage induced heterogeneous macrostructure with a mix of dense Δ clods embedded by large voids and porous matrix as shown on the morphological profile on Figure 2. Ten morphological profiles (not showed here) were performed perpendicular to the traffic line and this complex structure remained the same on each profile. The structural heterogeneity of the tilled layer greatly altered resistivity that varied then from ~ 25 to $\sim 250 \Omega\text{m}$ and the electrical resistivity was highly variable in the first 10 cm for each electrical profile. For the electrical profiles positioned outside the compacted band (ERT1, ERT2, and ERT5), resistivity was approximately equal to 50 – $70 \Omega\text{m}$. For the electrical profiles located in the position of the initial compacted band (ERT3 and ERT4), resistivity exceeded largely $70 \Omega\text{m}$ despite the presence of dense Δ clods. This last result was explained by void-surrounded clods. Even relatively small ones, voids generated noise in resistivity data, restricting the interpretation of ERT in terms of soil structure.

The high sensitivity of electrical resistivity to voids is then complementary to the morphological profiles that are, in turn, more efficient to describe the organization of Δ clods and loose material (Séger et al., 2009).

Cracks after drying (Villamblain site)

Samouëlian et al. (2004) have demonstrated, in laboratory conditions (on a soil block of 0.3 m^3), that the detection of cracks during a drying period was feasible through electrical resistivity measurements. Figure 1a–d shows the change in ERT in the field under natural conditions during several months after compaction (Villamblain site), not only due to moisture evolution but also due to structural evolution of the dense band.

First, the contrast in resistivity between compacted and non-compacted zones increased, as already mentioned (Figure 1a–c). It seems that the non-compacted zone dried out more rapidly in time than the compacted zone. This is consistent with a higher unsaturated hydraulic

conductivity expected for dense zones as suggested by Richard et al. (2001). Second, we observed high values of resistivity ($>100 \Omega\text{m}$) at three locations up to the dense band, that is, in the near soil surface (Figure 1b). These resistant zones extend during the drying period till beginning of August (Figure 1c). Anyhow, after a storm in August, the water content significantly increased in tilled layer and these zones had again a small resistivity (Figure 1d).

It seems that the cracks, as consequences of the severe drying that occurred in summer in the soil surface, enhanced resistivity values as previously shown in the laboratory. Cracks became preferential pores for water flows and therefore could again be characterized by a low electrical resistivity after a rainfall event.

Conclusions

Our results enhanced the feasibility of electrical resistivity measurements to characterize the heterogeneity of the soil structure at the profile scale without any soil sampling and soil pit. The geophysical method enables to define geometry of compacted band generated by traffic, to characterize the degree of fragmentation of the tilled layer with a decimetric resolution. Electrical Resistivity Tomography constitutes an alternative tool to the X-ray tomography for studies in the field. Further research is needed to improve quantification of the soil structure heterogeneity by geophysical methods and to elucidate the mechanisms responsible for the control of tillage on flow and transport.

ELECTROCHEMICAL MEASUREMENTS IN SOILS

Andrzej Bieganowski, Jolanta Cieśla
 Institute of Agrophysics, Polish Academy of Sciences,
 Lublin, Poland

Definition

Electrochemistry is a science (branch of chemistry) that deals with the electrical aspects of chemical reactions.

The main division of electrochemical methods used for testing of solutions is the following:

- Potentiometric methods – the potential of electrode is measured that depends on the ion activity of tested substance in the solution.
- Coulometric methods – the electrical charge transferred in redox (reduction/oxidation) reaction is measured (see [Oxidation–Reduction Reactions in the Environment](#)).
- Conductometric methods – the electric conductivity of tested solution is measured (see [Electrical Properties of Soils](#)).
- Voltammetric methods – the current–voltage characteristics of tested solutions are determined.
- Electrolytic methods – the mass of electrolysis products is measured.

Introduction

The use of electrochemical methods in soils encounters methodological problems that are not met in “solution” chemistry, which results from the fact that the soil is a three-phase and even a living (containing a huge number of living organisms) system (see [Agrophysical Objects \(Soils, Plants, Agricultural Products, and Foods\)](#)). The consequence of it is heterogeneity of the soil and variation of its properties in space and time. Moreover, what is very important in electrochemical measurements, it is very difficult to characterize the measurement conditions. Below soil water saturation state it is very difficult (and sometimes impossible) to describe the distribution of the liquid phase in the soil (see [Solute Transport in Soils](#) and [Hydraulic Properties of Unsaturated Soils](#)). A separate problem is the presence, practically always, of interfering substances in the soil.

Methodological problems cause different approaches to investigations in the soil. The easiest, and sometimes completely sufficient, are the measurements of soil extracts. These measurements do not practically differ from “pure” chemistry measurements.

The completely different approach of electrochemical measurements must be applied to measurements conducted directly in the soil (*in situ*). Most of the electrochemical methods can be applied in the laboratory as well in the field, but frequently the equipment must be different.

The specificity of tests in the soil causes that only a few methods can be applied for the measurement of this object. The most popular methods are (Brett, 2001) the following:

Potentiometric
 Voltammetric
 Conductometric

Potentiometric method

This method is based on measurement of the potential difference, which is created in an electrochemical cell composed of two electrodes (indicator electrode and reference electrode) immersed in the analyzed sample (Yu and Ji, 1993).

The measurement is made using a high-impedance voltmeter at zero current. Potentiometric signal is proportional to the logarithm of the investigated ion activity. However, the range of linear response of the electrode system is limited by many factors such as measurement conditions, sample composition, as well as electrode properties. The potentiometric method is simple, fast, and relatively cheap. The sensors are easily miniaturized.

Electrodes, which are used for potentiometric measurements, should give a stable and reproducible signal, have short recovery time, long lifetime, and strong mechanical construction.

The indicator electrode should be sensitive and selective enough to make analysis in the presence of other (interfering) ions. The signal of the reference electrode should be stable and independent of the ion activity of the analyzed component (Brzózka and Wróblewski, 1999). The calomel ($\text{Hg}/\text{Hg}_2\text{Cl}_2/\text{Cl}^-$) and silver/silver chloride (Ag/AgCl) electrodes are the most often used as the reference electrodes in potentiometric analysis of soil samples (Yu and Ji, 1993).

The most often used potentiometric sensors are the ion-selective electrodes. These electrodes consist of an ion-selective membrane, one side of which is in contact with the measured solution and the second side with the inner electrolyte solution. The permselective mass transfer (by the ion-exchange mechanism or other mechanism) across a phase boundary causes the Gibbs energy change and the potentiometric signal change in a consequence (Buck and Lindner, 1994).

An example of an ion-selective electrode is the pH glass electrode, which is built of aluminosilicate glass bubble containing an inert pH buffer solution and an inert reference electrode. At the sample solution/outside part of the glass membrane interface the thermodynamic equilibrium of hydrogen ions is obtained. If the hydrogen ions activity in both phases (sample and membrane) is different, then the ions are carried out. The resultant potential (E_1) depends on the activity of the hydrogen ions in the sample solution and the outside part of the glass membrane. The potential at the inside part of the glass membrane/inert pH buffer interface (E_2) depends on the hydrogen ions activity in the buffer solution and the inside part of glass. The total potential is equal to the difference between E_1 and E_2 . If the hydrogen ions activity in both parts of the glass membrane is the same and this activity in the buffer solution is constant, the potential of glass electrode depends only on the hydrogen ions activity in the sample solution (Brzózka and Wróblewski, 1999).

In the presence of interfering ions in the sample, the potential of the ion-selective electrode depends also on the activity of these ions and on the selectivity coefficient of the electrode.

According to IUPAC (International Union of Pure and Applied Chemistry) recommendation, there are three main types of ion-selective electrodes classified as (Buck and Lindner, 1994):

1. Primary ion-selective electrodes:

- (a) *Crystalline electrodes* (with *homogenous* or *heterogeneous* membrane). Homogenous membrane is prepared from a single compound or a homogenous mixture of compounds. In the heterogeneous type of electrodes, an active substance or mixture of substances is placed in a matrix of the ion-selective membrane.
 - (b) *Noncrystalline electrodes*, whose ion-selective membrane placed between two aqueous solutions is composed of an ion exchanger, a plasticizer solvent, and some selectivity-enhancing species. This type of electrodes can be divided into two groups:
 - *Rigid, self-supporting, matrix electrodes*, where the thin polymer with charged sites or a thin piece of glass is a sensing membrane. Selectivity of these membranes is determined by the polymer or glass composition.
 - *Electrode with mobile-charged sites* on the membrane (positively charged, hydrophobic cations on the membranes, which are sensitive to changes of the anions activity; negatively charged hydrophobic anions on the cation-selective membranes; uncharged ion carrier, which creates complexes with the anions or cations; hydrophobic ion pair electrodes of plasticized polymers containing a dissolved hydrophobic ion pair).
2. Compound or multiple (multi layer) ion-selective electrodes (gas-sensing electrodes and enzyme-substrate electrodes).
3. *Metal contact or all-solid-state ion-selective electrodes*, which do not have an inner electrolyte solution and the selective constituent is placed on the electronic conductor.

The potentiometric method can be used in different ways (Yu and Ji, 1993):

- *Direct indication* of ion activity basing on linear part of calibration curve. Some limitation is that the composition and ionic strength of calibration solutions and the sample should be nearly the same.
- *Known addition method*, when a small volume of standard solution is added to the sample and the potential is measured before and after the addition.
- *Known subtraction method*, when a small volume of precipitating or complexing agent solution is added to the sample to decrease the determined ion activity by about 50%. The potential is measured before and after the addition.

Most potentiometric measurements are carried out in solutions and/or in soil extracts, because solid phase affects the results due to the suspension effect. This effect is connected with an additional change of ion-selective electrode potential (*suspension effect of the first kind*) and reference electrode potential (*suspension effect of the second kind*) when they are immersed in the suspension. When

the ion-selective electrode is placed in a sediment or suspension, an additional potential is created due to the overlapping of the electrode diffuse double layer with the particle diffuse layers (see [Diffuse Double Layer \(DDL\)](#)). The second kind suspension effect is connected with changing the transference numbers of the cations and anions flowing out from the salt bridge solution of the reference electrode to the vicinity of surface-charged particles in the sample. The anomalous values of liquid junction potential are the results of the above (Oman et al., 2007a, b).

The potentiometric method is most often used in pH determination. The analyses are made by means of a glass electrode in a 1:5 (volume fraction) suspension of soil in water (pH in H_2O), in 1 mol/dm³ potassium chloride solution (pH in KCl), or in 0.01 mol/dm³ calcium chloride solution (pH in CaCl₂), according to the procedure of ISO 10390:2005 (Black, 1965; ISO 10390, 2005).

Potentiometric sensors are used mostly for analysis of liquid samples in laboratory conditions, according to the mentioned limitations of the method. However, some investigation are undertaken to apply the sensors in automatic mobile systems of soil monitoring. The ion-selective electrodes or ion-selective field effect transistors, due to the possibility of their miniaturization, are placed on machines, which are moving across the field and taking soil samples in combination with the geographical position registration. Some of the proposed equipment can extract soil solution in the field for making potentiometric analysis just after, and the other make ionometric measurements directly in moist soil (Adamchuk et al., 2004). However, it should be marked that the last method gives unreliable data due to unknown value of the suspension effect.

In soil research, the potentiometric titration is used also for characterization of the soil buffer capacity ([Buffer Capacity of Soils](#)) by acid-base titration and for surface charge of solid phase (minerals) by back-titration: subtraction of solution titration curve from the suspension titration curve gives solid phase variable charge vs. pH dependence.

Voltammetric methods

Voltammetric methods measure the electric current as a function of the applied electric potential and interpret the current–voltage relationship ([Figure 1](#)).

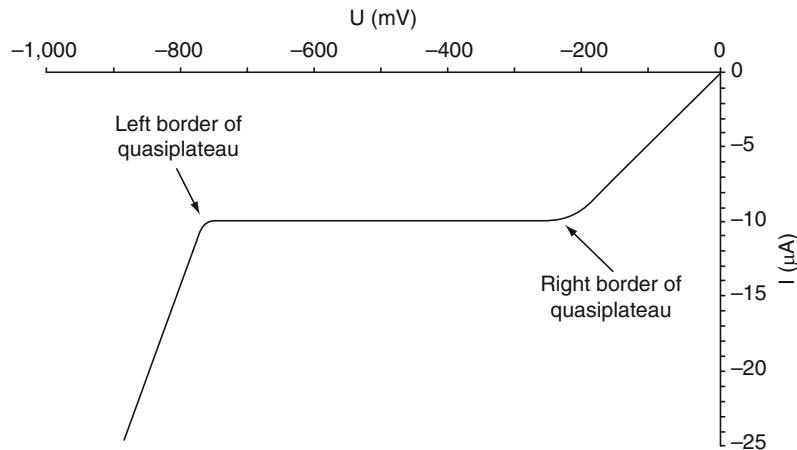

Common in soil science simplification of voltammetric methods is the amperometric one measuring the electric current in the system at an electric potential that is fixed at a constant value.

Oxygen diffusion rate (ODR) measured by amperometric method and oxygen flux density (OFD) measured by voltammetric method are important soil parameters.

The ODR describes the potential oxygen flux density in the soil. The measurement unit of ODR is g cm⁻² s⁻¹. The measurement can be realized in two ways:

1. The first proposition of Lemon and Erickson was based on a two-electrode setup. The cathode was made of platinum wire melted into the glass. The anode was a saturated calomel electrode (SCE) or a silver/silver chloride electrode. The potential, which was applied, had to be high enough to reduce the molecules of oxygen on the electrode but smaller than the potential of water electrolysis (usually -0.65 V). Due to the ambiguous determination of the real potential of platinum cathode in relation to the soil solute under a specific voltage applied to the electrodes, this method became a subject of criticism (Bieganowski, 2004).
2. The problem of precise controlling of the cathode potential was solved by Malicki and Walczak (1983) by incorporation into the measuring system a third electrode (a reference electrode) which, by the system of potentiostat, made it possible to arrange the potential of the platinum cathode (Bieganowski, 2004).

For determination of the OFD (g cm⁻² s⁻¹) the full current–voltage curve is registered (the potential of the cathode is linearly changed) and the values of the current at the plateau range ([Figure 1](#)) are used to calculate the oxygen flux density. The advantage of using the

Electrochemical Measurements in Soils, Figure 1 Idealized current–voltage curve (Bieganowski, 2004).

voltammetric method is the possibility of rejection of non-interpretable measurements (for instance when the soil moisture content is too small there is the lack of the plateau on the current–voltage curve and such a measurement should be rejected).

Both the ODR and OFD methods have the same assumptions:

- The only substance, which is reduced on the cathode (at established or changing potential) is oxygen.
- The concentration of oxygen on the cathode surface is equal to zero.
- The only way of oxygen transport to the electrode surface is diffusion (when this assumption is not valid there is a lack of plateau on the current–voltage curve).

In a real situation, the ODR and OFD methods can be used in saturated or nearly saturated mineral soils (organic substances can be reduced simultaneously with oxygen, which can be the source of the method error).

Applications of voltammetric methods in the soil solution and extracts measurements have less significance.

Conductometric method

Conductometric methods are based on the relation between the composition of a reference solution and the electrical conductance of tested solution/suspension. These methods are simple, rapid, nondestructive, and possible to use directly in the soil. The conductometric measurements characterize only the total amount of ions and not individual ions; however, the popularity of conductometric methods in the soil sciences lies in that the bulk conductivity of the soil solution is well correlated with soil total salt content. Therefore, the method is frequently used for saline soils and mineral fertilization status studies.

The interpretation of conductometric measurements in the soils is more complicated than in “pure” solutions because soil is a more complicated medium. The electric conductivity of soil as a whole can markedly differ from the conductivity of its equilibrium solution due to

- Additional electric current caused by movement of surface-charged soil colloids in the electric field together with ions.
- Input of surface conductance (the adsorbed ions in the electrical double layer can migrate in the electric field).
- Uneven and elongated paths of the ions and charged mineral/soil particles in complex soil pore system.
- Increased electrical resistance of air-filled soil pores.

The conductometric methods can be divided into two groups:

- AC methods – the alternating-current (AC) is used.
- DC methods – the direct-current (DC) is used.

Both groups of methods have specific advantages and limitations. The most important problems are the capacitance, inductance, and polarization. These phenomena

can be under control depending on the electrode construction, for instance. For details one can be referred to the very good study by Yu and Ji (1993).

Conductometric titration, a useful method in soil investigations (for instance for estimation of *Cation–Exchange Capacity, CEC*), must be carried out in soil extracts and therefore is beyond the scope of this entry.

In the second half of the twentieth century, there were attempts at using conductometric (or resistance – see *Electrical Resistivity to Assess Soil Properties*) methods for determination of soil moisture content. As it turned out, this approach failed because these methods are not selective, not stable, and highly dependent on the temperature, salinity, texture, density, and pH of the soil (Malicki, 1993).

Summary

Some of the electrochemical methods are very important in the measurements of soil properties. The most often used of them are potentiometric (in pH measurements and ion-selective electrodes for some soil solution ions) and conductometric (in soil solution conductivity measurements) ones. The electrochemical methods are comparatively simple, cheap, and reliable. The measuring procedures and equipment are continuously improved and developed.

ELECTROKINETIC (ZETA) POTENTIAL OF SOILS

Mieczysław Hajnos, Jolanta Cieśla

Institute of Agrophysics, Polish Academy of Sciences,
 Lublin, Poland

Definition

From a theoretical viewpoint, *zeta potential* is electric potential in the interfacial double layer (DL) at the location of the slipping plane versus a point in the bulk fluid away from the interface. Electrokinetic potential in colloidal systems is called zeta potential. In the colloidal chemistry literature, it is usually denoted using the Greek letter zeta, hence ζ -potential. Thus, zeta potential is the potential difference between the dispersion medium and the stationary layer of fluid attached to the dispersed particle.

Introduction

Soil colloids are particles of diameter below 0.002 mm. They are formed by clay minerals (crystalline aluminum silicates of kaolin, montmorillonite, and illite groups, crystalline hydrated aluminum and iron oxides, amorphous minerals, humus as well as clay – humus complexes).

Colloid is composed of (Delgado et al., 2005) the following:

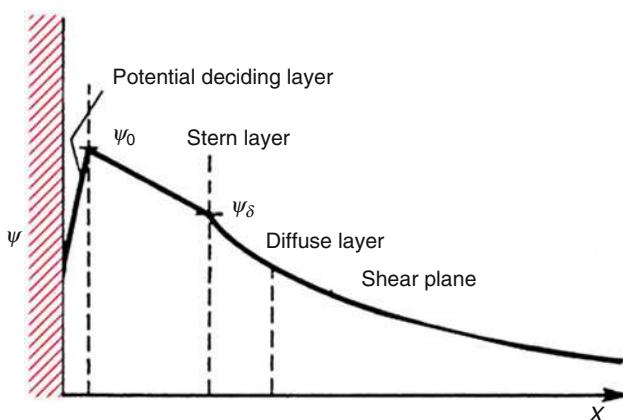

- (a) Kernel (micelle) of crystalline or amorphous structure and porous or dense construction
- (b) Internal layer of cations or anions, which constitutes a component of the kernel
- (c) External layer of compensating ions of opposite charge to the ions of internal layer

The most important colloid properties are determined by their electric charge occurred on the surface of colloid particles. Soil colloids are most often negatively charged (Sequaris and Lewandowski, 2003; Delgado et al., 2005).

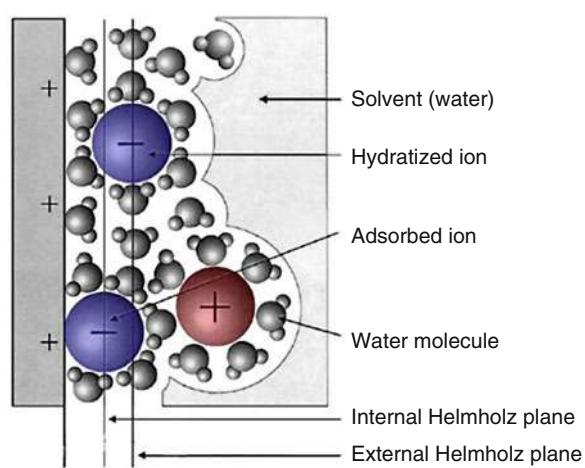

The value of electric charge depends on the composition of colloid kernel and sources of the charge are the following:

- (a) Unsaturated valencies occurring on the edges of silicate alumina layers, on the internal mineral surfaces as well as on the humus particles.
- (b) Interlayer exchange in crystals of minerals.

Electric charge of one symbol formed on the surface of colloid particles creates from the side of liquid, as a result of electrostatic interactions, the layer of opposite ions composed of exchangeable ions (dynamic Stern layer) (Figure 1) (Delgado et al., 2005). In the layer, ions are permanently connected with the micelle and can be taken into account as its component. Around the Stern layer are situated ions of the same charged sign as in Stern layer but there are hydrated ones. This layer is called as external Helmholtz layer (Figure 2). Next is situated the layer of heteronymous charged ions (diffusive layer). There are mobile ions, in which concentration decrease directly proportionally with the increase of distance from the micelle

Electrokinetic (Zeta) Potential of Soils, Figure 1 Dependence of potential against an interface distance.

Electrokinetic (Zeta) Potential of Soils, Figure 2 Structure of a double layer (DL).

surface, reaching ion equilibrium state with the solution. Ions of Stern layer and external Helmholtz layer hold on the colloid surface, whereas ions of diffusive layer are moving freely with the movement of solution in relation to solid. On the border of these two layers (mobile and immobile) called sliding layer, is found electric potential called electrokinetic potential or zeta potential.

The consequence of existence of electric double layer is electrokinetic phenomena (EKP).

Electrokinetic phenomena (EKP)

Electrokinetic phenomena (EKP) can be defined as all those phenomena involving tangential fluid motion adjacent to a charged surface. They are manifestations of the electrical properties of interfaces under steady-state condition and isothermal condition. In practice, they are often the only source of information available on those properties. For this reason, their study constitutes one of the classical branches of colloid science, electrokinetics, which has been developed in close connection with the theories of the electrical double layer (EDL) and of electrostatic surface forces (Dukhin and Derjaguin, 1974; Hunter, 1981; Lyclema, 1995; Hunter, 2001). From the point of view of nonequilibrium thermodynamics, EKP are typically cross-phenomena, because thermodynamic forces of a certain kind create fluxes of another type. For instance, in electroosmosis and electrophoresis, an electric force leads to a mechanical motion, and in streaming current (potential), an applied mechanical force produces an electric current (potential). First-order phenomena may also provide valuable information about the electrical state of the interface: for instance, an external electric field causes the appearance of a surface current, which flows along the interfacial region and is controlled by the surface conductivity of the latter. If the applied field is alternating, the electric permittivity of the system as a function of frequency will display one or more relaxations. The characteristic frequency and amplitude of these relaxations may yield additional information about the electrical state of the interface.

A brief description of the main and related EKP (Buckman and Brady, 1969; Dukhin and Derjaguin, 1974; Hunter, 1981; Lyclema, 1995; Hunter, 2001, Delgado et al., 2005):

Electrophoresis is the movement of charged colloidal particles or polyelectrolytes, immersed in a liquid, under the influence of an external electric field. The electrophoretic velocity, v_e (m s^{-1}), is the velocity during electrophoresis. The electrophoretic mobility, u_e ($\text{m}^2 \text{V}^{-1} \text{s}^{-1}$), is the magnitude of the velocity divided by the magnitude of the electric field strength. The mobility is counted positive if the particles move toward lower potential (negative electrode) and negative in the opposite case.

Electroosmosis is the motion of a liquid through an immobilized set of particles, a porous plug, a capillary, or a membrane, in response to an applied electric field. It is the result of the force exerted by the field on the

countercharge in the liquid inside the charged capillaries, pores, etc. The moving ions drag the liquid in which they are embedded along. The electroosmotic velocity, v_{eo} (m s^{-1}), is the uniform velocity of the liquid far from the charged interface. Usually, the measured quantity is the volume flow rate of liquid ($\text{m}^3 \text{s}^{-1}$) through the capillary, plug, or membrane, divided by the electric field strength, $Q_{eo,E}$ ($\text{m}^4 \text{V}^{-1} \text{s}^{-1}$), or divided by the electric current, $Q_{eo,I}$ ($\text{m}^3 \text{C}^{-1}$). A related concept is the electroosmotic counterpressure, Δp_{eo} (Pa), the pressure difference that must be applied across the system to stop the electroosmotic volume flow. The value Δp_{eo} is considered to be positive if the high pressure is on the higher electric potential side.

Streaming potential, U_{str} (V), is the potential difference at zero electric current, caused by the flow of liquid under a pressure gradient through a capillary, plug, diaphragm, or membrane. The difference is measured across the plug or between the ends of the capillary. Streaming potentials are created by charge accumulation caused by the flow of countercharges inside capillaries or pores.

Sedimentation potential, U_{sed} (V), is the potential difference sensed by two identical electrodes placed some vertical distance L apart in a suspension in which particles are sedimenting under the effect of gravity. The electric field generated, U_{sed}/L , is known as the sedimentation field, E_{sed} (V m^{-1}). When the sedimentation is produced by a centrifugal field, the phenomenon is called centrifugation potential.

Measurement of the zeta potential of soil material

For the measurement of the zeta potential of soil material, two groups of methods are most frequently used. The first group consists of methods based on the electrophoretic phenomenon, and the second based on electroosmosis. The application of the electrophoretic methods in soil material, however, is limited because they allow the measurement to be carried out only on the colloidal fraction (Delgado et al., 2005).

The *electroosmotic methods* are more suitable for soil material because they make possible the carrying out of measurements in soils of natural granulometric composition.

The value of the zeta potential can be calculated by substituting the experimental data for the Smoluchowski equation (Smoluchowski, 1921)

$$\zeta = -\frac{\eta \chi V}{\varepsilon E} \quad (1)$$

where χ – proper conductance of solution; V – velocity of liquid transportation – electroosmotic velocity; E – current intensity; η – dynamic viscosity of liquid; ε is the dielectric constant of the medium.

In the *electrophoresis method* (Buckman and Brady, 1969; Hunter, 2001), the ζ -potential can be determined by placing fine particles in an electric field and measuring their mobility, V_E , using a suitable microscopic technique.

The mobility is then related to the ζ -potential at the interface using the Smoluchowski equation

$$\zeta = \frac{V_E \eta}{\varepsilon} \quad (2)$$

where η is liquid viscosity, ε is the dielectric constant of the medium.

The *streaming potential technique* has been extensively applied to flat surfaces to study solid–liquid interface electrical properties (Delgado et al., 2005) in a parallel plate microchannel. In this technique, the downstream convection of ions via pressure-driven flow induces a streaming potential which, for steady incompressible and laminar flow, can be related to the ζ – potential:

$$\zeta = \frac{\eta \chi V_{str}}{\varepsilon P} \quad (3)$$

where η is liquid viscosity, ε is the dielectric constant of the medium, P is the pressure causing flow, V_{str} is the streaming potential measured, and χ is the proper conductance of solution.

Other techniques for determination of electrophoretic mobility or zeta potential of minerals as well as soil particles in suspension are electrophoretic light scattering (ELS), known as laser Doppler velocimetry method (Chip et al., 2003; Delgado et al., 2005) and electroacoustics – especially the electrokinetic sonic amplitude (ESA) measurement (Chip et al., 2003; Greenwood et al., 2007).

Laser Doppler velocimetry is the optical method based on the phase analysis light scattered by charged colloidal particles, which are immersed in liquid and moved in external electric field (Delgado et al., 2005). The frequency of the light scattered by the moving particles is shifted in comparison with the light emitted from the source (Doppler effect). If the directions of the incident light, the scattered light and particles movement are known, this shift is proportional to the particles' speed. As a monochromatic coherent light source in the measurement systems, the Helium–Neon or Argon–Ion lasers are very often used. Application of alternating electric field during measurement, whereas the particles are still able to move according to their electrophoretic mobility, reduces the polarization of electrodes and eliminates the influence of electroosmotic effect on the results. Laser method is automated, quick, and it needs only small volume of soil suspension (a few milliliters). On the other hand, there are some requirements for the analyzed samples (Delgado et al., 2005):

- (a) The continuous phase should be transparent liquid with refractive index different from that of dispersed particles.
- (b) The upper size of charged particles should be rather lower than 30 μm (diameter), because of sedimentation occurrence.
- (c) Dilution must be enough for particles not to interfere with each other.

- (d) Fluorescence of sample may inhibit measurement by reduction in the signal-to-noise ratio.

Electrokinetic sonic amplitude (ESA) is connected with the application of alternating electric field to a suspension where particles density differs from that of continuous phase. Electrophoretic motion of particles in this electric field causes the increase of a sound wave (Delgado et al., 2005).

It should be noticed that the used method affects in some way the obtained results, and even by the same measurement conditions as well as sample preparation techniques, the values of electrophoretic mobility or zeta potential may be different.

Zeta potential effects on soil

Zeta potential decides on surface phenomena occurring on solid–liquid interface. Such phenomena are processes of aggregation and peptization of soil colloids. The phenomena follow from the occurrence of opposite forces, which result from the distribution of ions surrounding the colloid kernel. Sphere of ions (ion layers) around the micelle leads to rise repulsing and attraction forces. Repulsion forces appear in moment of approach of two particles, when their double electrical layers begin to overlap. For connection of two particles, the energy is needed of higher level than repulsion forces. The level of indispensable energy markedly increases when particles are closer and closer. Maximum electrostatic repulsion force describes surface potential of particles.

Van der Waals attraction forces are the result of interaction of individual molecules of every colloid particle in such a way that every molecule of first particle attracts every molecule of the second one. Total attraction force is a sum of interaction of all molecules. The theory interpreting surface interactions (balance of repulsion and attraction forces) is elaborated by Derjaguin, Landau, Verwey, and Overbeek and in short called DLVO theory. The theory interprets phenomena such as aggregation, coagulation, flocculation, and peptization of colloids.

Aggregation consists in joining of individual colloid particles in larger agglomerations called aggregates. Run of the process can perform in double manner: coagulation and flocculation, that is, joining of colloids by hydration layers, without previous decrease of electrokinetic potential

Coagulation, that is, joining of colloids as a result of decrease of electrokinetic potential, can happen in soils under the influence of electrolytes (mineral fertilizers) introduced to soils. Strong concentration of ions in internal micelle layers and decrease of their electrokinetic potential takes place as the result of it. Moreover, the degree of coagulation interaction of ions on negatively charged colloid particles is the greater, the higher diameter and valency as well as lower hydration of ion. Especially strong influence on soil colloids is exhibited by hydrogen and aluminum ions.

Flocculation, that is, joining of colloids by hydration layers, without previous decrease of electrokinetic

potential, in soils can run spontaneously or under influence of flocculants. Often flocculation occurs during desiccation of soils or during consecutive periods of their freezing and defreezing when dehydration of soil colloids occurs. Synthetic flocculants are organic substances (ionic and nonionic polymers), which bind colloids together with the aid of hydrogen bonds.

Peptization is the process responsible for the formation of stable dispersion of colloidal particles of soil in water.

Summary

Potential zeta or electrokinetic potential is a property of charged interfaces, for example, soil surface/soil solution. The consequence of existence of electric double layer is electrokinetic phenomena such as electrophoresis, electroosmosis, streaming potential, and sedimentation potential. Zeta potential can be measured mainly by electroosmotic and electrophoretic methods. Zeta potential decides on surface phenomena occurring on solid–liquid interface. Such phenomena for example are processes of aggregation and peptization of soil colloids.

ELECTROMAGNETIC FIELDS, IMPACT ON SEED GERMINATION AND PLANT GROWTH

Stanisław Pietruszewski

Department of Physics, University of Life Sciences,
Lublin, Poland

Introduction

The germination, growth, yield, and quality of crops are determined by the properties of seed material, which can be improved by pre-sowing treatment with the involvement of various physical factors such as the electric field, magnetic field, laser radiation, and microwave radiation. Physical methods applied in the treatment of greenhouse plants include also the use of magnetically treated water.

The first experiments investigating the effect of magnetic fields on biological organisms, including plants, were carried out in the second half of the nineteenth century. The first publication on the subject was the study by J. Reinke dating back to 1876, which discussed the results of experiments into the magnetic field's effect on plant development (Reinke, 1876). This study did not report a relationship between the magnetic field and seed germination and plant growth. Similarly D'Aste (1882) did not find any links between the magnetic field and seed germination, while Tolomei (1893) observed that the magnetic field speeded up germination. Tolomei was also the first scientist to discover the effect of magnetotropism. This phenomenon was further investigated by Audus (1960). Volume 1 and Volume 2 monograph by W. J. Danilewski (1901) in which the author discussed the experimental and theoretical grounds of the effect of magnetic fields on various biological structures, ranging from cells to entire organisms.

Another classic and historical publication is a study of Eward (1903). Eward observed that when aquatic plants (*Valisneria* and *Chara*) were placed in a magnetic field, their cytoplasmic motion ceased when magnetic field lines were perpendicular to the direction of that motion. This effect was not observed in a parallel magnetic field. Thirty years later, this phenomenon was validated by Sawostin (1930). He noted that cytoplasmic motion was reduced by 15–30% in a parallel magnetic field with the intensity of 7,000 Oe (0.7 T). Cytoplasmic motion was speeded up in a perpendicular magnetic field with the same intensity. Sawostin also observed that the magnetic field accelerated root growth and increased cell membrane permeability. The above findings enabled the researcher to grow wheat germs 100% longer than average (Presman, 1971). Biomagnetic research flourished only in the 1960s

when a number of breakthrough publications reporting on the magnetic field's effect on live biological organisms were published in the USA (Barnothy, 1964, 1969) and the former USSR (Presman, 1971).

The pre-sowing effect of magnetic fields on seed material

The pre-sowing stimulation of seeds with a magnetic field may involve a constant magnetic field produced by permanent magnets and electromagnets as well as a variable magnetic field. A variable magnetic field is produced by specially designed electromagnets. In general, magnetic fields speed up seed germination and plant growth. The intensity of the applied magnetic fields and the time of seed exposure vary greatly.

In an experiment involving a very weak constant magnetic field of 0.5 mT, Nowitzky et al. (2001) noted an increase in leaf size as well as higher protein and chlorophyll levels in onion sets. Aladjadjiyan (2002) observed the effect of lengthening of monopodiums of sweet corn cultivated under 150 mT constant magnetic fields and in the case of alternating magnetic fields of 60–200 mT also the growth in the crop yield. Carbonell et al. (2000) noted higher rice seed germination rates under the influence of 150 and 200 mT magnetic fields as well as faster growth rates of barley subjected to a magnetic field with the intensity of 125 mT with exposure time of 24 h (Martinez et al., 2000). Atak et al. (2003) subjected soybean seeds to magnetic fields of 2.9–4.6 mT and noted accelerated root growth as well as an increase in the levels of chlorophyll *a* and *b*.

Rochalska and Grabowska (2007) demonstrated that a variable magnetic field of 16 Hz, 5 mT, lowers the activity of alpha-amylase and beta-amylase enzymes in wheat. Aksenov et al. (2001) noted an increase in the growth rates of wheat roots and germs under the influence of a 50 Hz, 30 mT magnetic field. The effect of a weak magnetic field with the intensity of 20 µT and frequency of 16% Hz increased the weight and height of sunflower plants and enhanced wheat germination rates (Fischer et al., 2004). Ratusnyak et al. (2008) demonstrated that high-frequency magnetic fields of 30–60 GHz with a stream from 10^{-16} to 10^{-10} W cm⁻² and exposure time of 5–15 min stimulated the growth of microflora in pine seeds.

The above data indicate that the results noted at various research centers are difficult to compare. Difficulties are also encountered when interpreting the results of pre-sowing stimulation of seeds with an electric field. This is related to a very broad range of intensity of magnetic fields and varied exposure times. To facilitate the comparison of results from various studies a common unit, being the product of magnetic (electric) field density and exposure time, has been proposed (Pietruszewski, 1999; Pietruszewski et al., 2007). The density of a magnetic field or an electric field is determined with the use of the following formula:

$$\rho = \frac{1}{2} \varepsilon_0 E^2 = \frac{1}{2} \mu_0 H^2 = \frac{1}{2\mu_0} B^2 \quad (1)$$

where ε_0 – vacuum permittivity, μ_0 – vacuum permeability, E – electric field intensity, H – magnetic field intensity, B – magnetic induction.

The exposure dose is described by the following dependence:

$$D = \rho \cdot t \quad (2)$$

where t – exposure time.

The magnetic exposure dose dependencies of germination kinetic and the wheat crop yield were previously by Pietruszewski and Kania (2010).

Mechanism of interaction

The discovery that an external magnetic or an electromagnetic field affects the development of living organisms prompted scientists to postulate various hypotheses explaining this phenomenon. They attempted to develop a scientific model based on the classical laws of electrodynamics. Researchers assumed that an external magnetic field should affect the permeability of the cell membrane and, consequently, the diffusion of ions, mainly sodium Na⁺ and potassium K⁺ ions and hypothesized that:

1. Changes in the rate and mechanism of diffusion and in the biological orientation of macromolecules with a magnetic susceptibility
2. Changes in the probability of mutual interactions in biochemical reactions owing to the magnetic field's effect on the electron structures of molecules

Although the above hypotheses offer some fascinating insights, they are difficult to validate experimentally due to a very broad range of the applied intensity levels as well as the characteristic attributes of fields (constant and variable fields). Constant magnetic fields exert a different effect on organic structures than variable fields. According to Wadas (1991), a magnetic field's effect on living organisms can be through the effects on: non-compensated electron spins, liquid crystals in the organisms, and moving positive and negative charges.

The generation of induction microcurrents is yet another effect that can be attributed to a variable (alternating) magnetic field. Wadas (1991) argued that a magnetic field whose intensity falls below a given threshold level, which is difficult to determine and which varies between organisms, stimulates enzymatic activity and speeds up metabolism. An increase in enzymatic activity under the influence of a magnetic field is also observed in animal organisms. This observation prompted Wadas to formulate a hypothesis that the above is a general law of nature. It should also be noted that magnetic field does not exert a selective effect on living organisms, but impacts all molecules, including those that do not need it.

In his work entitled *Magneto-Biophysics – A New Dimension in Research*, Weiss (1989) writes that although the effect of magnetic fields on living organisms (humans, animals, plants) had fascinated scientists for centuries, magneto-biophysics is still in its infancy as a science. Weiss believes that magnetic fields will have numerous applications in biology, medicine, agriculture, and food economics in the nearest future. Magnetic ions and molecules are found in an excited state only in living organisms. Such states are ascribed to the effect of electrostatic, magnetostatic, electromagnetic, and gravitational fields. The mutual interactions between those fields and their effect on cells and living organisms continue to pose new challenges for physicists and biologists (Wadas, 1991).

Conclusion

Pre-sowing treatment involving the exposure of seed material to a magnetic or an electromagnetic field improves germination rates, seedling growth and yield. This effect is determined by seed type, magnetic field, and the time of exposure. Owing to a high variety of the applied fields, a unit of measure that best describes the pre-sowing stimulation of seeds is the magnetic exposure dose that accounts for both field intensity and exposure time. The mechanism of magnetic and electromagnetic fields' interaction with biological structures has not been fully elucidated to date. The presented hypotheses describe a specific phenomenon, and they do not propose a general theory. The discussed methods of pre-sowing treatment of seeds are environmentally friendly, and they should find a broad range of applications.

ENERGY BALANCE OF ECOSYSTEMS

Andrzej Kędziora
 Institute for Agricultural and Forest Environment, Polish Academy of Sciences, Poznań, Poland

Definition

The set of all energy fluxes incoming and outgoing from any active surface or layer of any object are called energy

balance. Usually fluxes incoming to the system are taken as positive, while the outgoing as negative.

Introduction

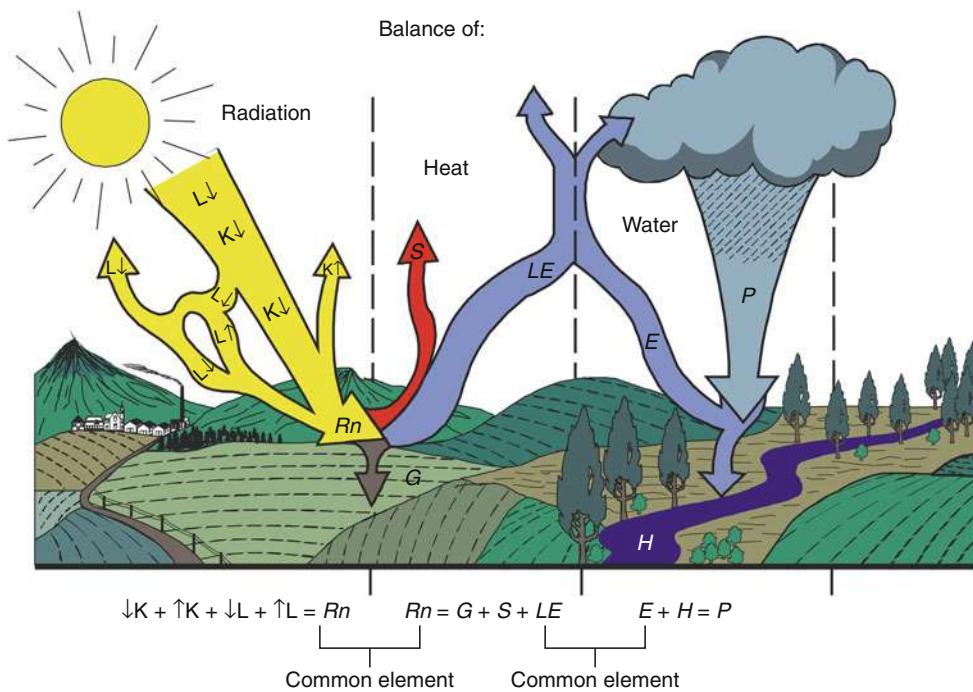

On a global scale, there are two processes that form the basis for all other processes occurring in nature. These are energy flow and matter cycling (Ryszkowski and Kędziora, 1987, 2004). Energy supply, at least, from the theoretical point of view is not limited (because of the sun activity), but water supplies are limited and not restored. These two processes are strongly linked and their quantitative characteristics are best accomplished by water and energy balances.

Electromagnetic radiation coming from the sun is the main input of energy for the earth ecosystems. Incoming solar radiation is composed predominantly of visible and near infrared shortwave radiation characterized by the high capacity to perform works during its transformations (Rosenberg, 1974). The output of energy into the cosmic space is mainly in the form of long infrared radiation of which intensity depends on temperature of the body surface, showing lower capability for performing work (higher entropy).

The conversion of solar energy is the driving force for processes in the majority of ecosystems or landscapes under normal conditions (Frangopoulos, 2003; Ryszkowski and Kędziora, 2004). The influx of solar energy can be partitioned mainly into fluxes used for evapotranspiration – ensuring water cycling, then for air heating – determining local temperatures and air mass transfers and for soil and water heating. In addition to these four main (from the quantitative point of view) fluxes, there are much smaller fluxes, but very important from the functionality point of view. They are the flux of advection, photosynthesis, and flux stored in the biomass.

Energy balance

There are three balances that should be considered together if anyone would like to characterize the energy balance in the ecosystem fully. They are radiation balance, heat balance, and water balance (Figure 1). Radiation balance determines the energy (leaving out nuclear and geothermal energy) being the moving force of all processes and support of life, as well as the source of energy used by human community. The set of all energy fluxes is called the heat balance equation. In the same way, the set of all water fluxes incoming into the system or outgoing is called the water balance equation (Kędziora and Olejnik, 1996; Piccolo, 2009). All energy fluxes incoming into the system and outgoing must be balanced to keep the system in equilibrium. The heat balance and the water balance are joined by latent heat flux (heat balance) and evaporating water (water balance). It means that the heat balance determines the energy, which can be used for evapotranspiration, but on the other hand, the water balance affects the structure of heat balance. In the nature some kind of “rule of evapotranspiration priority” exists,

Energy Balance of Ecosystems, Figure 1 Radiation, heat, and water balances of an agricultural landscape.

which says that if in the system there is enough available water for evaporation, the system directs all energy fluxes toward evaporating surface to cover the energetic cost of this process, using not only whole net radiation but also changing the direction of sensible and soil heat fluxes (Monteith, 1975; Kędziora and Ryszkowski, 1999; Olejnik et al., 2002).

This phenomenon can be explained as follows. Intensive evapotranspiration of plant cover occurs in relatively lower temperature, because most of the net radiation is used for this process, so much less energy can heat leaves and air. Thus, during the process of evapotranspiration the entropy production is higher than in the other processes (entropy is equal to the useful energy divided by temperature in which the process occurs). According to thermodynamics laws, this process is realized first, which produces the highest amount of entropy.

Taking into account the impact of ecosystems on energetic effect of solar energy point of view, intensively evaporating surface can be called “coolers of environment” while the dry surfaces, like the field after harvesting, can be called “heaters of environment.”

Radiation balance of a system

Radiation balance is usually written down in the form:

$$Rn = Rs(i) + Rs(o) + Rl(i) + Rl(o)$$

The net radiation (Rn) is the result of incoming and outgoing shortwave and longwave radiation fluxes and the reflection coefficient (albedo) of the ecosystem surface.

Incoming shortwave radiation flux, $Rs(i)$, depends mainly on sky cloudiness and solar elevation, which is a function of a day in a year and latitude. Outgoing shortwave radiation flux, $Rs(o)$, depends on albedo (α) of an ecosystem $Rs(o) = \alpha \cdot Rs(i)$. Incoming longwave radiation flux, $Rl(i)$, depends only on temperature of upper atmosphere during sunny days and on temperature of cloud bottom during cloudy days, while outgoing longwave radiation flux, $Rl(o)$, depends on the earth surface temperature. Solar energy reaching the earth system is determined by “solar constant,” which is defined as “solar radiation flux density measured at the earth orbit.”

Heat balance of a system

As it was said in the “Introduction” that the heat balance and the water balance are strongly linked, so the further description will relate to these two balances.

Heat balance equation is usually written in the form:

$$Rn + S + G + LE + A + F + M = 0,$$

where Rn , net radiation; LE , latent heat of evapotranspiration; S , sensible heat of air heating; G , soil heat; A , heat of advection; F , heat of biogeochemical processes; and M , heat stored by plant cover (all expressed in $\text{W} \cdot \text{m}^{-2}$). Usually the last three components are omitted because their values do not exceed a few $\text{W} \cdot \text{m}^{-2}$. But in some cases the advection must be included into equation. For example, when intensively evaporating ecosystem is surrounded by dry areas (forest island located between

grain crop fields after harvesting) the advection flux density can reach as much as 40% of net radiation.

The water balance equation is usually written in form:

$$P + E + H \pm \Delta R = 0,$$

where P , precipitation; E , evapotranspiration; H , run-off; ΔR , changes in soil water retention (all expressed in mm). There are many factors that determine the value of particular components of the heat and water balances. The main factors are as follows:

Net radiation is a function of:

- Solar radiation determining the density of energy flowing toward active surface and depending on season and latitude
- Relative sunshine expressing the time of full solar radiation
- Temperature of evaporating surface determining the energy flux density emitted from the surface
- Temperature of the atmosphere
- Water vapor pressure in the atmosphere, which is main factor determining the atmospheric ability for absorption of the energy emitted by the earth surface, and the same determining amount of energy reemitted by the sky toward earth surface
- Albedo of evaporating surface determining the amount of solar energy reflected by the active surface

Sensible heat flux is a function of:

- Plant cover
- Net radiation
- Surface temperature
- Vertical gradients of wind speed and air temperature
- Aerodynamic characteristic of active surface
- Habitat moisture
- Stability of the atmosphere

Soil heat flux depends mainly on:

- Plant cover
- Temperature gradient in the soil, which is the driving force of energy flow into the soil
- Thermal diffusivity of soil determining the rate of heat flux inflowing into the soil
- Soil moisture and porosity

Latent heat of evapotranspiration and *evapotranspiration* mainly depend on:

- Plant cover
- Habitat moisture
- Energy available for evapotranspiration processes
- Evaporation demands of the atmosphere
- Stability of the atmosphere

Heat advection is a function of:

- Horizontal gradient of air temperature, which is the driving force of horizontal flow of heat
- Aerodynamic parameters of active surface determining the coefficient of turbulent exchange

- Wind speed determining the intensity of horizontal flow of air mass

Energy available for evapotranspiration is a sum of net radiation and heat advection.

Habitat moisture depends mainly on:

- Precipitation
- Soil water retention

Atmospheric demand of evaporation is a function of:

- Wind speed
- Saturation water vapor pressure deficit

Surface runoff depends mainly on:

- Intensity of rainfall,
- Coefficient of water infiltration of the soil
- Physiography

Most of these factors are controlled by plant cover (Jaeger and Kessler, 1997; Kędziora et al., 1989; Olejnik et al., 2002). The well-developed plant cover the higher intensity of evapotranspiration and in turn the lower temperature of the active surface and the higher pressure of water vapor in the atmosphere. Cooling of the active surface caused by the intensively evaporating plant cover causes the horizontal temperature gradient. Plant cover impacts on micrometeorological condition of the landscape as well as condition of surface runoff and water infiltration rate. The higher plant covers the higher roughness parameter of the surface and the intensive turbulent exchange of energy and matter between earth surface and atmosphere.

Structure of heat balance of ecosystems

Structure of heat balance of ecosystem or landscape depends on many factors from which the most important are:

- Plant cover (leaf area index and development phase)
- Moisture condition of habitat (water availability for evapotranspiration)
- General climatic conditions (climatic zone)
- Landscape structure

Plant cover affects the heat balance structure by changing net radiation, increasing evapotranspiration, decreasing sensible and soil heat fluxes, and generating advection heat. An ecosystem having high leaf area index (ratio of total one side leaves area to the area on which plants are growing), usually has lower albedo than areas covered by poor vegetation or bare soil (excluding black soil), which have higher net radiation. Such an ecosystem decreases the solar radiation flux reaching soil surface, and the same decreases the soil heat fluxes. The ecosystems of plants having deep root systems are able to use water from deeper soil layers and, as a result, they can evaporate very intensively. This process cooling the canopy of the plants causes decrease of sensible heat flux (smaller vertical gradient of air temperature) and origin

of advection process (increasing horizontal gradient of air temperature).

Seasonal course of heat balance components in an agricultural landscape

The annual course of heat balance components depends mainly on seasonal changes of plant biomass, precipitation, and solar radiation. From this point of view, in temperate zone, ecosystems can be divided into four types:

- Forests and other ecosystem growing continuously from spring to autumn
- Meadows and other perennial crops (alfalfa for instance) having two or more periods of growth interrupted by harvest
- Winter crops (wheat or rape seed for example) having growth period in the spring and early summer
- Ecosystems having growth period in the late spring and in summer (row crop, spring crops, maize)

In the first type of ecosystem, always the latent heat flux prevails and consists about 80–90% of net radiation, depending on habitat moisture. Well-developed forest growing on very moist area can use for evapotranspiration the whole net radiation flux or even more. Sensible heat consists about 10–25% while the soil heat does not exceed a few percent.

In the second type of ecosystem during the majority of each growth period, latent heat prevails, especially in the period of fully developed stage. In this time, latent heat consists about 60–80% of net radiation, sensible heat consists about 20–30% while soil heat about 10–20%. Only in the summer period when moisture of habitat is very low, after harvesting, sensible heat flux can for the short time overcomes latent heat.

In the third type of ecosystems, in the spring, when soil moisture is high, the latent heat is much higher than sensible heat flux reaching up to 90% of net radiation. As water supplies run low the proportion of sensible to latent heat (Bowen ratio) increases reaching in the mature period values equal 1. After harvest (and of August and September) sensible heat flux can be higher than latent heat, depending on soil moisture.

In the last type of ecosystems the situation is quite different. In the early spring (time before germination) when soil moisture is very high, the evaporation of bare soil is intensive and latent heat flux is higher than sensible heat flux. During sunny days, when solar radiation is very intensive, the soil heat can be the biggest component of heat balance (Stohlgren et al., 1998; Pielke and Avissar, 1990; Kimura et al., 2005). As soil heat runs low, evapotranspiration decreases, and for the short time (two 10-days) the sensible heat flux prevails over latent heat flux. Then, as plant development increases, latent heat flux also increases and latent heat flux becomes higher than sensible heat, and soil heat is very small. Such a situation exists up to the end of vegetation period.

Conclusion

The heat balance is the best energetic characteristic of ecosystem or landscape that enables us to understand the processes of energy flow and matter cycling in the agricultural areas. It should be kept on mind that plant cover is the most important factor controlling heat and water balances of the landscape. Thus, it allow us, through the proper management of landscape structure, to control the structure of heat and water balance and microclimatic condition of the agricultural areas, and the same to optimize the use of solar energy toward maximizing the use of the environment potential for production of the food and to ensure the sustainable development of rural areas.

Definition

Soil enzymes. Enzymes in any of the states of occurrence in soils (Ladd et al., 1996).

Numerous processes in soil depend on enzymatic catalysis, including organic matter decomposition, gas emission and sink, pollutants breakdown, energy flow, and nutrient cycling in ecosystem.

Enzymes in soils are associated with different soil constituents. Intracellular enzymes are present in proliferating microorganisms (primarily bacteria and fungi), plant roots, and soil microfauna, or attached to dead cells and cell debris. Numerous extracellular enzymes usually operate at a distance from the parent cell; the capacity to produce and secrete biocatalysts is of survival importance for soil microorganisms and plants. Enzymes in the liquid phase (extracellular as well as released from lysed cells) have generally a short half-life due to rapid denaturation and degradation. However, when complexed with clay minerals or humic colloids, enzymes retain their catalytic properties for a long time, usually at the cost of some loss of the activity. Thus, enzymes may persist and may be active in soil in which no proliferation takes place (*accumulated* or *abiotic* enzymes). While some enzymes (e.g., polysaccharidases) as a rule are extracellular, others are considered to act only intracellularly, hereby reflecting the actual activity of the soil biota (e.g., dehydrogenases) (Burns, 1978; Nannipieri et al., 2002; Skujins, 1967).

Many enzymes are measured in soils, predominantly of the classes of hydrolases and oxidoreductases. The assays are generally simple, sensitive, and relatively rapid. The standard methods determine an overall enzyme activity in soil, and combined with molecular techniques can elucidate many aspects of microbial activity in soil (Bastida et al., 2008).

Soil enzymes are sensitive to variations induced by environmental factors and anthropogenic disturbances, are strongly affected by physical conditions, soil type, and vegetation, and respond to changes in soil management more quickly than other soil variables. Numerous studies confirm that soil enzymes correlate with other indices of fertility and biological activity and are useful in making predictions about the soil environment. There is growing interest in the applications of soil enzymes as the early and sensitive indicators of soil ecological stress and soil quality change in agroecosystem and natural or contaminated soils.

Definition

Mineral soils. Soils composed predominantly of minerals. **Quartz.** One of the most common constituents of the Earth's crust, abundant in sandstones, granite, and soils. It is made up of silica (SiO_2) having a superior ability to conduct heat.

Thermal conductivity of soils. The bulk property of soils describing their ability to conduct heat. It is measured in Watts per Kelvin per meter (W/K/m).

Introduction

Thermal conductivity of soil solids (λ_s) is an essential parameter required by a majority of models in the prediction of soil thermal conductivity (λ). The value of λ_s depends strongly on the fraction of quartz (Θ_q) in soil solids and its thermal conductivity (λ_q), whose value is considerably higher than the remaining soil minerals. For that reason, Θ_q is a key parameter for assessing λ_s , but data on Θ_q is very scarce and often contradictory with soil texture. Quartz (SiO_2) occurs mainly in coarse soil fractions (i.e., sands and gravels) as it does not break up easily and is more water and weather resistant than other soil minerals. Up to this date, the only available set of mineral composition data is that for 19 soils by Kersten (1949), and it shows considerable Θ_q inconsistency with respect to soil texture; for that reason, it cannot be successfully applied to other soils. Many of the soils studied by Kersten are not fully formed due to their young origin (post-glacial time) and the volcanic environment of Alaska. Peters-Lidard et al. (1998) published rough Θ_q estimates for 12 standard soils by the United States Department of Agriculture (USDA), assuming that Θ_q was roughly equivalent to mass fractions of sand. These estimates, however, were never verified by laboratory measurements. As a result, λ_s was assumed as a fitting parameter in a large majority of predictive models (de Vries, 1963; Johansen, 1975; Gori, 1983, etc.). Purushothamaraj and Judge (1977) presented the λ_s from the measured λ data of various soils. Values of λ_s varied from 3.2 to 9 W/m K for sand solids, 2.4–5.9 W/m K for silt solids, and 2.8–4.8 W/m K for clay solids; due to large λ_s variation, this data is hard to apply. There are several instrumental techniques that could be potentially applied

to the determination of minerals in soils: the most frequently used are chemical analysis, differential thermal analysis (DTA), and X-ray diffraction (XRD) (Rowse and Jepson, 1972; Hardy, 1992). The chemical methods, however, often produce problematic Θ_q due to the presence of SiO_2 in other minerals. The DTA technique is based on the analysis of temperature difference between the soil sample and temperature stable reference material, both being heated in an oven at a constant temperature and compared to that of pure minerals tested separately as references of similar size, origin, and crystallinity (Karathanasis and Harris, 1994). The method is error prone due to sample packing, peak height, and instrument reproducibility (Rowse and Jepson, 1972). According to Hardy (1992) and Bish (1994), the XRD technique is in general less accurate than the chemical methods but recent design advances in XRD equipment makes this technique fast and reliable for regular mineral recognition. Recently, Tarnawski et al. (2009a) proposed a new way of assessing quartz content using inverse modeling of soil thermal conductivity at full saturation (λ_{sat}). This modeling approach produced reasonable results to experimental Θ_q data of ten soils studied by Kersten (1949). This approach, however, requires further verification against XRD data which represent a broad variety of mineral soils.

Quantitative X-ray diffraction method

Theoretical background

The majority of soil minerals, with the exception of poorly crystalline clays, can be described as a crystal lattice made of repeating planes of atoms. When the X-ray beam confronts the crystal lattice, it can pass through, be absorbed, refracted and scattered, and diffracted. Each mineral diffracts X-rays in its own unique pattern that depends on the crystal lattice structure. The X-ray beam is generated by a high energy source (15–60 kV) within a sealed vacuum tube (XRD apparatus). The X-ray beam is directed on a slide containing a finely powdered soil, usually ground to particle sizes less than 10 μm . The resulting diffraction is recorded at specific angles by a rotating detector and then converted into quantifiable images

by specialized software. A typical X-ray powder diffractogram is obtained by changing the angle of glancing diffraction (θ) between the X-ray source, the powder slide, and the detector. The diffractogram peaks indicate positions where the X-ray beam has been diffracted by the crystal lattice. A peak area or peak height is usually considered as a measure of diffracted intensity (I). The wavelength of the incident X-ray beam (λ) is a characteristic constant of the X-ray tube target. Then, the distance between adjacent planes of crystal lattice structure (d) and θ obey the Bragg law.

$$N \cdot \lambda = 2 \cdot d \cdot \sin \theta \quad (1)$$

where N is the order of reflection (integer).

A proper examination of mineral specific peaks (area or height) leads to quantitative assessment for a particular mineral. The XRD technique has two main sources of error, namely: interference from other minerals and peak height reproducibility (Rowse and Jepson, 1972).

Experimental procedure and results

Samples of ten natural soils (Table 1) were analyzed by X-ray diffraction (Siemens D 500). A small amount of soil sample was required to fill in a small disk. In order to have clearly interpretable diffraction patterns for natural soils, fine grains are advantageous as they produce a very large number of crystal orientations exposed to the X-ray beam. According to Hardy (1992), a slope of the calibration curve varies insignificantly within 5–20 μm . A large majority of tested soils have a very small fraction of clay, therefore, soil grains were pulverized, in a tungsten carbide grinding mill, to a particle size <20 μm . The grain size distribution was checked using a particle size analyzer. Then, slides containing pulverized soil grains were exposed to X-ray beam. A working calibration curve (Equation 2) was established from six standard samples, a mixture of known quartz fraction (0, 0.1, 0.5, 0.7, 0.9, 1.0) and talc. In the obtained calibration curve, the intensity of quartz reflection (I_q) with respect to Θ_q obeys the following relation:

Estimation of Quartz Content in Mineral Soils, Table 1 Physical characteristics of ten fully saturated soils with XRD and TCP analyses

Soil name	n	m_{cl}	m_{si}	m_{sa}	$\lambda_{\text{s-cal}}$	λ_{sat}	$\theta_{q-\text{XRD}}$	$\theta_{q-\text{cal}}$
Ottawa sand (C109)	0.40	0.00	0.00	1.00	8.3	2.9	1.0	1.0
Ottawa sand (C190)	0.40	0.00	0.00	1.00	8.1	2.9	1.0	1.0
Acadia	0.55	0.10	0.57	0.33	4.2	1.5	0.5	0.6
Alberta	0.55	0.10	0.52	0.38	3.8	1.4	0.6	0.5
Cumberland	0.45	0.05	0.34	0.61	5.0	1.9	0.7	0.7
PEI	0.41	0.03	0.14	0.84	4.5	2.0	0.6	0.6
Pugwash	0.40	0.05	0.37	0.57	5.1	2.1	0.6	0.7
Toyoura	0.40	0.00	0.00	1.00	6.9	2.6	0.8	0.9
Red Y	0.60	0.43	0.23	0.34	3.0	1.2	0.4	0.3
Tottori Sand	0.42	0.03	0.05	0.92	4.5	1.9	0.5	0.6

Note: $\lambda_w \approx 0.61 \text{ W/m K}$ at 25°C; $\lambda_q \approx 7.60 \text{ W/m K}$ at 25°C

$$I_q = 117.46 \cdot \Theta_q + 0.515(nm) \quad r^2 = 0.99. \quad (2)$$

The calibration curve (Equation 2) was used to convert the peak intensity values in the powdered soils to quartz content. The precision of Θ_{q-XRD} estimates was usually better than $\pm 10\%$ (Table 1). The advantages of the XRD technique are, among others, simple sample slide preparation and rapid measurements. The XRD technique requires, however, expensive laboratory equipment (XRD apparatus, tungsten carbide grinders, etc.) and highly trained personnel. Therefore, recently more research attention is focused on indirect estimation of Θ_q from measured soil λ at full saturation.

Modeling quartz content from measured λ_{sat}

Theoretical background

The content of quartz (Θ_q) can also be assessed from λ_{sat} using a weighted geometric mean model (Tarnawski et al., 2009a).

$$\lambda_{sat-cal} = \lambda_s^{1-n} \cdot \lambda_w^n \quad (3)$$

where, λ_w is the thermal conductivity of water; $\lambda_{sat-cal}$ is a calculated λ_{sat} ; n is soil porosity.

Due to its simplicity and good predictions, this model has been frequently used for assessing λ of saturated two-component porous media (Woodside and Messmer, 1961; Johansen, 1975). For saturated soils, the model gives good estimates of λ_{sat} . This model has also been successfully applied to evaluating λ_s .

$$\lambda_s = \lambda_q^{\Theta_q} \cdot \lambda_{o-min}^{1-\Theta_q}, \quad (4)$$

where λ_{o-min} is a lump thermal conductivity of all soil minerals without quartz.

A lumped λ value of the remaining minerals (λ_{o-min}), other than quartz, is usually assumed to be about 2 W/m K (Farouki, 1986).

In spite of simplicity, the above equations (Equations 3 and 4) are difficult to use due to a lack of Θ_q and λ_q data. Accurate estimates of these parameters do not exist and, therefore, they are usually chosen subjectively to artificially enhance the λ model predictions.

Both parameters, however, can be assessed indirectly from the λ_{sat} measured data. By combining Equations 3 and 4, λ_s and Θ_q can be calculated from the following relations:

$$\lambda_{s-cal} = \left(\frac{\lambda_{sat-exp}}{\lambda_w^n} \right)^{1/(1-n)} \quad (5)$$

$$\Theta_{q-cal} = \frac{\ln(\lambda_{s-cal}/\lambda_{o-min})}{\ln(\lambda_q/\lambda_{o-min})}. \quad (6)$$

Quartz is a dominant component of many rocks and natural soils, and its λ is notably higher than other soil minerals. The quartz itself is an anisotropic mineral, whose ability to conduct heat depends on heat flow

direction; along the direction perpendicular to the c-axis (threefold crystallographic axis) $\lambda_{q-\perp}$ is 6.5 W/m K, while along the c-axis the $\lambda_{q-\parallel}$ is 11.3 W/m K (Farouki, 1986). A further modeling complication is due to a fact that quartz grain orientation in a soil system with respect to the flow of heat is usually unknown. Therefore, a lumped thermal conductivity of randomly oriented quartz crystals is used. Its value is usually assessed by a weighted arithmetic mean (de Vries, 1952)

$$\lambda_q = \frac{1}{3} \cdot (2 \cdot \lambda_{q-\perp} + \lambda_{q-\parallel}) \quad (7a)$$

or by a weighted geometric mean (Farouki, 1986)

$$\lambda_q = \lambda_{q-\perp}^{2/3} \cdot \lambda_{q-\parallel}^{1/3}. \quad (7b)$$

The large majority of predictive λ models assume λ_q as temperature (T) independent, but in reality λ_q declines with T . A fitted λ_q vs. T relation, based on data published by Clauser and Huenges (1995) and Equation 7b, has the following form ($r^2 = 0.99$):

$$\lambda_q = 8.128 - 0.021T(0^\circ C < T < 100^\circ C). \quad (8)$$

The thermal conductivity of water was obtained from experimental data published by Sengers and Watson (1986).

$$\lambda_w = 0.57109 + 0.0017625T - 0.0000067036T^2. \quad (9)$$

Measurement of λ_{sat}

Fully saturated soil samples are not easy to prepare due to difficulty in removing trapped air between soil particles. A calculated mass of soil, equivalent to the assumed dry bulk density, was added to a known volume of a sampler. Soil compaction was accomplished by repeatedly tapping the lateral surface of the cylinder. For coarse soils (e.g., C109, C190), water, free of dissolved oxygen, was gradually added along the cylinder's perimeter until the total weight of added water was equal to calculated mass of water corresponding to the relative volume of the tested soil. For fine soils, the saturated soil sample was placed in a laboratory exicator and exposed to $p_{vacuum} = 1-10$ mmHg, thus speeding up the removal of trapped air. The value of λ_{sat} for ten soils was determined using a thermal conductivity probe (TCP) that consists of a stainless steel tubular sheath, containing a constantan heater wire and a T-type thermocouple. The internal space of the sheath was filled in with a low-viscosity epoxy. To simulate a line heat source, the ratio of the probe length to the probe diameter should be at least 50. The time of λ_{sat} measurements was approximately 120 s. More details about the theoretical and practical considerations regarding the probe design and operation, as well as the experimental set-up, can be obtained from Tarnawski et al. (2009b). For λ_{sat} measurements, the temperature rise of the probe was kept below 4°C by maintaining a constant

current of 0.21 A (supplied to the probe heater), resulting in a TCP source strength of 9.9 W/m. Uncertainties of λ measurements for saturated soils were from 3% to 6%. A summary of soil physical characteristics such as clay, silt, sand, and gravel mass fractions, soil porosity (n), λ_{sat} , and Θ_q data (rounded to decimal point) are given in [Table 1](#).

The inverse modeling of quartz content from measured λ_{sat} is a very promising and inexpensive method producing very close results to $\Theta_{q-\text{XRD}}$ data. However, this approach requires accurate λ_{sat} data.

Assessment of quartz content from available λ data
The available λ data of soils is often incomplete and without λ_{sat} data. Therefore, λ data was carefully scrutinized in terms of soil origin, limited dispersion of λ data, and wide coverage of the degree of saturation (S_r). Only soils with extensive λ data spread over a wide range of wetness were selected for inverse modeling, i.e., $S_{r-\min} < 0.07$ and $S_{r-\max} > 0.5$. The soils studied by Kersten (1949) and Lu et al. (2007) were considered for comparison purposes only. The Alaskan soils tested by Kersten (1949) were not fully formed due to their young post-glacial and volcanic origin. Those investigated by Lu et al. (2007) show a considerable diversity of quartz occurrence. Finally, 11 soils were selected and their physical characteristics were

summarized in [Table 2](#). A prevailing number of soils have λ data in a very close vicinity to the dry condition, while λ_{sat} records are very rare. Missing λ_{sat} values were obtained by fitting existing experimental λ data of a particular soil to a three-parameter function given by Lu et al. (2007). Among five normalized conductivity functions tested by Tarnawski et al. (2009a), the exponential function in [Equation 10](#) is the most suitable for modeling thermal conductivity of soils.

$$\lambda = \lambda_{\text{dry}} + \exp\{\alpha \cdot (1 - S_r^{\alpha-\beta})\} \cdot (\lambda_{\text{sat}} - \lambda_{\text{dry}}), \quad (10)$$

where α , β , and λ_{sat} are fitting parameters.

The λ data at $S_r < 0.02$ was assumed to represent λ at dryness (λ_{dry}). In a case when λ_{dry} and λ_{sat} were not available, a four-parameter fitting was applied.

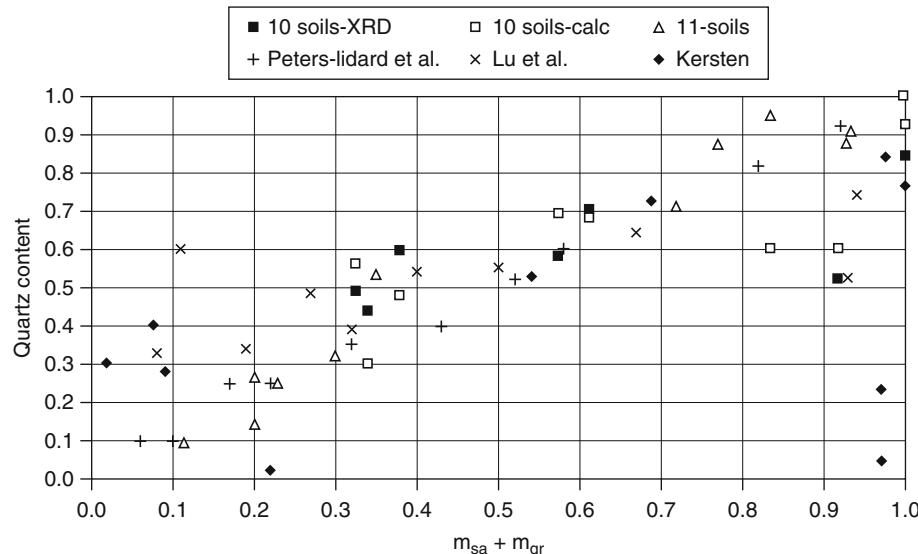

A similar reverse modeling of λ_{sat} , based on an iterative approach, was described by Tarnawski et al. (2009a). Once an experimental or fitted λ_{sat} is obtained, the lumped λ_s can be evaluated using [Equation 5](#). The average λ_s (4.61 W/m K) of the 11 soils is higher than the average λ_s used by Johansen (3 W/m K). Taking into account newly confirmed $\lambda_{\text{sat-exp/fit}}$ given by [Equation 10](#), the $\Theta_{q-\text{cal}}$ can be evaluated by [Equation 6](#), considering $\lambda_{o-\min} \approx 2$ W/m K and $\lambda_q \approx 7.60$ W/m K. A summary of fitting results such as α , β , $\lambda_{\text{dry-exp/fit}}$, $\lambda_{\text{sat-exp/fit}}$, and $\Theta_{q-\text{cal}}$ for 11 soils under consideration is given in [Table 3](#).

Estimation of Quartz Content in Mineral Soils, Table 2 Physical properties of 11 soils from literature

Estimation of Quartz Content in Mineral Soils, Figure 1 Predicted and experimental Θ_q data vs. m_{co} .

Summary of results and discussion

Quartz is a very hard and weather resistant mineral, therefore, its dominant occurrence is mainly in coarse soils. Figure 1 displays the estimated Θ_q , as a function of soil coarse mass fraction ($m_{co} = m_{sa} + m_{gr}$), for the 11 soils under investigation, together with Θ_q data from Lu et al. (2007), Kersten (1949), and Peters-Lidard et al. (1998) as default Θ_q for 12 USDA standard soils, and Θ_{q-XRD} values from Table 1. Figure 1 shows a relatively close match between some of the 11 soils' Θ_q (Table 3) and the XRD data of 10 soils (Table 1). In turn, the Θ_q data by Peters-Lidard et al. (1998) fairly agrees with that of the 11 soils and Θ_{q-XRD} of 10 tested soils. The values of Θ_q by Lu et al. (2007) fairly agree with the Θ_q of the 11 soils, with the exception of two coarse and a silty-loam soil. In turn, quartz fractions given by Kersten (1949) often show erratic variation with soil texture that could be caused by a completely different soil origin.

Conclusions

Predictions of soil thermal conductivity are strongly influenced by the content of quartz, for which data is very scarce. Inverse modeling of quartz content from measured thermal conductivity at saturation is a very promising and relatively inexpensive approach that may partially resolve this issue. This approach, however, requires accurate thermal conductivity data at full saturation, which can be either measured directly using, for example, a TCP or obtained by fitting λ data over a wide range of wetness. However, it has to be kept in mind that soil mineralogy is strongly influenced by the parent material from which soils were formed. Therefore,

a wide range of variation of quartz content may occur in soils having very similar texture, but coming from different places of dissimilar genesis history. For example, some of Kersten's natural soils have a relatively young origin, dating the post-glacial time of Alaska, and therefore show very deviant records of quartz content with respect to soil texture. More reliable data from XRD, on soil thermal conductivity in full range of wetness, and on mineralogical composition of soils from different origins are needed to further confirm this inverse modeling approach.

EVAPOTRANSPIRATION

Viliam Novák

Institute of Hydrology, Slovak Academy of Sciences, Bratislava, Slovakia

Definition

Evapotranspiration as a process is referred to simultaneous losses of water from plants and soil surfaces to the atmosphere. It consists of two particular processes: transpiration and evaporation. Transpiration is referred to water losses from the plant; evaporation is water loss directly from the soil surface, or from evaporating surfaces other than the plants. The precondition of transpiration is transport of the water from soil through plant to the atmosphere. Therefore, evaporation of water previously intercepted by the plant canopy surface from rain (intercepted water), is treated as evaporation too. Physically, evapotranspiration is phase change of the liquid water to water vapor and its transfer to the atmosphere. The evaporation surfaces during transpiration are mostly internal stomata surfaces.

Introduction

Evapotranspiration role in an environment can be characterized by

1. Evapotranspiration as a part of the earth's water balance
2. Evapotranspiration as a part of energy balance of the earth
3. Transpiration participates in biomass production process

The role of evapotranspiration in a root zone water balance can be expressed by the water balance equation; this equation is relating gains and losses of water in the soil root zone in the defined time interval Δt as

$$P + I_r = I + O + (E_e + E_t) + I_d + \Delta W \quad (1)$$

where P and I_r are precipitation and irrigation, I is infiltration to the soil, O is surface runoff, E_e and E_t are evaporation and transpiration, I_d is rate of water movement through bottom of the root zone, which can be capillary rise or deep percolation, and ΔW is the soil root zone water

content change during the period under consideration. All the terms are expressed in mm of water layer over the soil surface (or in kg m^{-2}), during the time interval Δt (usually in hours or more frequently in days).

Evapotranspiration $E = E_e + E_t$ is usually the most important term of the right side of the [Equation 1](#). Expressing the water balance of Central European countries during the hydrological year, the ratio of evapotranspiration and precipitation annual sums is 0.65 for Slovakia, 0.77 for Poland, but 0.91 for Hungary, in the average. It depends on characteristics of the landscape, prevailing in particular country, but it can be seen that “hilly” landscape of Slovakia is utilizing smaller part of precipitation for evapotranspiration than Hungary, with flat landscape and higher air temperature and thus higher potential (maximum possible) evapotranspiration. Analyzing agricultural cropped field, during the vegetation period, the ratio E/P is usually 0.8; during the periods with higher evapotranspiration than precipitation, the soil water content is depleting, or capillary rise from groundwater can take place.

The water movement and its balance are intimately connected with the energy balance, since it involves processes that require energy. Evaporation and transpiration are those processes through which both water and energy balance are connected.

The important feature of evapotranspiration is the high consumption of energy during the evaporating process. As it is known, evaporation of 1 g of water (and transpiration as well), needs 2,450 J of energy (at 20°C). It is 5.8 times more than it is used for heating of 1 g of water from 0°C to 100°C. During the sunny day in Central Europe, the part of energy consumed as latent heat of evaporation is about 0.8 of the net radiation, R_n . It is the energy at the evaporating surface level, which can be utilized for processes performing at that level. The annual portion of energy consumed as latent heat of evapotranspiration over the Earth is 0.56 R_n , transpiration consumes 0.4 R_n (Baumgartner and Reichel, [1975](#)). Over Slovakia, it is about 0.53 R_n and 0.42 R_n , respectively, close to the Earth's averages.

Therefore, evapotranspiration is an important process, strongly influencing the energy balance structure of the landscape and of the field. The lack of evapotranspiration due to absence of water or plants should lead to overheating of the land, and thus increasing its air temperature as well. The energy balance of the evaporating surface can be written as

$$R_n = G + H + LE \quad (2)$$

R_n is the net radiation flux density, G is the soil heat flux, H is the sensible heat flux; it is heat flux from the soil (and canopy) to the atmosphere, and LE is the latent heat flux, determining the energy consumed by evaporation, i.e., for transition of water from the liquid to the gas phase. (Dimension of all terms is $\text{J m}^{-2}\text{s}^{-1}$.) Here L is the latent heat of vaporization ($L = 2.45 \cdot 10^6 \text{ J kg}^{-1}$). The consumption of energy by photosynthesis is small (usually less than 0.02 R_n) and in the above equation is neglected.

Transpiration and biomass production

The aim of soil and water management is to maximize the biomass production by soil and water management. As it was found from numerous measurements (Hanks and Hill, [1980](#)), dry matter production Y_d is proportional to the seasonal transpiration total E_t :

$$Y_d = n \cdot E_t \quad (3)$$

where n is the water efficiency coefficient. It is related to the plant and environmental properties, and for particular canopy and soil, can be treated as a constant. The value of this constant, which represents dry biomass production in kg m^{-2} per unit transpiration rate (expressed in kg m^{-2} or in mm of the water layer), ranges between 0.002 and 0.006, depending on the site conditions. From [Equation 3](#) it follows that the maximum (potential) yield Y_{dp} can be reached at the potential transpiration rate E_{tp} :

$$Y_{dp} = n \cdot E_{tp} \quad (4)$$

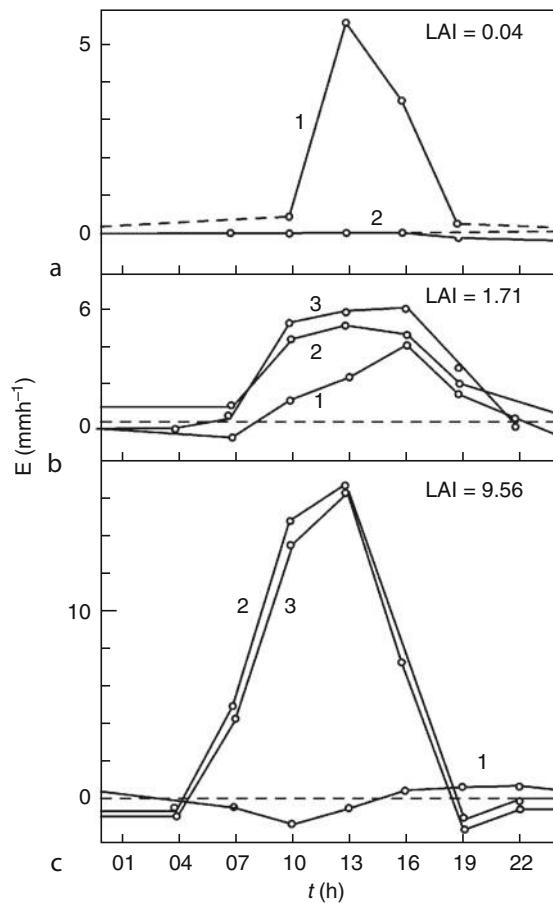

Therefore, precondition of the maximum yield at given conditions is to manage soil irrigation to ensure the potential transpiration.

Daily courses and totals of evapotranspiration

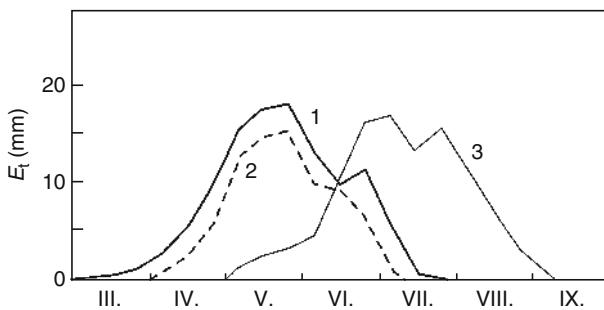

Daily courses of potential evapotranspiration and of its components (transpiration and evaporation), usually follow the most important atmospheric characteristics of an atmosphere: net radiation, air temperature, air humidity, and wind velocity (Novák et al., [1997](#)). Actual evapotranspiration (and its components) are strongly influenced by the soil water, which can limit the root extraction rate. [Figure 1](#) presents daily courses of the potential evapotranspiration, transpiration, and evaporation, during sunny days for winter wheat and different leaf area index (LAI), strongly influencing the evapotranspiration structure. The higher the LAI, the smaller is the evaporation, the higher is the transpiration and the biomass production. Daily evapotranspiration rates of canopies grown in Central Europe are less than 7 mm day^{-1} , but rates between 2 mm day^{-1} and 4 mm day^{-1} are the most common during the summer. Even in tropical conditions, maximum daily rates of E are usually less than 10 mm day^{-1} .

Seasonal courses of evapotranspiration

Seasonal courses of evapotranspiration depend mostly on characteristics of the atmosphere, and on the soil water content seasonal courses. The transpiration–evaporation ratio depends mostly on LAI seasonal courses. [Figure 2](#) presents annual courses of the decade transpiration sums during the vegetation period, of the winter wheat, the spring barley, and the maize. Different positions of curves depend on the beginning of the vegetation period of the particular plant and on its duration. Transpiration totals during the vegetation period were estimated as 120 mm for winter wheat, 105 mm for maize, and 80 mm for spring barley. The ratios of $E_t/E = 0.8$, $E_e/E = 0.2$, and $E_t/E_p = 0.8$, respectively,

Evapotranspiration, Figure 1 Evaporation from soil surface (1), transpiration (2), and evapotranspiration (3) of winter wheat daily courses for different leaf area index (LAI). May 4, 1978, Cerhovice site, Czech Republic.

Evapotranspiration, Figure 2 Ten day transpiration totals of winter wheat (1), spring barley (2), and maize (3) seasonal course, calculated by Penman-Monteith (PM) approach. 1981, Trnava site, South Slovakia.

were estimated for winter wheat canopy in year with average precipitation total in Central Slovakia; E_p is potential evapotranspiration total during the whole vegetation period.

Determination methods of the evapotranspiration and of its components

The oldest, but still reliable method of evapotranspiration determination is the use of lysimeters. Lysimeters are impermeable vessels big enough to allow for non-limited growth of plants. They are located in the field, not disturbing the canopy height and density. Evapotranspiration is usually evaluated from differences in lysimeter weight during the rain-free periods. Other, but less accurate method is estimation of the evapotranspiration, by using water balance equation from the soil water content profiles during precipitation-free time intervals, which should be not shorter than 2 weeks, because of the standard measurement errors.

Another, contemporary method of evapotranspiration measurement is the eddy correlation technique (Dyer, 1961). This method allows for evaluation of the instantaneous evapotranspiration fluxes using observed data of the air temperature, air humidity, and wind velocity fluctuations.

Energy balance method is a reliable one for evapotranspiration rate estimates. This method is based on evaluation of the term E from the [Equation 2](#), when other terms are estimated independently. As this method needs nonstandard data, it is used only seldom. There is a wide family of empirical methods for estimation of the evapotranspiration and of its components. The equations of Thornthwaite, Blaney-Criddle, Hargreaves, Priestley-Taylor, Türc, and others are frequently used (Novák, 1995).

Evapotranspiration is often evaluated as proportional to some meteorological characteristics (net radiation, air temperature, and air humidity). Such approaches are used for approximative estimation of the average evapotranspiration rates, for weeks and months. Their use is limited, they are valid usually only for the regions where they were developed and calibrated.

Generally accepted and widely used are the methods of evapotranspiration calculation, using the (Penman's 1948) approach. Penman combines energy balance equation ([Equation 2](#)) and heat and mass transfer equations

$$H = \rho_a c_p D(T_s - T_2) \quad (5)$$

$$E = \rho_a D(q_s - q_2) \quad (6)$$

where E is the water vapor (evaporation) flux ($\text{kg m}^{-2} \text{s}^{-1}$), H is the sensible heat flux ($\text{J m}^{-2} \text{s}^{-1}$), ρ_a is air density (kg m^{-3}), c_p is heat capacity of air at constant pressure (J kg^{-1}), D is the eddy coefficient of turbulent diffusion (m s^{-1}), T_s and q_s are air temperature and specific air humidity at the evaporating surface, T_2 and q_2 are the same as above, but at standard height, 2 m above the soil surface.

The problem complicating the use of such approach is estimation of the air humidity and of the temperature at the evaporating surface. To eliminate this need, Penman (1948) introduced linear relationship between the surface temperature and the temperature at standard height. This

approach allows to evaluate surface temperature using standard temperature measured at the 2-m height. Other necessary data, needed in Penman's equation can be measured easily. Penman's formula made possible to estimate the potential evapotranspiration. It is used to calculate evapotranspiration from the bare soil, from the dense canopies well supplied with water, and from the water table, generally from evaporating surfaces under not limiting water conditions.

The next important step put forward to calculate different canopies transpiration rate E_t was made by Monteith (1965) by proposing the bulk canopy resistance r_c , characterizing the effect of particular canopy as a whole. This is the famous, "big leaf" approach, which represents canopy as one homogeneous evaporating layer. This approach was proved very useful and this, so-called Penman–Monteith (PM) equation is the most widely used evapotranspiration model:

$$LE_t = \frac{\Delta (R - G) + \rho c_p \frac{d}{r_a}}{\Delta + \gamma \left(1 + \frac{r_c}{r_a}\right)} \quad (7)$$

where E_t is the transpiration rate ($\text{kg m}^{-2}\text{s}^{-1}$), ρ is the dry air density (kg m^{-3}), c_p is the specific heat of the air at constant pressure ($\text{J kg}^{-1}\text{K}^{-1}$), d is the air saturation deficit (Pa), r_a is the bulk aerodynamic resistance (s m^{-1}), r_c is the bulk canopy resistance (s m^{-1}), γ is the psychrometric constant (Pa K^{-1}), and Δ is the temperature derivative of the saturated vapor pressure curve (Pa K^{-1}).

The specific features of different canopies transpiration in the above mentioned equation can be expressed by the net radiation term R_n , soil heat flux G , by the canopy resistance r_c , and by the value of aerodynamic resistance r_a . The daily courses of R_n should be measured, the daily totals or daily averages of R_n can be calculated using procedure described by Novák (1995), in which albedo of the evaporating surface plays an important role. The daily courses of G should be measured when calculating daily courses of evapotranspiration. Calculating daily totals of E_t , G can be neglected. The aerodynamic term r_a depends on wind speed and dynamic roughness parameter z_0 , d is the air saturation deficit, and Δ is the same as mentioned above. A specific form of the Penman–Monteith equation, in which the aerodynamic resistance and bulk canopy resistance are specified, is recommended by FAO for calculating reference crop evaporation, i.e., evaporation from dense crop, well supplied with water (Allen et al., 1998).

A crucial problem of using this equation to calculate transpiration is in estimation of the canopy resistance r_c , which depends on a variety of environmental parameters, mainly R_n and the leaf water potential. Leaf water potential depends on the soil water potential. The higher the soil water content, the smaller is the r_c (Jarvis, 1976; Choudhury and Monteith, 1988). Canopy resistance r_c is changing during the day and season and is specific for particular plants. To overcome this, the simplified versions of PM equation are used to calculate the potential evapotranspiration, and

then the empirical relationship between the relative transpiration and soil water content is used. (Ritchie and Burnett, 1971; Novák, 1995; Feddes and Raats, 2004).

Conclusions

Evapotranspiration is a key process in water and energy balance of the Earth. Energy utilized for evapotranspiration is 0.53 of the net radiation (transpiration consumes 0.42 part of the net radiation); only the rest is used for all the energy-consuming processes. Transpiration as a part of evapotranspiration is vital for biomass production, stomata are entrance for CO_2 , and exit for water vapor, both processes occur simultaneously. Evapotranspiration is also vital for air temperature stabilization of the Earth.

EXTRUSION, EFFECT ON PHYSICAL AND CHEMICAL PROPERTIES

Leszek Mościcki

Department of Food Process Engineering, University of Life Sciences, Lublin, Poland

Synonyms

Extrusion-cooking of vegetable raw materials; Food extrusion

Definition

Extrusion-cooking. HTST processing of grinded vegetable raw materials at relatively high pressure (up to 20 MPa) and temperature (up to 200°C) to achieve new generation food and feed products of different/engineered physical and chemical properties.

Extrusion-cooker or food extruder. A processing machine unit, specially designed for.

Extrudates. Products of extrusion-cooking.

Introduction

The extrusion technology, well-known in the plastic industry, has recently become widely used in agri-food industry, where it is referred to as *extrusion-cooking*. It has been employed for the production of so-called engineered food and special feed. Generally speaking, extrusion-cooking of vegetable raw materials consists in the extrusion of grinded material at barothermal conditions. With the help of shear energy, exerted by the rotating screw, and

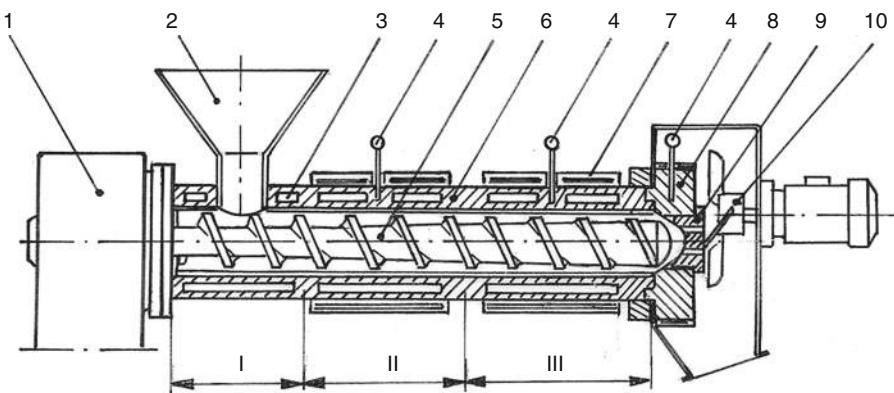

additional heating by the barrel, the food material is heated to its melting point or plasticating point (Harper, 1981; Mercier et al., 1998; Mościcki et al., 2007; van Zuilichem, 1992). In this changed rheological status the food is conveyed under high pressure through a die or a series of dies and the product expands to its final shape. That results in much different physical and chemical properties of the extrudates in comparison to raw materials used.

Food extruders (Figure 1 presents a design of single-screw extrusion-cooker) belong to the family of HTST (High Temperature Short Time)-equipment, with a capability to perform cooking tasks under high pressure. This aspect may be explained for vulnerable food and feed as an advantageous process since small time span exposures to high temperatures will restrict unwanted denaturation effects on, e.g., proteins, amino acids, vitamins, starches, and enzymes. Physical technological aspects like heat transfer, mass transfer, momentum transfer, residence time, and residence time distribution have a strong impact on the food and feed properties during extrusion-cooking and can drastically influence the final product quality. An extrusion-cooker is a process reactor (van Zuilichem, 1992), in which the designer has created the prerequisites in the presence of a certain screw lay-out, the use of mixing elements, the clearances in the gaps, the installed motor power, and barrel heating and cooking capacity, to control a food and feed reaction. This can be a reason “in itself,” when only mass is transferred in wanted and unwanted reaction products due to heating, e.g., the denaturation of proteins under presence of water and the rupture of starches, both affected by the combined effects of heat and shear. The reaction can also be provoked by the presence of a distinct biochemical or chemical component like an enzyme or a pH controlling agent. When we consider the cooking extruder to be more than was mentioned originally, a thorough investigation of the different physical technological aspects is more than desirable.

Application

Currently, extrusion-cooking as a method is used for the manufacture of many foodstuffs, ranging from the simplest expanded snacks to the highly processed meat analogues (Figure 2). The most popular extrusion-cooked products are the following:

- Direct extrusion snacks, RTE (ready-to-eat) cereal flakes, and diverse breakfast foods produced from cereal material and differing in shape, color, and taste and easiest to implement in terms of production
- Snack pellets: half products suitable for fried or hot air expanded snacks, pre-cooked pasta
- Baby food, pre-cooked flours, instant concentrates, functional components
- Pet food, aquafeed, feed concentrates, and calf-milk replacers
- Textured vegetable protein (mainly from soybeans, though not always) used in the production of meat analogues

Effects of extrusion-cooking

Extrusion-cooking is accompanied by the process of starch gelatinization, involving the cleavage of intermolecular hydrogen bonds. It causes a significant increase in water absorption, including the breakage of starch granules. Gelatinized starch increases the dough viscosity, and high protein content in the processed material facilitates higher flexibility and dough aeration (Mercier et al., 1998; Mościcki et al., 2007). After leaving the die hot material rapidly expands as a result of immediate vaporization and takes on a porous structure. In the extruded dough protein membranes, closing occurs creating cell-like spaces, and starch, owing to dehydration,

loses its plasticity and fixes the porous nature of the material. Rapid cooling causes the stiffening of the mass, which is typical for carbohydrate complexes embedded in a protein matrix and their total enclosure by the membrane of hydrated protein. The resulting product is structurally similar to a honeycomb shaped by the clusters of molten protein fibers.

Starch occurs primarily in cereal grains and potatoes. It takes the form of granules of different and characteristic shape, depending on the origin as well as on the variety and type of fertilization. As commonly known, two main components of starch are amylose and amylopectin displaying different physical and chemical properties, for example, chemical structure. The technological assessment of extrudates takes two factors into account: the water solubility index (WSI) and the water absorption index (WAI). These properties were studied in many laboratories and the conclusions were that WAI of many starch products increases together with the temperature rising in the extruder's barrel. It has been assumed that the maximum value is obtained around the temperature ranges from 180°C to 200°C (Mercier et al., 1998). When these temperatures are exceeded, WAI drops and causes the WSI increase. The lower the material initial moisture content used in extrusion, the higher the extrudate's WSI rate that can be obtained. A noticeable influence on the product properties has the percentage of amylose and amylopectin and its ratio in the processed material (Camire et al., 1990; Cheftel, 1986; Mercier et al., 1998).

The extrusion processing of starchy materials certainly impacts the changes in product viscosity (pasting characteristic) after dissolving in water. This feature is very important for the technological point of view. Using Brabender viscometer we can see that the characteristic viscosity curve for starch is clearly reduced through extrusion; at the same time, the decrease of viscosity is greater if higher temperatures were applied during the extrusion-cooking. The application of higher pressure during the extrusion (compression changing) does not affect the extrudate viscosity; however, it affects on viscosity

stability of products retained at a temperature of 95°C. In some cases, the properties of extrudate may be arranged by amylose bounding with fatty acids or monoglycerides.

Another factor determining changes in the starch molecules during the extrusion-cooking process is the pressure and the values of existing shearing forces (Meuser et al., 1987). In order to obtain certain technological properties of extrudates, which are often semi-finished products intended for further processing, it is necessary to set proper parameters of the extrusion process. This is achieved by the use of screws with varying compression degrees, relevant rpm of the working screw, appropriate die size, SME input, etc.

An interesting and important extrudate feature is the digestion rate of starch. Research on starch digestibility processed by extrusion-cooking has shown (Anderson et al., 1970; Cheftel, 1986) that it mostly depends on the generated structure. The researchers concluded that maize starch extruded at a temperature of 135°C was significantly less digestible if coarse. Fine ground extrudate treated with α -amylase displayed a 20% higher degree of enzymatic hydrolysis than non-ground material, and after grinding it into flour, the hydrolysis degree reached 80%. Such differences in digestion were not present with extrudates obtained after the application of process temperature of 225°C. In addition, with such thermal treatment, the highest expansion of extruded maize was observed.

Thermoplastic processing of vegetable materials by the extrusion-cooking also causes significant changes in protein substances, which can be found in vegetable materials. Mercier et al. (1998) demonstrated, for properly setting the parameters of thermoplastic processing, that it is possible to obtain cereal extrudate of a relatively high amyloytic activity. Nevertheless, the influence of extrusion on the enzymatic activity must be taken into account, particularly when it is important from the technological point of view (the purpose of the product), or when these processes are carried out in order to explore the mechanism of starch dextrinization that occurs during extrusion.

Polysaccharides and lignins – the basic fiber components – perform differently during barothermal treatment such as extrusion. The degree of fiber degradation depends on the size of shear stresses. Björck and Asp (1984) found that extrusion processing almost twice increased the content of water-soluble fiber in processed wheat grain. It was simultaneously confirmed by Varo et al. (1983) who used many different analytical methods during the cereal extrudates testing. There were no statistically significant changes in the quantity of fiber in relation to the input material before extrusion.

The decomposition of fiber to glucose and lignin, combined with the use of urea during the extrusion of pine sawdust for the purpose of feed, was measured by Mościcki and Van Zuilichem (1986). The obtained results confirmed the usefulness and effectiveness of extrusion technique in the process of cellulose degradation, and the final product, energy and protein-rich, has proved to

be a good alternative as a valuable feed component for ruminants which have the capacity to absorb inorganic origin proteins.

Vitamins can be destroyed through the action of temperature or by oxidation. Since extrusion mostly involves thermal treatment at temperatures of 100°C or higher, some loss of vitamins in the processed material is expected, especially of the temperature-sensitive ones, such as vitamin C. Many authors presented some works on these matters and confirmed the occurrence of this phenomenon, but because of the HTST-type shock treatment, they found that the extent of losses was much less compared with conventional methods such as static, long-term cooking. Since the basic raw materials used in the processing of extruded products are cereals, much attention was attached to the changes in B-group vitamins, particularly thiamine B₁, riboflavin B₂, and niacin (Beetner et al., 1976; Harper et al., 1977; Mustakas et al., 1970). Thiamine being the most sensitive to temperature is damaged during extrusion, depending on the processing conditions, temperature rise, and screw speed. Riboflavin losses are much lower (retention post-extrusion was 92%) and decrease with the increasing water content in the mixture (Camire et al., 1990).

Starch extrudates, due to a high stability of viscosity, are widely used in the manufacture of starch modifiers and functional substances. In bakery, extruded maize is used as a binding agent for meat fillings and as a raising agent in baking cakes. It improves their texture (crispiness) and taste. Physicochemical properties of starch extrudates (low solubility and viscosity) make such products very competitive if compared with those obtained through chemical modifications. Extrusion of lipid-free starch increases its digestibility as a result of the oligosaccharides formation – this determines the usefulness of this technique in the baby food manufacture (Mercier et al., 1998).

The greatest interest of extrusion-cooking technique is in production of snacks, breakfast cereals, and textured proteins obtained from soybeans and used as animal protein replacements in food processing. Although soy proteins play a key role, there are experiments performed with other vegetable materials such as broad bean or faba bean, which can substitute this plant.

It is also worth noting that extruded products demonstrated long shelf life. Partial lipids binding by the processed mass increases their resistance to oxidation processes, while lipases and lipoxygenase are almost completely inactivated. In addition, thermal processes cause deep sterilization, therefore microbiological contamination of the obtained products is limited. If in proper storage conditions, these products can be stored for more than a year.

Summary

A utilitarian importance of the extrusion-cooking of vegetable raw materials has made it widely implemented for the food and feed manufacture all over the world. The manufacturers adapted twin-screw extruders report significant economic benefits. These machines are more

efficient and less energy consuming than single-screw extruders. The extrusion reveals great potential for further expansion in the domestic food and feed industry. It is not only on account of its growing application abroad, especially in developed countries. Extrusion is a giant step in the use and marketing of those products which are regarded as having little or no economic value, such as the seeds of leguminous plants.

FATS: RHEOLOGICAL CHARACTERISTICS

Fernanda Peyronel, Thamara Laredo,
Alejandro G. Marangoni
Department of Food Science, University of Guelph Food
and Soft Materials Science, Guelph, ON, Canada

Definition

Rheology is the study of the way that materials flow or deform under an applied stress.

Jan Gliński, Józef Horabik & Jerzy Lipiec (eds.), *Encyclopedia of Agrophysics*, DOI 10.1007/978-90-481-3585-1,
© Springer Science+Business Media B.V. 2011

Introduction

Rheology tries to explain the relationship between stress and strain (deformation) or strain rate (flow) in a material by giving information as to whether the material is elastic, viscous, or plastic (Steffe, 1996; McClements, 2005). Fats are known to behave like rigid solids until a deforming stress exceeds the yield value at which point the product starts to flow like a viscous liquid (de Man and Beers, 1987). This plasticity arises from the fact that the crystallized material forms a fat crystal network that entraps liquid oil (Marangoni, 2005). This characteristic of fats makes rheology an excellent technique to study them. Some of the textural properties that humans perceive when consuming fat products, like hardness, creaminess, brittleness, and tenderness, are largely rheological in nature. It is common in rheology to work with the so-called “constitutive relations” or rheological equation of state. The basic equations are: Modulus = Stress/Strain and Viscosity = Stress/Shear rate, both of which describe the relationship between a “driving” force and the effect upon the system. When studying viscoelastic materials, two moduli are always calculated, the storage modulus (G') that reflects the energy-conserving or elastic characteristics, and the loss modulus (G'') that describes the energy dissipated as heat.

For example, G' has been found to be a suitable indicator of the hardness for milk fat and butter (Wright et al., 2001) and many other fats (Narine and Marangoni, 1999, 2001), as well as giving information regarding spreadability and mouth feel (Rousseau and Marangoni, 1999).

This entry focuses first on developing a mathematical formulation of some of the basic concepts used in rheology, followed by a section that explains the rheometer used in our laboratory.

Basic concepts: strain and stress

A body of matter can be thought as composed of interacting point masses. Each point mass is defined by

a pair (m, P) , which defines the mass, m , and the position P in space. Deformation is the process through which these point masses change their relative position with respect to the center of mass of the body.

Strain, s , is a displacement defined as a relative change in length. It is a dimensionless quantity. Stress, σ , is the acting force per unit area responsible for deformation. It is composed of a normal (tensile or compressive) and a tangential (shear) component. The SI units of stress are Pascals (Pa) which is equivalent to one Newton per square meter.

What follows is an overview of the mathematical description of both tensile and shear strain. Consider a rectangular bar, of a given material, to which a tensile stress has been applied. The bar will elongate as a result, as shown in [Figure 1](#). The resulting length, L , of the bar will be:

$$L = L_0 + \delta L \quad (1)$$

where L_0 is the initial length of the bar and δL is the increase in length. This deformation can be expressed in terms of the strain, s ,

$$s_c = \frac{\delta L}{L_0} = \frac{L - L_0}{L_0} = \frac{L}{L_0} - 1 \quad (2)$$

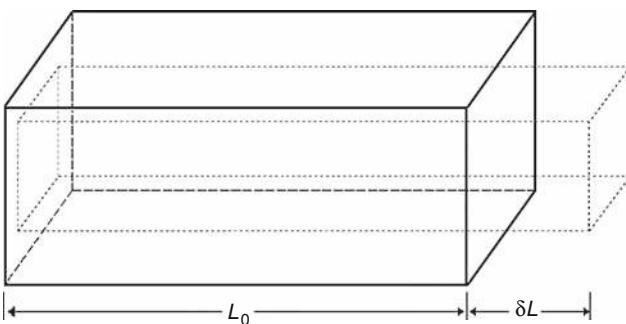

This is known as the Cauchy strain, s_c .

The Hencky strain s_h (or true strain) is obtained by integrating over an infinitesimally small incremental strain dL/L_0 from L_0 to L :

$$s_h = \int_{L_0}^L \frac{dL}{L} = \ln \frac{L}{L_0} \quad (3)$$

The Hencky strain or logarithmic strain is used when deformation takes place in a series of increments, taking into account the influence of the strain path (Rees, [2006](#)).

Consider the same rectangular bar, but now the force applied is tangential, such that the upper surface has been displaced by δL and the bottom surface is stationary, as seen in [Figure 2](#). This type of strain is called simple shear. In this case the angle of shear, or shear strain, γ , may be calculated as:

Fats: Rheological Characteristics, Figure 1 Linear elongation of a rectangular bar (Adapted from Steffe ([1996](#))).

$$\tan \gamma = \frac{\delta L}{h} \quad (4)$$

where h is the height of the bar. For small deformations, $\tan \gamma$ is approximately equal to γ in radians.

Ideal and nonideal matter

Food can have a wide range of rheological properties which usually give way to very complex behaviors. However, it is possible to characterize many types of foods in terms of the simpler *ideal* solid, liquid, or plastic. Complex systems can then be explained by combining two or more of these simpler models.

Solids

In an ideal or Hookean solid the deformation is strictly proportional to the applied force. Hence, the behavior of an ideal solid with respect to an applied external force can be expressed in terms of a single parameter: the proportionality constant between the deformation and the force producing it, such that,

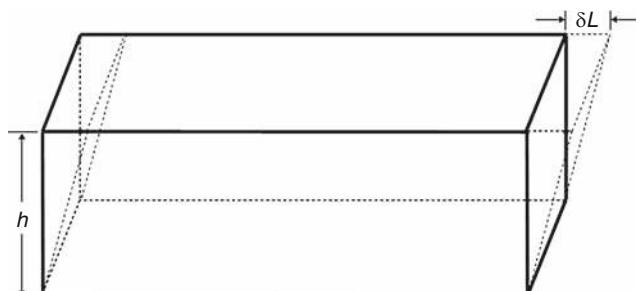

$$\sigma = G\gamma \quad (5)$$

where G is known as the shear modulus and σ and γ are the stress and the deformation, respectively.

Only elastic solids display Hookean behavior. Some solid materials in food behave as an ideal solid only for small deformations. At strains above this hookean region, the stress is no longer proportional to the strain and an apparent modulus (which is a function of the strain) is defined. Even though the material does not obey Hooke's law it will still return to its original shape once the force is removed. However, there is a point above which the solid does not return back to its original shape once the force is removed. This occurs because the forces that hold together the structural units, at the appropriate length scale, are exceeded, making the solid either break or flow (Prentice, [1984](#)).

Fluids

A fluid is distinguished from a solid in that it does not possess a rigid structure. Upon the application of an external

Fats: Rheological Characteristics, Figure 2 Shear deformation of a rectangular bar (Adapted from Steffe ([1996](#))).

force, and because an ideal liquid is isotropic, the elements will move without modification of the structure for as long as the force is applied. The characteristic property in this case is that the rate at which the material deforms is proportional to the applied force. The proportionality constant in this case is the viscosity, η :

$$\sigma = \eta \dot{\gamma} \quad (6)$$

where σ is the applied stress and $\dot{\gamma}$ is the strain rate. Under certain conditions, a number of fluids such as water, tea, honey, or syrups will exhibit ideal Newtonian behavior.

The rheological properties of Newtonian liquids are independent of the shear rate and the previous shear histories, and are dependent only on the temperature and composition.

The viscosity of non-Newtonian liquids is not constant and can be dependent on the rate and/or the time over which the shear force is applied. The word viscosity is generally reserved for Newtonian liquids; for non-Newtonian liquids the viscosity at a given shear rate is called the apparent viscosity. Usually, the symbols η and η_a are used for the viscosity and apparent viscosity, respectively. When the behavior of a non-Newtonian liquid under a shear force is dependent on the shear rate but independent on the time, the system is under such stress that the fluid is said to have a nonideal shear rate-dependent behavior. In particular, if the apparent viscosity decreases when the shear rate is increased, the fluid is a shear-thinning or a pseudoplastic fluid. If the apparent viscosity increases as the shear rate is increased, the fluid is a shear-thickening, or dilatant, fluid. Non-Newtonian liquids that are also dependent on the time over which they are under shear, are said to have a nonideal time-dependent behavior. They are subdivided into two categories. At a constant temperature and shear rate, if the viscosity decreases as a function of time, then the fluid is thixotropic; however, if the viscosity increases with time, the fluid is rheopectic.

Plastics

The rheological behavior of an ideal (or Bingham) plastic is described by two equations:

$$\sigma = G\gamma \quad (\text{for } \sigma < \sigma_0) \quad (7)$$

$$\sigma - \sigma_0 = \eta \dot{\gamma} \quad (\text{for } \sigma > \sigma_0) \quad (8)$$

where σ_0 is defined as the yield stress and all other symbols are as previously defined. Below the critical yield stress, application of a stress leads to elastic deformation of the sample. Above σ_0 some bonds in the sample break, leading to its plastic deformation or to the flow of the sample. Whereas in ideal plastics there is a clear definition between elastic and viscous behavior, nonideal plastics exhibit these two behaviors simultaneously. These are said to be viscoelastic materials (Prentice, 1984).

Solid fats have a plastic behavior that results from the presence of a certain percentage of crystallized fat within

a lipid matrix. This crystal network consist of a three-dimensional array of interlaced particles, arranged as branched and interlinked chains, formed by separate crystals or preformed aggregates. Before discussing the rheology of fats, it is convenient to define a few concepts usually used to describe the rheological behavior of matter.

Definitions of moduli

The tendency of a sample to be deformed is a measure of its elastic modulus, which is defined as the slope of its strain–stress curve in the linear (elastic) region. Depending on what stress is applied and how the strain is measured, different moduli can be determined. For example, when shear stress is applied, the shear modulus, G , is:

$$G = \frac{\sigma}{\gamma} \quad (9)$$

which is [Equation 5](#) rearranged.

For tensile and compressive stresses, the Young's modulus of elasticity, E , is defined as

$$E = \frac{\sigma}{s} \quad (10)$$

The bulk modulus, K , is used when there is a change in the volume of the sample upon the application of a three-dimensional stress:

$$K = \frac{\Delta P}{\Delta V/V_0} \quad (11)$$

where ΔP is the change in pressure and $\Delta V/V_0$, the relative change in volume of the solid (Eirich, 1956).

Basic concepts in dynamic measurements

Two types of experiments can be carried out to characterize the viscoelastic properties of food materials: transient ones and dynamic ones. In transient experiments, a simple shear stress is applied on a sample and the corresponding strain observed during the time of the load and as it relaxes.

The dynamic method consist of the application of a continuous stress or strain in an oscillatory fashion, where the material is subjected to a sinusoidal perturbation, either in the form of deformation (for controlled rate instruments) or stress (for controlled stress equipment). In a controlled rate experiment, the time dependence of the amplitude of the input strain wave is given by:

$$\gamma = \gamma_0 \sin(\omega t) \quad (12)$$

where γ_0 is the maximum amplitude of the strain and ω is the frequency expressed in rad/s, which is equivalent to $\omega/(2\pi)$ hertz. The periodic shear rate can then be found by taking the derivative of [Equation 12](#),

$$\dot{\gamma} = \gamma_0 \omega \cos(\omega t) \quad (13)$$

For a Kelvin–Voigt viscoelastic solid, the total stress (Δ) on the system corresponds to the sum of the elastic (Δ_e) and viscous (Δ_v) stresses, and thus

$$\Delta = \Delta_e + \Delta_v = G \cdot \gamma + \eta \dot{\gamma} \quad (14)$$

where η is the viscosity. Substituting Equations 12 and 13 into 14 results in

$$\Delta = G' \cdot \gamma_0 \sin(\omega t) + G'' \gamma_0 \cos(\omega t) \quad (15)$$

where G' is the shear storage modulus and G'' is the shear loss modulus ($G'' = \eta \cdot \omega$). Both of these are functions of frequency that can be expressed in terms of the phase shift and the amplitude ratio between the shear stress and strain

$$\Delta = \Delta_0 \sin(\omega t + \delta) \quad (16)$$

where Δ_0 is the maximum amplitude of the shear stress and δ is the phase lag or shift angle relative to the strain wave. The ratio of these two moduli is a common material function used to describe viscoelastic behavior:

$$\tan(\delta) = \frac{G''}{G'} \quad (17)$$

$\tan(\delta)$ is directly related to the energy lost per cycle divided by the energy stored per cycle. Additional frequency-dependent material functions include the complex modulus (G^*), complex viscosity (η^*), dynamic viscosity (η'), complex compliance (J^*), storage compliance (J') and loss compliance (J''), among others.

When the sample is an ideal (or purely elastic) solid, the maximum strain occurs when the maximum stress is applied. The stress and strain are said to be in phase. If the material is purely viscous, the stress and strain are out-of-phase by 90° . Viscoelastic materials exhibit a behavior that lays somewhere in between these two extremes, where the phase shift δ is $0^\circ < \delta < 90^\circ$ (Steffe, 1996).

Dynamic measurements allow for the study of the viscoelastic behavior of materials. This is performed by applying an oscillatory stress or strain to the sample. Typically, a sinusoidal strain is applied to the sample causing some level of stress to be transmitted through the material. The magnitude and time lag of the transmission depend on the viscoelastic nature of the test substance. If the material is more liquid-like, much of the stress is dissipated in frictional losses; in more elastic materials the stress is mostly transmitted. Likewise, the phase shift (or lag) is large for highly viscous materials but small for materials that exhibit a high degree of elasticity. Oscillatory testing is referred to as “small amplitude oscillatory testing” because small deformations must be employed to maintain linear viscoelastic behavior.

Experimental aspects of fat rheology

One aspect of fat rheology is that the variables and parameters over which the user has control on a rheometer are dependent on the type of rheometer used. Another aspect

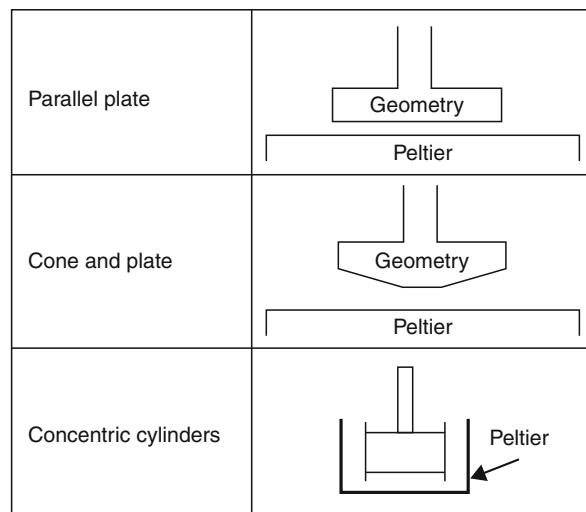

is the sample preparation, which ideally has to be, highly reproducible and simple. What follows, is a discussion of these two aspects together with a brief interpretation of data obtained on cocoa butter.

Rotational rheometers

Fats are commonly studied under the dynamic method with an oscillatory rheometer. In this kind of rheometer, the material is placed between two surfaces: the bottom surface, which is usually fixed, and the top surface, called *the geometry* that rotates. The instrument can be operated in steady shear mode (constant angular velocity) or oscillatory mode (dynamic). In the dynamic mode, samples are subjected to sinusoidal stress and the resulting sinusoidal strain is measured, or vice versa. Typical geometries include parallel plate, cone-and-plate, and concentric cylinders type (Figure 3).

The geometry is chosen based on the prior knowledge of the material under study, which involves some knowledge of its viscosity and/or flow. Usually concentric cylinders are used for low viscosity liquids, cone-and-plate are used for liquids and dispersion with particles smaller than $5 \mu\text{m}$, and parallel plates are used for gels, pastes, soft solids, and polymer melts.

Since the top geometry comes in different physical sizes, it can accommodate the study of a variety of materials. Large diameter geometries (60 mm, 40 mm) are used for low viscosity materials, while smaller diameters (20 mm, 15 mm, 10 mm) are used for high viscosity materials. The rheometer uses the geometry specifications to give a result that is independent of the geometry used. This makes the design and loading of the sample an important aspect in the measurement. In a controlled stress rheometer, a shear stress is applied to the material and the resulting strain or strain rate is measured. In contrast, in

Fats: Rheological Characteristics, Figure 3 Three different geometries and their corresponding base plates, commonly used in rotational rheometers.

a controlled strain rheometer a strain or strain rate is applied, and stress is measured. In most materials, the relationship between stress and strain can be understood using either rheometer design. However, the focus of next section is on stress control rheometers, as this is the instrument used in our laboratory.

Controlled stress rheometer

Figure 4 shows a rotational controlled stress Rheometer. It consists of a main unit mounted on a cast metal stand [1], with the electronic control circuitry contained within a separate electronics control box [2] and the sample holder [3].

The sample holder includes the temperature control system which uses the Peltier effect to rapidly and accurately control heating and cooling. Since the Peltier system operates as a heat pump, it is necessary to have the system hooked to a water pump or waterbath, to provide sufficient fluid flow through the Peltier heat exchange jacket built into the plate.

This controlled stress instrument uses an air bearing to provide “frictionless” movement of the upper fixture (**Figure 5**) and a noncontact drag cup motor to generate controlled torque on the shaft. A position indicator is used to measure displacement.

In this kind of rheometer, torque is applied to either control the stress at a desired level or to drive the strain

to a desired amount (Steffe, 1996). In some cases the applied motor torque and the measured amplitude are coupled.

Rheological parameters

Fundamentally, a rotational rheometer applies or measures torque, angular displacement, or rotational speed. The relationship between stress and deformation is a property of the material. Hence, rheology is a powerful technique that allows for the understanding of the material at the microscale level.

The information commonly obtained for fats from a rheometric measurement comes from the values of G' , G'' , and $\tan \delta$, which can be expressed as a function of time, temperature, frequency, stress, or strain. **Table 1** summarizes the physical parameters used in rheometry as well as the rheological parameters obtained from the measurement, for both stress- and strain-controlled instruments.

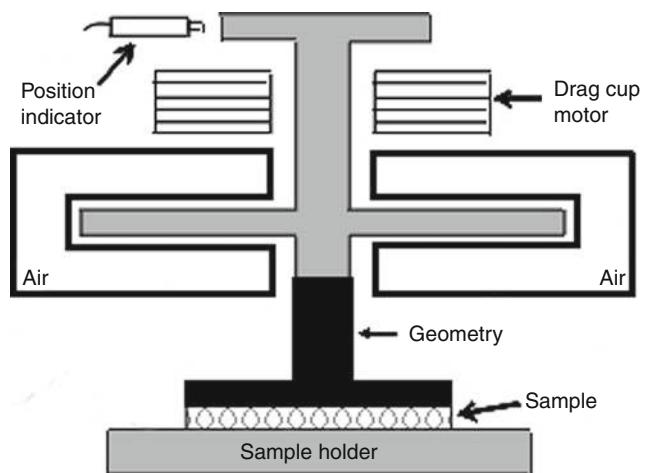

The advantages of using dynamic mechanical testing are that the shear rates involved are low, that only a small sample is required, and that both the elastic and viscous components of a material are probed simultaneously (Ferry, 1980).

Fats are usually analyzed in the so-called linear viscoelastic region, LVR (**Figure 6**), which is the region where the material's properties do not depend on the magnitude of the stress, the magnitude of the deforming strain, or the strain rate.

The yield stress or yield point, is the point that signals the beginning of structural breakdown and it is determined by a change in the slope of both G' and G'' curves. G' and G'' are used to characterize the system only when the samples are measured in the linear viscoelastic region. The LVR is determined from experimental data, usually running a stress sweep at a frequency of 1 Hz. Once the LVR is found, it is recommended that a frequency sweep

be performed using the appropriate values of stress obtained in the LVR region.

Fat sample preparation

Specific molds to make fat samples were designed and built in our laboratory. The molds have three distinctive parts: a flat bottom, an intermediate template with holes of 10 mm in radius and either 1 mm or 3.2 mm in height, and a flat cover. The cover can be screwed in place with

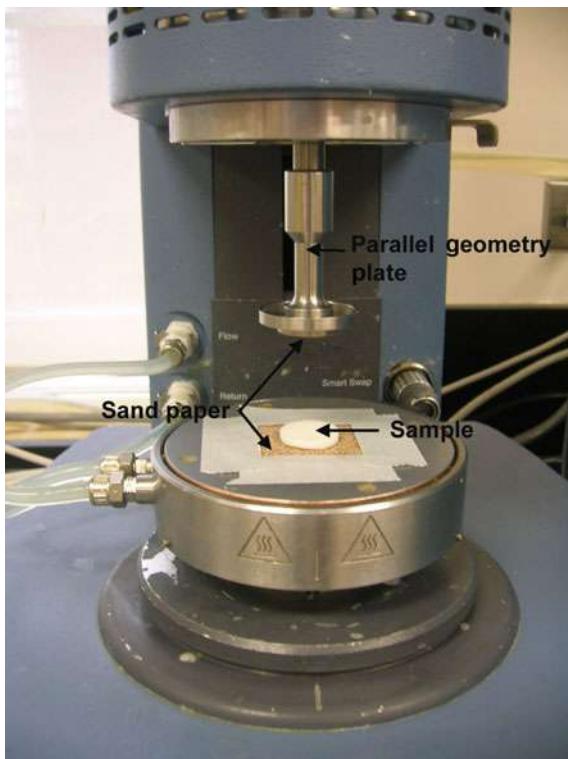

butterfly screws, as shown in Figure 7. Plastic molds (Figure 7a) are the standard ones that can be used at room temperature or at a specific temperature in an incubator. The aluminum mold (Figure 7b) has the extra advantage that allows the control of the cooling rate via a waterbath.

The typical procedure followed in our laboratory for sample preparation consists of the following steps:

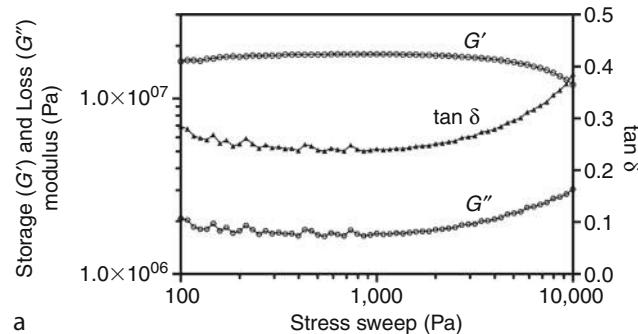

1. Melt the desired material in the oven, at a high enough temperature to erase all crystal history. In general, 60°C

- for 30 min or 80°C for 15 min are typical values used in our laboratory.
2. Place molds, a piece of parafilm, and a piece of aluminum foil in the oven at 60°C to equilibrate them. Parafilm does not withstand temperatures higher than 60°.
 3. Assemble the bottom part of the molds by placing first a piece of aluminum foil and then a piece of parafilm. Assemble the middle template and pour the molten material into the holes.

4. Cover the holes with a layer of parafilm and a layer of aluminum paper before screwing in place the cover of the mold. The parafilm and aluminum paper help in creating a smooth surface on the fat and on the removal of the fat samples once they are crystallized.
5. Crystallize samples inside the mold under the desired conditions and de-mold when ready.
6. In order to prevent slippage it is necessary to glue sandpaper on the geometry of the rheometer and on the Peltier plate, to prevent slippage. Usually a 50 grit sandpaper is attached with Krazy Glue™ as seen in Figure 8.

Fats: Rheological Characteristics, Figure 8 Position of the sample, the sand paper, and the geometry on the rheometer.

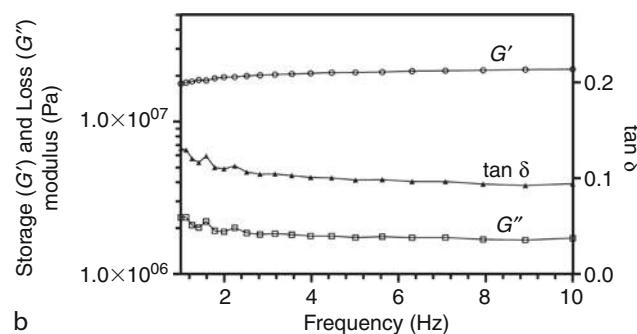

Fats: Rheological Characteristics, Figure 9 G' , G'' , and $\tan \delta$ obtained with our rheometer for Cocoa Butter. Figure (a) is a stress sweep at a constant frequency of 1 Hz, while Figure (b) is a frequency sweep at a constant stress of 1,000 Pa.

Cocoa butter example

Fats are complex systems made of many different molecules, and a complex structural hierarchy at the nano, micro, and macro scales, which make the rheological testing very complex. Preliminary measurements are usually needed to find the optimal conditions under which the rheological analysis should be performed for the sample under study. An oscillatory test using stress as the variable provides information regarding the LVR region, as well as optimal values for the frequency that can then be used to do an oscillatory frequency test. It is common to report results of G' and G'' as a function of either stress or strain. Figure 9 shows values of G' , G'' , and $\tan \delta$ for cocoa butter using: (a) shear stress and (b) frequency, as the controlled variables.

Conclusions

Rheology is a powerful analytical method for the study of fats. It provides insight on the molecular interactions that give rise to the specific properties of the sample. However, the choice of the experimental conditions is crucial for obtaining results that represent the behavior of the sample. In this sense, the use of controlled stress rheometers working in a dynamic mode has proven to be a reliable method for the measurement of rheological properties in fats. The small oscillation amplitude and stresses achievable with these instruments allow for the interpretation of the fat

behavior at different length scales, which in turn is what is needed to fully understand the properties of the material.

FERTILIZERS (MINERAL, ORGANIC), EFFECT ON SOIL PHYSICAL PROPERTIES

Kuntal Hati¹, Kalikinkar Bandyopadhyay²

¹Division of Soil Physics, Indian Institute of Soil Science, Bhopal, Madhya Pradesh, India

²Central Institute for Cotton Research, Coimbatore, Tamil Nadu, India

Definition

Fertilizer. Any organic or inorganic material of natural or synthetic origin (other than liming materials) that is added to a soil to supply one or more plant nutrients essential to the growth of plants.

Mineral fertilizer: A fertilizer material in which carbon is not an essential component of its basic chemical structure. They are also called as inorganic or chemical fertilizer.

Organic fertilizer. A material containing carbon and one or more plant nutrients in addition to hydrogen and/or

oxygen is called organic fertilizer. This generally means that the nutrients contained in the product that are derived solely from the remains or a by-product of an organism.

Physical properties (of soils). Those characteristics, processes, or reactions of a soil that are caused by physical forces and that can be described by, or expressed in, physical terms or equations. For example, size, density, temperature, water, hydraulic conductivity, porosity, and pore-size distribution are physical properties.

Introduction

Fertilizers are common amendments that are routinely applied to agricultural soils for sustaining or improving productivity of crops by supplying mineral nutrients to plant. Fertilizer technologies developed significantly as the chemical needs of growing plants were discovered. Commercial fertilizers are used in modern agriculture to correct known plant-nutrient deficiencies; to maintain optimum soil fertility conditions; to provide nutrition, which aid plants in withstanding stress conditions; and to improve crop quality. The use of modern synthetic fertilizers has significantly improved the quality and quantity of the food available today, although environmentalists debate over their long-term use. The main nutrients supplied routinely as fertilizers to agricultural soils are nitrogen, phosphorus, and potassium. In addition to this, fertilizers containing secondary nutrients (Ca, Mg, S) and micronutrients (Fe, Mn, Zn, Cu, Mo, B) are also applied by farmers as per the deficiency of these nutrients in soil and crop requirement. Fertilizers are generally placed into two categories namely, organic fertilizer and mineral or inorganic fertilizer. Organic fertilizers are composed of naturally occurring compounds such as peat or compounds manufactured through natural processes (such as composting). The word organic fertilizer generally means that the nutrients contained in the product are derived solely from the remains or a by-product of an organism. Cottonseed meal, blood meal, fish emulsion, manures, slurry, worm castings, peat, seaweed, guano, different types of composts, and sewage sludge are examples of organic fertilizers. Green manure crops, grown to add nutrients to the soil, are also considered as organic fertilizer. Microorganisms in the soil decompose the organic fertilizers, making its elements available for use by plants. Mineral fertilizers are compounds occurring either as natural deposits (Chilean sodium nitrate, mined rock phosphate) or are synthesized in a chemical factory (diammonium phosphate, ammonium nitrate, ammonium sulfate, single super phosphate, muriate of potash). Inorganic fertilizers upon application to soil dissolve fully or sparingly in the soil–water system and release the nutrient(s) in the ionic form, which are absorbed by the plants. However, some fertilizers like urea, after application to soil undergo chemical transformation before releasing the nutrients in plant available form. Urea is a synthetic organic fertilizer, an organic substance manufactured from inorganic materials but it is generally categorized as an

inorganic fertilizer because of its rapid hydrolysis to form ammonium ions in soils. Inorganic (or mineral) fertilizers vary in appearance depending on the process of manufacture. The fertilizer particles are available in many different sizes and shapes like crystals, pellets, granules, or dust, and the fertilizer grades can include straight fertilizers (containing one nutrient element only, e.g., urea, single super phosphate, muriate of potash), compound fertilizers (containing two or more nutrients usually combined in a homogeneous mixture by chemical interaction, e.g., diammonium phosphate, ammonium sulfate), and fertilizer blends (formed by physically blending mineral fertilizers to obtain desired nutrient ratios).

The organic fertilizers are usually low in nutrient content and thus required in high volume or bulk to supply a desired amount of nutrient to the crops. Many governments and agricultural departments particularly in developing countries go to great lengths to increase the supply of organic fertilizers, such as organic manures and composting materials, but not enough of these fertilizers are available to meet the existing and ever increasing future fertilizer needs. Compared to organic compost, mineral or inorganic fertilizers have the added advantage of being less bulky. Being less bulky makes chemical fertilizer easier to transport, both overland and from the soil into the plants itself, because they get to be available to the plant relatively quickly when incorporated as part of the plant-food constituents. There has been much controversy over whether organic or mineral fertilizers are a better source of nutrients for plants. Here it is important to note that plants do not recognize the difference between the nutrients derived from organic and inorganic fertilizers. Their tiny root hairs can absorb only nutrients that have been broken down into inorganic, water-soluble forms. That means the plant makes no difference between the nutrient ions coming from a compost pile or a fertilizer factory. However, to obtain optimum crop yield it is essential for integrated application of both organic and inorganic fertilizers containing all the nutrients in balanced proportion as per crop demand. There are, however, advantages and disadvantages to each type of fertilizer material, organic or mineral.

Organic fertilizer

Advantages – There is less danger of overfertilization by adding decomposed organic material to a crop. It provides a slow release of nutrients as microorganisms in the soil break the organic material down into an inorganic, water-soluble form, which the plants can use. The addition of organic material generally increases the organic carbon content of the soil and improves soil structure or “workability.” It also improves the chemical and biological properties of the soil. Continued use of organic fertilizers results in increased soil organic matter, reduced erosion, better water infiltration and aeration, higher soil biological activity as the materials decompose in soil, and increased yields after the year of application (residual effects).

Limitations – For the most part, the nutrients in organic fertilizer are not immediately available to the plants due to their slow-release nature. Thus, if there is an immediate need for nutrients to crop, organic fertilizer cannot supply them in a hurry. Furthermore, information on the amount of nutrients and the exact elements in an organic fertilizer such as manure is not readily available to the crop growers. The organic fertilizers are usually required in high quantity to have desired effects as they are low in nutrient content. This condition makes them uneconomical to transport them far from their point of production. The possibility of nitrogen depletion is another drawback of organic fertilizers. Because of complex bacterial action, the addition of a large amount of organic material with high C/N ratio can cause a temporary nitrogen depletion in the soil and therefore in the plants because of immobilization process. Indiscriminate use of animal manures and human waste (sewage sludge), as has been practiced for their disposal in some areas, can create human health hazards through the accumulation of nitrates, phosphates, heavy metals, and pathogens in the soil. Other than this use, there are other competing uses of organic residues like fuel and animal feed in developing countries, which makes them unavailable for agricultural purpose.

Mineral fertilizer

Advantages – The primary advantage of using packaged mineral fertilizer is that nutrients are immediately available to the plants. As mineral fertilizers contain precise and guaranteed levels of nutrients, in forms that are readily available for plant uptake and use, the exact amounts of a given element can be calculated and given to plants. Because of their high nutrient content, mineral fertilizers are easy and economical to ship to great distances from their point of production.

Limitations – Commercial fertilizer, especially nitrogen, is easily washed below the level of the plant's root system through the leaching of rain or irrigation, which may pollute the ground water or may cause eutrophication in lakes and water bodies. Improper use of these fertilizers can lead to volatilization loss of ammonia under high soil pH and also emission of nitrous oxide because of denitrification under anaerobic condition. An application of too heavy dose of fertilizers close to the roots of the plants may cause “burning” (actually a process of desiccation by the chemical salts in the fertilizer). As well, overly heavy applications of commercial fertilizers can build up toxic concentrations of salts in the soil, thus creating chemical imbalances. Excessive use of straight fertilizers leads to soil mining of essential nutrients causing multi-nutrient deficiencies and unsustainable crop yield.

Fertilizer effect on soil physical properties

Favorable effects

Fertilizers are applied to soils in order to maintain or improve crop or pasture yield. The increased plant biomass produced by fertilizer results in increased return of

organic material to the soil in the form of decaying roots, litter, and crop residues. Mineral fertilizers indirectly influence soil organic matter content by increasing crop productivity and thereby the amount of organic matter returned to the soil in various crop residues. The effect of mineral fertilizers may therefore be compared to that of straw incorporation. But when animal manure with a plant nutrient content equivalent to that of the mineral fertilizer dressing is applied, the soil receives an additional input of organic material, which contributes to the soil organic matter pool. The increase in organic matter formed due to mineral fertilizer-induced crop yield increases is generally of a more aromatic nature and thus has a higher Cation Exchange Capacity (CEC) than that formed due to organic fertilizer (farmyard manure) addition (Schjonning et al., 1994). Increased organic matter inputs stimulate the microbial and faunal activity of the soil and consequently favor improved soil physical conditions. Increasing soil organic matter content characteristically leads to a decrease in bulk density and surface crusting and an increase in water holding capacity, macroporosity, infiltration capacity, hydraulic conductivity, and aggregation. These aspects are discussed below in detail:

1. Structure and aggregation: Soil aggregates are the basic unit of soil structure and are composed of primary particles and binding agents (Tisdall and Oades, 1982; Haynes et al., 1991). Soil aggregation is the process by which aggregates of different sizes are joined and held together by different organic and inorganic binding agents. In surface soils, organic matter is the main binding agent responsible for the water stability of soil aggregates by the formation of clay humus complex. The aggregate stability is positively correlated with the soil organic carbon content (Hati et al., 2008). Therefore, it is expected that addition of organic-fertilizers or materials rich in organic carbon such as manure or sludge will lead to an improvement of the aggregation status of soil. Long-term fertilizer studies have shown that application of fertilizers to soil induces an increase in number and size of water stable aggregates. Inorganic fertilizer additions can have physicochemical effects on soil, which influence soil aggregation. Phosphatic fertilizers and phosphoric acid can favor aggregation by the formation of Al or Ca phosphate-binding agents while where fertilizer NH_4^+ accumulates in the soil at high concentrations, it behaves like Na^+ and causes dispersion of clay colloids.
2. Bulk density and porosity: Application of organic-fertilizer in long-term normally reduces the bulk density of the soil due to higher organic matter content of the soil, better aggregation and a consequent increase in volume of pores and increased root growth. Furthermore, addition of large quantity of organic manure or wastes reduces the bulk density of the soil due to a dilution effect caused by mixing of the added organic
- material with the denser mineral fraction of the soil (Khaleel et al., 1981). Organic fertilizer addition leads to an increase in total pore volume of the soil. Besides total pore volume, pore-size distribution also changes with fertilization. Organic matter addition through sludge and compost increases the percentage of transmission (50–500 μm) and storage (0.5–50 μm) pores while reduces the percentages of fissure ($>500 \mu\text{m}$) (Metzger and Yaron, 1987).
3. Water retention properties: Water retention by soils is controlled primarily by the following: (1) the number of pores and pore-size distribution of soils; and (2) the specific surface area of soils. Because of increased aggregation with application of organic-fertilizers, total pore space in soil is increased. Furthermore, as a result of decreased bulk density, the pore-size distribution is altered and the relative number of small pores increases, especially for coarse-textured soils. Organic-fertilizer application improves water retention properties of soil through its effect on pore-size distribution and soil structure. Organic-fertilization increases soil–water retention more at lower suctions due to increase in micropores and inter-aggregate pores caused by enhanced soil organic matter content and higher activity of soil fauna, e.g., earthworms and termites. At higher tensions close to the wilting point (1.5 MPa), nearly all pores are filled with air and the surface area and the thickness of water films on soil particle surfaces determine moisture retention. Following an addition of organic matter, specific surface area increases resulting in increased water holding capacity at higher tensions.
4. Water transmission properties: Fertilization indirectly influences the water transmission properties of the soil through their influence on aggregation status and on porosity. As good structural conditions are usually associated with adequate water transmission properties, it can be inferred that fertilization will generally improve the water transmission properties.
 - (a) Hydraulic conductivity: Addition of organic manure and mineral fertilizer results better aggregation, increase in effective pore volume and an increase in continuity of pores due to enhanced root growth and formation of bio-pores, increased faunal activity and earthworm population and burrows. As soil permeability is a function of effective pore volume, increased pore volume has a positive influence on the saturated hydraulic conductivity of the soil (Hati et al., 2006).
 - (b) Infiltration: Infiltration through the soil surface depends on the soil surface features and the hydraulic conductivity in the underlying soil. The application of organic fertilizer generally improves both the initial and steady-state infiltration rate due to the beneficial effect of fertilization on the water stability of soil aggregates, consequent reduction in crust formation, and increase in hydraulic conductivity.

Detrimental effects

Excess or imbalanced application of fertilizers to soil can have some negative effect on soil physical properties. An application of ammonium containing or forming fertilizers sometimes shows adverse effect on soil aggregation. When the monovalent NH_4^+ ion accumulates in soils in large amount it becomes a dominant exchangeable cation and like Na^+ it favors dispersion of soil colloids (Haynes and Naidu, 1998). In many cases, application of fertilizer K alone particularly in humid temperate region decreases the aggregate stability of the soil owing to an increase in the proportion of exchangeable cations present in monovalent form and leaching of Ca and Mg. Long-term application of N-containing mineral fertilizer alone in Alfisols of humid tropics can deteriorate the physical properties of the soil due to reduction in pH and yield of crops (Hati et al., 2008).

Application of organic fertilizers to soil at rates far in excess of traditional rates for the purpose of disposal of wastes (e.g., animal manure from feed lots, composted municipal wastes, and sewage sludge) also have detrimental effects on soil physical properties like surface crusting, increased detachment of soil particles by raindrops, and decreased hydraulic conductivity. The primary reason for this soil structural breakdown is the high content of monovalent cations (Na^+ and K^+) in animal waste materials and accumulation of high concentration of NH_4^+ through mineralization of N in organic wastes. Sometimes excessive NO_3^- formed in the animal manure feedlot can leach down the profile and pollute the ground water. Besides this, at a high rate of organic matter application to soil, the soil tends to become water repellent due to production of water-repellent substances by fungi involved in the decomposition of the manure (Weil and Kroontje, 1979).

Summary

Fertilizers, both organic and mineral, are essential for sustainable crop production. Organic fertilizers play a significant role in improving the soil physical properties like soil aggregation, pore-size distribution reduction in soil compaction and crusting, and also improving the soil water retention and transmission characteristics. However, there is limitation in availability of the organic fertilizers sufficient enough to meet the crop demand to produce food, feed, and fiber for the growing population. The role of inorganic fertilizers cannot be ignored to meet the immediate crop demand. Besides this condition, the inorganic fertilizers also help in addition of organic residues to soil through enhanced biomass production and root growth. Therefore, both organic and inorganic fertilizers should be applied in integrated manner and in balanced proportion to improve soil health, minimize environmental pollution, and sustain crop yield at higher level.

FIELD WATER CAPACITY

Karl Vanderlinden¹, Juan V. Giráldez²

¹Centro Las Torres-Tomejil, IFAPA,
Alcalá del Río (Seville), Spain

²Department of Agronomy, University of Córdoba,
Córdoba, Spain

Synonyms

Field capacity; In situ field capacity

Definition

Field water capacity is defined by the Soil Science Glossary Terms Committee (2008) as the content of water, on a mass or volume basis, remaining in a soil 2 or 3 days after having been wetted with water and after free drainage is negligible.

Field water capacity or *field capacity* (FC) is the upper limit of the *available soil water* (AW) reservoir, from which water can be released but not necessarily absorbed by plants, until the *permanent wilting point* (PWP) is reached. An earlier definition of the concept by Veihmeyer and Hendrickson (1931, p. 181), “the amount of water held in soil after the excess gravitational water has drained away and after the rate of downward movement of water has materially decreased,” is rather subjective. The water content at FC has been operatively approximated as the equilibrium volumetric soil water content at values of the matric potential ranging from -1 to -50 kPa, with -33 kPa as a generally accepted reference value. Since FC depends on field conditions (e.g., porosity, structure), in situ determination is considered more accurate (Ritchie, 1981). The dynamic aspect, implicit in the definition of FC, was not considered until Nachabe (1998) and Meyer and Gee (1999) proposed to estimate the water content at FC, θ_{FC} , as the value at which the hydraulic conductivity of the soil reaches a fixed low value, $q_{FC} = k(\theta_{FC})$, considering that the free drainage flow is essentially gravity driven, with unit potential gradient, and that the flux density of the water, q , equals the hydraulic conductivity, $q = k(\theta)$. Nachabe (1998) suggested a value of $q_{FC} = 0.05$ mm/day = $5.8 \cdot 10^{-10}$ m/s, and Meyer and Gee (1999) chose a range (10^{-8} – 10^{-10} m/s) to include soils with different textural classes. In both cases, the conductivity-derived water contents at field capacity were very close to the field estimated data of Ratliff et al. (1983) and to some of the retention-curve-derived values for a matric potential of -33 kPa. Nachabe (1998) used a simplified model to describe the soil water redistribution process, adopting the Brooks and Corey hydraulic conductivity expression, $k = k_s \cdot \Theta^n$, with k_s , the saturated conductivity, Θ , the effective saturation, and n , a coefficient to determine the time required to reach FC:

$$t_{FC} = \frac{I}{n} \left(\frac{1}{q_{FC}} - \frac{1}{k_s \Theta_i^n} \right) \quad (1)$$

Equation (1) indicates the influence of the initial infiltration depth, I , and effective saturation, Θ_i on the drainage time, yielding larger values than 2 or 3 days of the original definition. Minasny and McBratney (2003) introduced a physical estimation of the PWP by introducing the integral energy or the integral of the water retention curve as a measure of the energy required to extract the water of the soil to a certain level. These approaches allow a more precise estimation of the ill-defined and commonly used concepts of FC, PWP, and AW.

FINGERING

The appearance of protrusions in the normally smooth wetting front during infiltration. Such “fingers” may propagate downward into the subsoil and carry plumes of water and solutes while bypassing the greater volume of the soil matrix. The phenomenon is also called “wetting-front instability” and “unstable flow.”

Bibliography

FIRMNESS

Resistance to externally applied load.

FISSURES

Fissures in soils are cracks at or near the soil surface resulting e.g., from soil compaction or lowering of the water table by excessive groundwater pumping.

FLEXURAL STRENGTH

Strength of a material in blending, that is, resistance to fracture.

FLOCCULATION AND DISPERSION PHENOMENA IN SOILS

Emil Chibowski

Maria Curie-Skłodowska University, Lublin, Poland

Synonyms

Agglomeration; Aggregation; Coagulation; Peptization; Suspension

Definition

Flocculation – process during which particles, for example, of a soil, dispersed in a solution contact and adhere each other, forming clusters, flocks, flakes, or clumps of a larger size. The term originates from the word “floc,” which is the flake of precipitate that comes out of solution. The floc may float to the top or settle to the bottom of the liquid, as well can be readily filtered from the liquid. Flocculation is synonymous with agglomeration and coagulation.

Dispersion – a system in which solid or liquid particles are dispersed in a continuous phase (liquid, gas, or even solid) of different composition. In soils dispersion occurs when a soil contains clays. When such a soil is wetted the clay particles are detached from each other and form dispersion, that is, separation of the soil into single particles occurs.

Introduction

Various physicochemical processes take place in soil–water systems, among others flocculation and dispersion. Usually they are complicated because of very complex character of soils, their mineralogy, content of clay minerals, organic substances, etc. Many factors affect course of the processes, that is, type of ions present, the ionic strength, adsorption of the ions, pH, and temperature (Pils et al., 2007 and the references therein). Taking into account the content of clay fraction natural soils can be classified as: sand (<10 wt%), loamy sand (<15 wt%), sandy loam (<20 wt%), sandy clay loam (<30 wt%), sandy clay (<55 wt%), and clay (Pivovarov, 2006). Soils can be also classified with respect to the soluble salts (EC) and sodium adsorption ratio (SAR) amounts and these two parameters indicate somehow the soil structure. In this way four types of soils can be distinguished, as shown below (Walworth, 2006).

Soil	EC	SAR	Soil status
Normal	<4	<13	Flocculated
Saline	>4	<13	Flocculated
Sodic	<4	>13	Dispersed
Saline-sodic	>4	>13	Flocculated

In soils, the flocculation process concerns mostly the clay particles present. Clay particles usually possess net negative charge and therefore they electrostatically attract positively charged ions, such as Ca^{2+} cations, which form bridges, holding the particles together. Therefore, these cations can induce flocculation of clay particles. Three main types of clay can be distinguished: illite (muscovite), kaolinite, and montmorillonite (Pivovarov, 2006). In the clay fraction, an average content of Al amounts about 20 wt%. These silicate minerals have different lattice structure and hence different affinity to bind sodium cations. They consist of layer platelets and in case of kaolinite, the platelets are formed of octahedral alumina layer on one side of which there is tetrahedral silicate layer and no cations can be exchanged between the kaolinite plates. Hence, kaolinite possesses exchangeable cations on its surface. In case of muscovite on both sides of alumina platelet there are tetrahedral silicate layers. There is electric charge on the muscovite surface because each fourth Si atom is replaced by Al atom and the exchangeable cations are placed in the lattice (Pivovarov, 2006). In montmorillonite clays, the platelets are weakly bound and are affected by sodium ions the most, while in the kaolinite the least. The same trend is also true as for their swelling and dispersion. Dispersion being the process of separation of soil into single particles is governed by soil texture, clay type, soil organic matter content, soil salinity, and the exchangeable cations present. Dispersion and slaking have a large effect on the soil behavior. The dispersed clay particles may plug in the soil pore structure and thus decrease water penetration. Occurrence of dispersion process is generally a major cause of the soil erosion, as well as after such soil repeated wetting and drying its structure may become cemented. These two processes will be described in some detail below.

Flocculation

Generally flocculation process is applied to remove solid particles from a solution. It can occur naturally, but in practical industrial applications more efficient process needs addition of some flocculants. It is used to a large scale, for example, in waste water treatment. Flocculation may be desired process (e.g., sedimentation of the particles from waste waters) or undesired (e.g., in some dairy processes) (Smith, 2009). Flocculated soil particles form aggregates which may also form cemented clusters of clay, silt, and sand particles (Walworth, 2006). In dispersed

clay, suspension being in quiescent conditions, flocculation of its particles may occur spontaneously because negative charges present on the platelets faces attract positive charges on their edges thus forming flakes. Such aggregates facilitate water penetration between them as well as growth of plant roots. In soil, most common cations are sodium Na^+ , potassium K^+ , magnesium Mg^{2+} , and calcium Ca^{2+} . The bivalent cations are good flocculants while the monovalent are good dispersants. The relative flocculating power of the above-mentioned cations is: 1.0, 1.7, 27.0, and 43.0, respectively (Walworth, 2006). All cations in water are hydrated and the smaller charge and the larger hydrated radius, the cation is the poorer flocculant. The flocculation power is determined as the Sodium Adsorption Ratio (SAR) expressed by the cation molar concentrations:

$$\text{SAR} = \frac{[\text{Na}^+]}{\sqrt{[\text{Ca}^{2+}] + [\text{Mg}^{2+}]}} \quad (1)$$

The lower the value of SAR (i.e., larger bivalent cation concentration), the more flocculated is the soil. Also, if the content of soluble salt is high (high ionic strength) the soil will flocculate, even at an elevated content of sodium ions (Walworth, 2006). Fine particles of soil (clay minerals), say less than 0.1 μm (100 nm), usually possess electric charge (typically negative one) and in aqueous solution repel each other and remain suspended. Once their electrostatic charge is neutralized by the addition of an electrolyte or other chemical compound (flocculant), the particles start to collide and due to attractive van der Waals forces flocculate forming agglomerates. Generally, stability of colloidal particles including soil colloids can be evaluated using the Derjaguin–Landau–Verwey–Overbeek (DLVO) theory of colloid stability, which balances the electrostatic repulsive forces, resulting from the presence of electrical double layer at the particle surface and the attractive van der Waals forces between them (Israelachvili, 1985). It explains the effect of increasing ionic strength and the ion charge on flocculation of the particles, which is caused by the compression of thickness of the diffuse part of the double layer. However, the theory fails in case of very hydrophilic particles, because it does not consider hydration force and/or the Lewis acid–base interactions, which in most cases are the hydrogen bonding. This is taken into account in the extended DLVO theory proposed by van Oss et al. (1990) (Wiacek and Chibowski, 1999). Classical DLVO theory also does not predict formation and destruction of smectite quasicrystals (Pils and Laird, 2003). From kinetics point of view, flocculation may be classified as transport-controlled or surface reaction-controlled process. The transport-controlled flocculation is termed if the process rate is determined by the movement of two or more particles toward one another prior to their close encounter and immediate coalesce to form a large particle. The surface-controlled flocculation occurs if it is particle coalesce instead of particle movement toward collision that limits the rate of flocculation

(Sposito, 2008, p. 244). Then, three mechanisms of transport-controlled flocculation are possible, that is, (1) the Brownian motion or *perikinetic flocculation*, which occurs in case of diffusing particles in a question suspension (smaller than 1 μm), (2) *orthokinetic flocculation* caused by stirring, (3) *differential sedimentation* due to gravitational or centrifugal forces. These later two mechanisms involve also particles larger than 1 μm . The details on the flocculation kinetics can be found in Sposito (2008) monograph, *The Chemistry of Soils*. As was mentioned above flocculated/dispersed state of soil colloidal particles largely depends on the amount of electrolyte concentration (EC) and the cations valency, and when the attractive van der Waals forces overcome repulsive electrostatic ones the rapid flocculation (coagulation) process should take place. The concentration at which it happens is termed *critical flocculation concentration* (CFC) (Zhang, 2002). It should be also mentioned that synthetic polymers have been also applied in practice to enhance flocculation in soil (Zhang, 2002; Pivovarov, 2006). The presence of humic substances in soil may enhance clay particles flocculation by binding the particles together (Pils et al., 2007). On the other hand, Heil and Sposito (1993) investigated the influence of organic matter on flocculation of soil colloidal particles depending on the electrolyte concentration, pH, and exchangeable or dissolved bivalent cations. They found that the flocculation increased with increasing content of organic matter. With increasing pH flocculated amount also increased, but this relationship reversed if the organic matter had been removed. Generally, they stated that the electrolyte concentration needed to flocculate the soil, effect of pH, and effectiveness of calcium versus magnesium cations – all these factors depend on the organic substances content in the soil (Heil and Sposito, 1993).

Dispersion

The dispersion and slaking processes, like flocculation, affect greatly soil properties. As a result of their occurrence, the individual particles are liberated and the structure and/or aggregation of the soil is destroyed. It has fundamental meaning for water infiltration, redistribution, and evaporation in the subsoil (Khan and So, 2006). The 7–10% content of dispersion Khan and So (2006) denoted as “critical dispersion,” then at 10–13% rapid water blockade takes place, and at a level of 15% and more extremely low rate of water infiltration will be observed. The suspension is a heterogeneous system consisting of solid particles (the internal phase) and a liquid (external phase). The dispersed soil colloidal particles among others cause the soil erosion, the siltation in rivers, ponds, lakes, and other reservoirs, the transportation of nutrients, and the crusting of surface soils. The suspended in runoff water clay particles will not sediment as long as the water velocity is sufficient to cause turbulence, which churns and mixes the flow. If the particles are sufficiently large (larger than 1 μm), due to gravity they will finally sediment if left in quiescent conditions. During a longer time period the sediment

forms large deposits. Such processes cause the largest pollution in stormwater runoff and may have serious destroying impact on ecosystems (Web page 2, 2008). However, to sediment in water particles smaller than 0.1 μm , even in quiescent conditions, some flocculant agent has to be used, and in some systems a multivalent cation like Ca, Al, Fe, Mg (see above) might be sufficient, or a suitable polymer can be added. Here pH and temperature may play an essential role too. As was mentioned above, appropriate concentration of sodium cations in soil is very important for its dispersiveness. Moreover, some investigations have shown that in the absence of montmorillonite, dispersion did not occur even at high amount of Na^+ present in the soil pore water (Bhuvaneshwari et al., 2009). Generally, dispersion may result of two processes occurring simultaneously, that is, mechanical and physicochemical (Alvarez-Benedi et al., 2004), and the dispersion phenomena can be studied on local, fluid, and macroscopic levels, depending on how big volume element is taken into account (Fried and Combarnous, 1971). The macroscopic level is considered in case of porous media with a solid matrix and here, the averaged parameters characterizing the dispersed system are obtained. Mechanical dispersion is obtained when liquid flows through a porous system and originates from boundary and geometrical effects and increases with the liquid velocity (Álvarez-Benedi et al., 2004). Physicochemical dispersion originates from the molecular diffusion caused by gradient in chemical potential. This mechanism is not dependent on the fluid velocity flow and takes place even in quiescent conditions. In this case, an increase in the temperature will affect (increase) the diffusion coefficient too, and thus the dispersion occurrence (Álvarez-Benedi et al., 2004). In studies of dispersion phenomena in soils often the term *dispersion coefficient* appears, which is defined in different ways. For example, it was defined as percentage of clay matter present in the soil that could be dispersed by contact with water, hence its value might range from 0% to 100%, depending on the degree of the soil flocculation (0%) or dispersion (100%) (Web page 1). But, the same term is also used to describe the displacement of solution (solute) in a porous soil, and hence can be termed as coefficient of proportionality between the dispersive flux of a solute and the gradient of its concentration. Then the equation describing the solute displacement involving also adsorption of the solute components is following:

$$\frac{\partial C}{\partial t} + \frac{\rho \partial s}{\theta \partial t} = D \frac{\partial^2 C}{\partial x^2} - V \frac{\partial C}{\partial x}, \quad (2)$$

where C is the solute concentration, ρ is the bulk density, s is the adsorbed concentration, D is the *dispersion coefficient* ($\text{cm}^2 \text{s}^{-1}$), V is the velocity of water in the pores, t is the time, x is the distance, and θ is the volume content of water. Here, the dispersion coefficient expresses the dispersion of solute during its movement and involves its mechanical dispersion and molecular diffusion

(Ahmad, 2002). Moreover, notations *unsaturated dispersion coefficient* and the *saturated dispersion coefficient* are also met. The dispersion coefficient is also expressed as:

$$D = D_o + \alpha v \quad (3)$$

where D is the dispersion coefficient (cm^2/s) and D_o is the effective molecular diffusion in a porous medium (cm^2/s), while α is the *dispersivity* (cm), and v is the mean pore water velocity (cm/s) (Matsubayashi et al., 1997). These authors found that according to the above equation under saturated conditions, the dispersion coefficient increases linearly with increasing pore water velocity. The same was true under unsaturated conditions but only to defined rate of the velocity. Moreover, at the same pore water velocity the coefficient was larger in unsaturated solution than in saturated. For more advanced models of the solute dispersion and the solute transport see Chap. 3.4.3 in Alvarez-Benedi et al. (2004). Field experiments showed that the dispersion coefficient depends on the ground water velocity and it is practically constant at low velocities (when molecular diffusion is the principal factor), but it increases linearly with the ground water velocity increase, when the hydraulic dispersion is dominating. Hence the dispersion coefficient D can be expressed as a sum of two components: effective molecular diffusion coefficient D_d and hydraulic dispersion coefficient D_h (Kuo, 1999). Similar studies on field soils showed that the dispersivity lies between 0.7 cm (sand) and 16–38 cm (clay loam) (Lal and Shukla, 2004). The nature of organic carbon, cations, electrolytes, and pH present in soil, all of them influence dispersivity of soil aggregates (Bronick and Lal, 2005 and the references there in). Also, larger amounts of ammonium cation originating from a fertilizer can disperse the soil clay. Contrary, an amount of added gypsum reduces the dispersivity by affecting the electrolyte concentration and its composition. Moreover, manuring usually increases the dispersion of soil aggregates (Bronick and Lal, 2005).

Summary

Good wettability (hydrophilicity) of a soil (Reddi and Inyang 2000; Ritsema and Dekker, 2003) is of crucial importance for water infiltration and plants vegetation. Flocculation and dispersion phenomena occurring in the soil play a very essential role for water transport, too. While the flocculation processes usually lead to the soil aggregates formation and hence an easier water penetration and fertilizers delivery to the plant roots, so the dispersion processes may cause blockade of soil pores and thus hinder the water flow and fertilizers transport. Because of very complex nature of composition and structure of soils, a general detailed forecast of these processes run is difficult. Nevertheless, some their general features can be described and they were briefly described above.

Definition

Flooding soils: They are those in which water covers the soil, or is present either at or near the surface of the soil all year or for varying periods of time during the year. Flooding soils are classified as Fluvisols, Planosols, and Gleysols in the FAO-UNESCO Soil Map (2000). Fluvisols are covered part of the year by surface water from river overflows; Planosols are soils having an impervious Bt horizon, supporting perched water during short periods; and Gleysols are soils affected by stagnant water tables during long periods.

Soil structure: It is concerned with the organization of soil constituents into larger aggregates and arrangement of porosity and pore size distribution.

Introduction

Soil structural behavior of flooded soils received considerable less attention, as compared with agricultural, dryland soils. A key factor determining soil structural behavior is the quality of flooding water, which depends on soil profile characteristics. Soils without a tough Bt horizon have no limitations for free down- and upward water movements throughout the profile. In them, water table rises can reach their top horizons and deposit soluble salts in them. In soils with a tough, impervious Bt horizon, water

table rises are controlled by this horizon and cannot reach the topsoil (Lavado and Taboada, 1988). Flooding water in them is typically of rain origin and does not cause severe consequences on soil properties and vegetation (Taboada et al., 2001; Insausti et al., 2008).

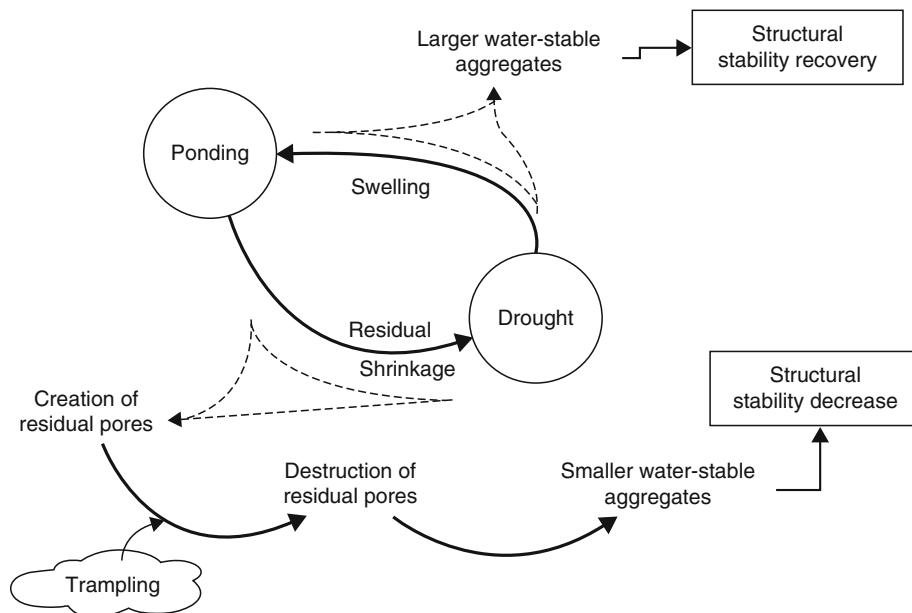

Soil structural behavior in flooding soils

Flooding soils are subjected to seasonal flooding and subsequent dry periods. They undergo drastic structural changes due to alternate wetting and drying (W/D), which

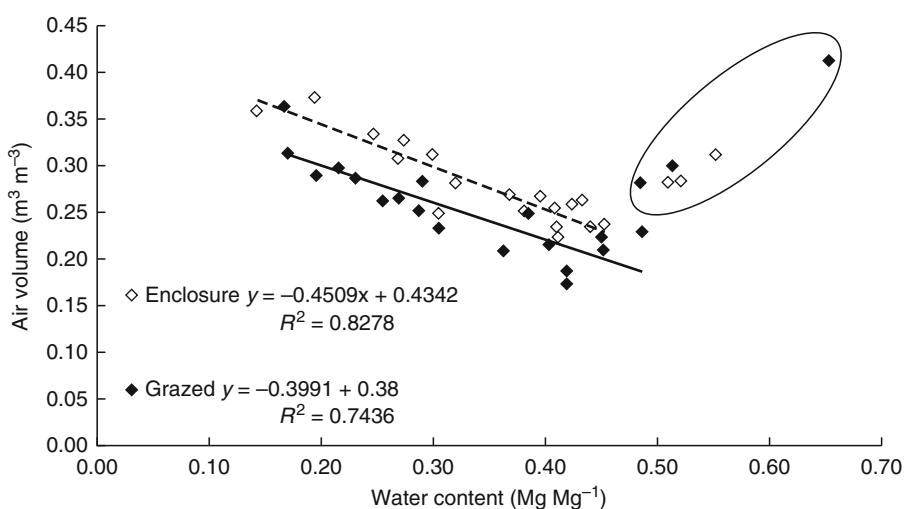

exert strong influences on: (1) soil structural stability, (2) soil mechanical properties, and (3) trapped air volumes.

Soil structural stability

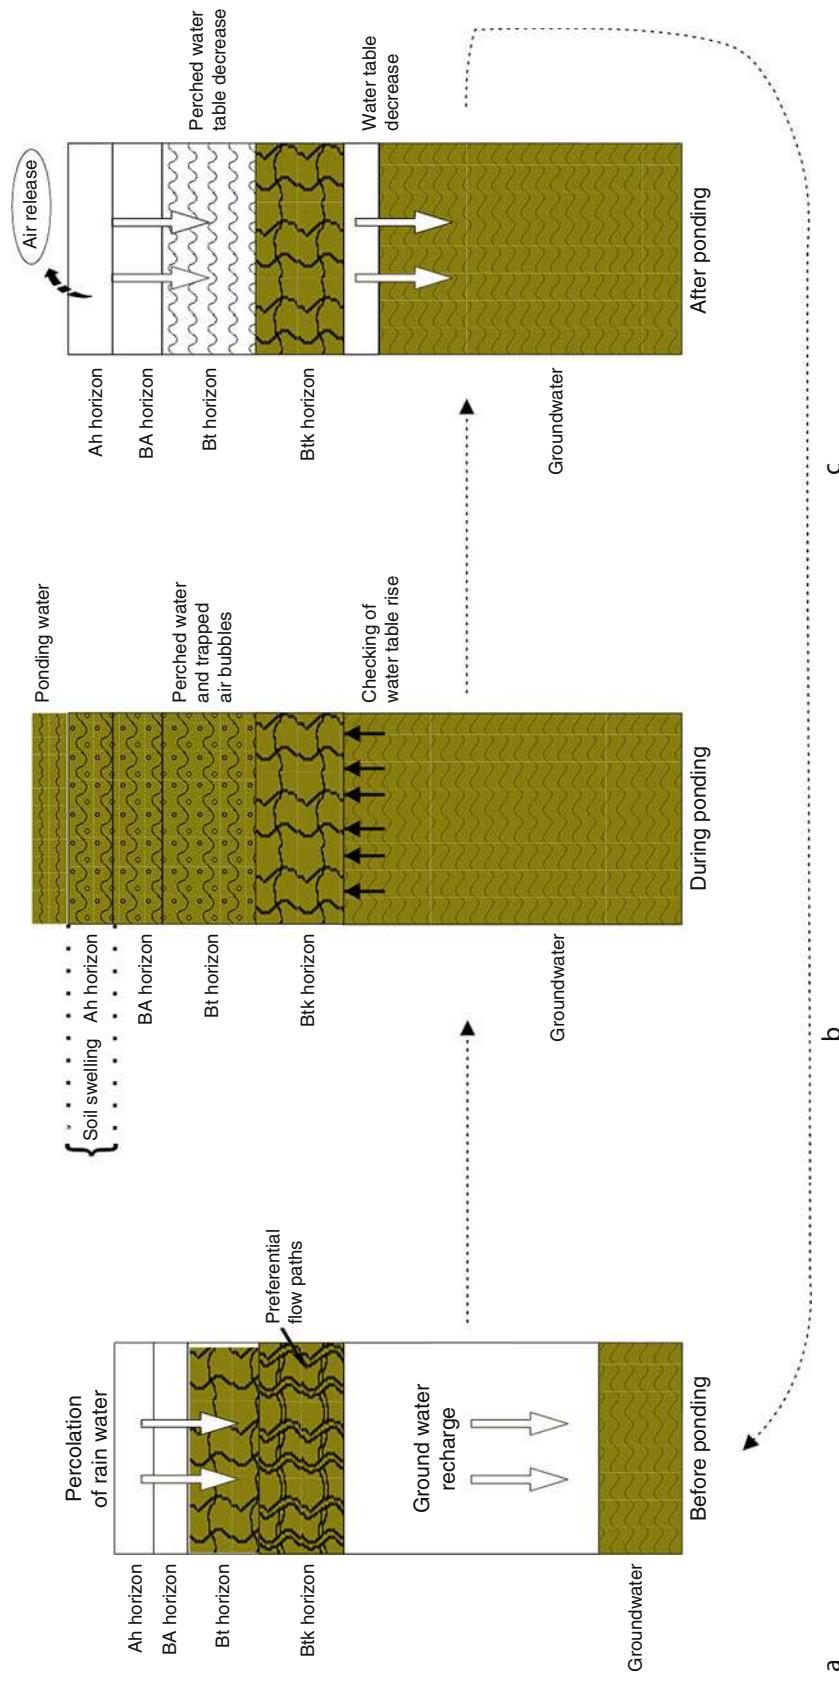

Soil aggregates are biologically stabilized either by bonding between organic compounds and soil mineral particles or physical binding due to fine grass roots and fungal hyphae (Tisdall and Oades, 1982; Oades, 1993). The abiotic stabilization of soil structure depends on soil chemical

Flooding, Effects on Soil Structure, Figure 1 Conceptual model showing the process of soil structural destabilization when the soil dries and the process of structural recovery when the soil wets. (Adapted from Taboada et al., 1999).

Flooding, Effects on Soil Structure, Figure 2 Soil air volume calculated in enclosed and grazed situations in Typic Natraquoll from the Flooding Pampa of Argentina. (Adapted from Taboada et al., 2001).

Flooding, Effects on Soil Structure, Figure 3 Conceptual model describing the process of soil swelling because of air entrapment. (a) Before ponding; free water and air movements throughout the profile (bio-opened system); (b) during ponding: soil swelling by air trapped within water table perched over the impervious Btk horizon (air-occluded system); (c) after ponding: soil shrinkage after perched water and water table decreases and rapid air escapes to the atmosphere. (Adapted from Taboada et al., 2001).

composition, and also swell–shrink soil capacity during W/D cycles (Dexter, 1988; Oades, 1993). The role of polyvalent cations in the aggregate stability of flooding soils is great and it masks the contribution of other aggregating agents. The Fe, Al, and Mn dynamics of these soils and the prevailing condition of seasonal waterlogging encourage soil aggregate stability. These polyvalent metals may form bridges between clay and organic matter in the formation of aggregates (Igwe and Stahr, 2004). Caron et al. (1992) observed that the extreme W/D cycles of flooded soils might lead to breakdown of aggregate stability of soils, due to the extinction of interparticle cohesion, which is also known as the “antecedent soil moisture effect” (Gerard, 1987; Perfect et al., 1990). Soil mellowing, which consists in their partial slaking by trapped air pressures, often results when soils are carried to high water contents (Grant and Dexter, 1990).

Results obtained in grazed grassland soils of the flooding Pampa (Taboada and Lavado, 1993; Taboada et al., 1999) show that flooding by rainwater does not destabilize topsoil structure. In this region, soil water content was the primary cause of changes in total porosity, because of shrink–swell processes. The periods when trampling affected topsoil porosity and aggregate stability were in summer when soil is dry. A conceptual model shows the process of soil structural destabilization when the soil dries and the process of structural recovery when the soil wets (Figure 1).

The conceptual model postulates that decreases in structural stability result from crushing air-filled pores by cattle hooves. Only at low water contents was the structure of the topsoil destabilized by grazing. The recovery of structural stability began in the fall and was completed in the winter, when the soil was flooded. The structural recovery results from swelling, when the smaller aggregates created by trampling of dry soil are bound again into larger structural units. Soil swelling as a result of trampling was also found by Mulholland and Fullen (1991), Mullins and Fraser (1980), and Scholefield et al. (1985).

Soil mechanical properties

According to soil rheology, soil undergoes elastic deformation and shallow compaction when loaded at a moist condition (Lal and Shukla, 2004). Flooding soils are typically devoted to livestock production on native grazed grasslands. Soil water content determines the magnitude of the stress caused by animal hoof impact mainly (Warren et al., 1986; Mulholland and Fullen, 1991). When a wet soil is trampled, there is plastic flow around the hoof (Mullins and Fraser, 1980; Scholefield et al., 1985). Repeated treading in these conditions produces deep hoofprints, this process is called poaching, and leads to damage the sward (Mullins and Fraser, 1980; Scholefield et al., 1985; Greenwood and Mc. Kenzie, 2001). This effect, generally, coincides with the presence of free surface water (Mulholland and Fullen, 1991), with a progressive loss of soil strength, and creates dense, unstable surface clods (Warren et al., 1986). At our site, the low stocking

rate was probably insufficient to create this repeated stress. Previously damaged soil pores can be regenerated, however, during W/D cycles. This depends on soil shrink–swell (Dexter, 1988; Drewry, 2006), provided the externally applied stress is decreased or removed. The regeneration mechanism depends on the formation of microcracks, as a compacted soil layer dries (Dexter, 1988).

Trapped air volumes

Seasonally flooded soils could present trapped air due to influence of soil wetting fronts (Taboada et al., 2001). Their influence is shown by air volume–water content relationships, determined in a flooding Pampa soil (Typic Natraquoll) in grazed and enclosed field situations (Figure 2). Straight negative lines show the expected air volume increases on drying. A group of points departed from the fitted lines, showing the occurrence of air entrapment when the soil is wet. Trapped air volumes cause the soil swelled by “inflation” (Gäth and Frede, 1995), which contributes to soil structural recovery found during flooding in this region (Taboada et al., 2001).

A conceptual model describes how the soil evolves from a “bio-opened” system when desiccation cracks are opened in the Bt horizon, to an “air-occluded” system when air becomes trapped within water table perched over the impervious Btk horizon (Figure 3).

Interesting to note, a similar “air inflation” process was recently found in agricultural soils from the North Pampas region (Fernández et al., 2010). In this case, trapped air volumes resulted from livestock trampling at waterlogged conditions at low stocking rates. These processes of air inflation can be pointed out as the main reason why the predictions based on soil rheology are not always accomplished in flooding and waterlogged soils.

Conclusions

Soil structural behavior of flooding soils cannot be easily explained, following the criteria established for agricultural, unsaturated soils. Despite they often sustain grassland vegetation, whose roots are permanent stabilizing agents, the stabilization of topsoil structure seems to be mainly abiotic, based on the drastic W/D cycles.

Grassland soils of the flooding Pampa of Argentina can be considered a good study case, which shows positive effect of flooding with rainwater in topsoil structure. In this region, structural damages occur in dry summer when livestock hooves crush surface aggregates.

The build-up of trapped air pressures is an important fact in flooded soils. It results in soil swelling by air inflation. The influence of this process on soil structural recovery during flooding needs further investigation.

Fractal modeling

Definition

Fractal. Rough or fragmented geometric shape that can be subdivided into parts, each of which is (at least approximately) a reduced-size copy of the whole.

Fractal analysis. Using fractals to approximate observed geometric shapes or shapes at graphs, depicting spatial or temporal distributions of nongeometric properties.

Introduction

The geometric irregularity is an intrinsic property of soils and plants. Soil pores and particles, organisms living in soils, as well plant roots and shoots, have a wide range of sizes and shapes. Soil and crop canopy surfaces are rough, and patterns on soil and yield maps have complex shapes. This geometric irregularity is easy to perceive and observe, but quantifying it has long presented a daunting challenge. Such quantifying is imperative because the geometric irregularity is the cause and the reflection of spatial and temporal variability that in turn strongly affects soil and crop management.

Geometric measurements in agrophysics are done at different measurement scales. *Measurement, or observation, scales* are lengths, areas, or volumes within which the shape irregularity is ignored and curves or surfaces are assumed to have a simple geometric shape, e.g., line segment or part of a plane. Measurement scale is often called support, resolution, or simply scale. There is ample empirical evidence that total length, total area, or total volume does not stay constant as the measurement scale changes. A decrease in measurement scale usually causes an increase in total length, area, or volume. Thus,

geometric properties of soil and soil cover as well as plants and crop canopies appear to be scale dependent.

One class of geometrical objects whose total length, area, or volume depends on the measurement scale consists of objects that reveal similar geometrical shapes when observed at different measurement scales. Such objects were termed *fractals* by Mandelbrot (1983), who suggested that fractals rather than regular geometrical shapes like segments are more appropriate to approximate irregular natural shapes that have hierarchies of ever-finer detail.

Fractals are rough or fragmented geometric shapes that can be subdivided into parts, each of which is (at least approximately) a reduced-size copy of the whole. Examples of geometrical fractals and their natural counterparts are shown in Figure 1. These examples illustrate that although fractals cannot represent each and every detail of the hierarchy of ever-finer detail in the real world, they can represent the shape similarity at different scales. Applications of fractal geometry in environmental sciences became very popular during the last 30 years because of its promise to relate features of natural objects observed at different scales.

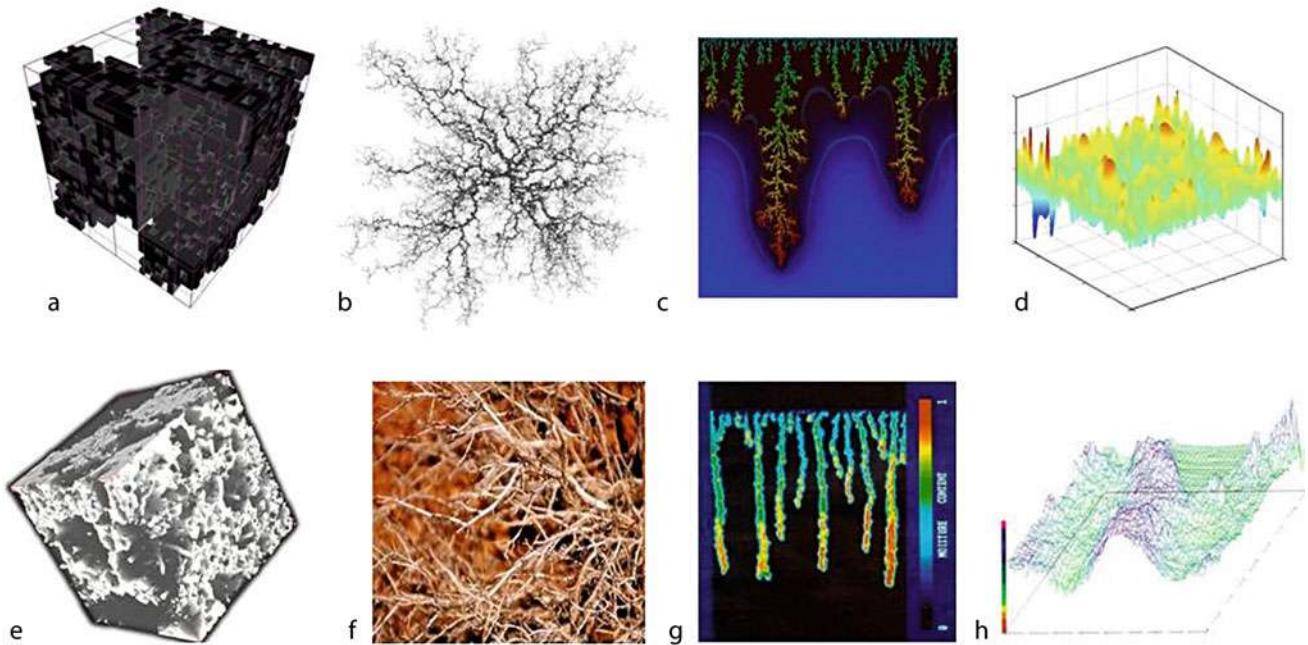

Although fractals are purely geometrical objects, fractal representations of nongeometrical properties, e.g., mass, concentration, or population density, have become ubiquitous. Such representations are possible because measurements of nongeometric quantities can be expressed as a graph which is already a geometric object and can be analyzed as such using the fractal concepts. Similarly, graphs of temporal dependencies have been analyzed to reveal fractal behavior in time, rather than in space.

Observations of natural objects at different scales have shown that not only the total amount of the observed property (length, area, or volume) depends on the measurement scale but also the distribution of this total amount among different measurement cells at this scale appears to depend on the cell size, i.e., scale. Analysis of the distribution change with scale reveals the degree of heterogeneity within the system. The more asymmetric the distributions become as the scale decreases, the more heterogeneous is the system. The class of geometric objects having such a property has been termed *multifractals* (Evertsz and Mandelbrot, 1992). Applicability of multifractal mathematical model has been demonstrated for many environmental systems. For example, soil porosity, organic matter content, bacteria populations, or chemical concentrations show large variability when measured at one specific observation scale, i.e., with the same support. The variability changes with support, and the multifractal model appears to be a plausible mathematical tool to simulate these changes.

The types of fractal objects used in agrophysics are manifold. This entry provides a brief introduction in concepts and techniques behind those applications.

Fractal objects and models

Geometrical fractal objects reveal similar features at different scales because they are constructed iteratively, by

Fractal Analysis in Agrophysics, Figure 1 Examples of geometric fractals (a–d) and natural objects exhibiting fractal properties (e–h); (a) Menger sponge, (b) diffusion-limited aggregation structure in three dimensions (From Bourke, 2006. With permission), (h) microtopography of the measured apple surface after storage. (From Fekete et al., 2007. With permission.)

repetition of the same form- or shape-changing operation at different measurement scales. An example of such construction is given in Figure 1a for the fractal object called Menger sponge. The *initial shape*, or *initiator*, is a cube. The shape-changing operation, or *generator*, is dividing the cube into 27 smaller equal cubes and extracting seven cubes, six from each facet and one from the center. Menger sponge is self-similar because it can be broken down into arbitrary small pieces, each of which is a small replica of the entire structure. If the Menger sponge is reduced by a factor of 1/3 and 20 copies are made, then these copies can be pasted together to give back the Menger sponge; 1/9 reduction requires 400 copies, 1/27 reduction requires 8,000 copies, etc. In all self-similar objects, there is a relationship between the reduction factor R and the number of pieces N into which the object is divided. Those relationships follow a power law:

$$N = R^{-D_{ss}}, \quad (1)$$

where D_{ss} is called the *self-similarity dimension*. The value of D_{ss} can be found by equating logarithms of both parts in Equation (1), i.e., $D_{ss} = -\log(N)/\log(R)$. For the Menger sponge, the reduction factor is 1/3, $D_{ss} = -\log(20)/\log(1/3) = -\log(400)/\log(1/9) = -\log(8000)/\log(1/27) = 2.727$.

Figure 1b provides another example of an iteratively built geometric fractal generated by the diffusion-limited aggregation (DLA) process (Feder, 1988). A sticky particle is randomly introduced on a “launching” circle and is allowed to follow a random path until: (1) it sticks to the growing cluster of particles by entering a grid adjacent to the cluster or (2) until it wanders across a larger “killing” circle. The resulting sparse, tree-like structure has been taken as an excellent representation of the dendritic growth patterns of roots and fungi (Turcotte, 2007).

The self-similarity dimension receives the physical meaning of fractal dimension when the fractal object is used as the model of the real system, and the geometric measures of this object are equated to geometric measures of the system. For example, let empty parts of the Menger sponge be used to simulate pores in soil at different measurement scales. Let V_0 be the volume of the initiator. The measurement scale is V_0R^3 , the number of similar pieces at this scale is N , and their total volume is:

$$V = NV_0R^3 = V_0R^{3-D_{ss}} \quad (2)$$

Because the fractal object represents remaining mass in this case, the dimension D_{ss} is interpreted as the *mass fractal dimension*.

Relationships (1), (2), and likes hold over a range of scales, i.e., they are scale invariant within this range. They are interchangeably referred to as scaling relationships, or fractal scaling laws, or simply scaling.

The iterative construction of ideal fractals continues ad infinitum, whereas natural objects have the minimum and the maximum observation scales, or *lower and upper cut-off scales* beyond which the relationship (1) usually breaks. The value of the measure for the initiator, for example, the V_0 value in (2), is not known if the fractal scaling is valid only within a specific scale range. Thus, four values – fractal dimension, upper-, and lower-scale cutoff, and the initiator measure – are parameters of a fractal model in agrophysical studies.

Ideal shapes as in Figure 1a–d cannot be found in real porous media in the same way as ideal geometric lines, spheres, cylinders, etc. cannot be found. Applying random changes in the generator procedure results in constructing stochastic fractals that look much more like fractals in nature (Peitgen et al. 2004). Because random changes are applied, realizations of stochastic fractals with the same initiator and generator differ. Stochastic fractals retain the important feature of dependence of geometric properties on measurement scale, only this feature is preserved in *statistical sense*. This means that Equation (1) will not hold exactly for any realization of stochastic fractals at any measurement scale. Nevertheless, the dependence measurement scale on the property of interest in log–log scale for each realization is close to the same power law dependence.

Data on surface roughness or topography along spatial transects do not follow the self-similarity law (1), but demonstrate another, anisotropic type of scale dependence, called self-affinity. If surface is self-affine then, to reveal the statistical similarity in this the surface, the change of the horizontal measurement scale λ times has to correspond to changing the vertical measurement scale λ^H times. The value H is called the Hurst exponent, $0 \leq H \leq 1$. Value of H is equal to one in isotropic, self-similar fractals such as Menger sponge in Figure 1a. Self-affine one-dimensional lines represent the type of geometric irregularity known as fractal *Brownian noise* (Mandelbrot and Van Ness, 1968). An example of such

noise is shown in Figure 2. When the self-affine curves are analyzed, high values of the Hurst exponent indicate some degree of memory, persistence, or autocorrelation in the data. Low values of H suggest an anti-correlation or self-correcting response in the observed process.

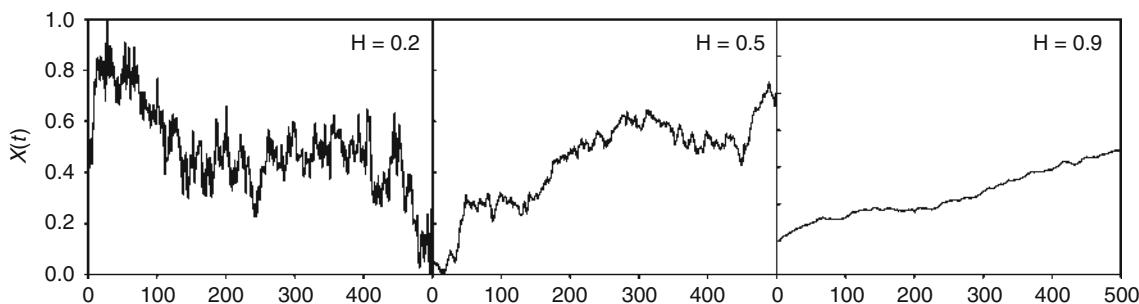

Multifractals present yet another example of scale-invariant object, where the dependence of statistical distributions on the measurement scale holds through certain range of scales, and therefore is scale invariant. If a property is measured at a particular measurement scale in many measurement cells (grid intervals in one-dimensional, grid cells in two-dimensional systems, or in 3D voxels in three dimensions), then the probability distribution function is obtained for so-called mass fractions μ that are measurements in each cell divided by the total value of the property measured in all cells at this scale. Changes in mass fraction distributions with scale are shown to characterize the inherent heterogeneity of the system.

One process of constructing the multifractal object is known as the multiplicative cascade (Figure 3). The cascade starts at the scale S (level 0) with an initial amount $\mu_0 = 1$. At the next scale, $S/4$, the measures in four measurement cells are obtained by multiplying μ_0 by the random factor $w_i < 1$, $i = 1,2,3,4$, and w_i are selected so that $\sum \mu(S_i) = \mu(S)$. The resulting mass distribution is a multifractal when this process continues *at infinitum*. The selection of the statistical distribution for the factor w_i values controls properties of the resulting multifractal.

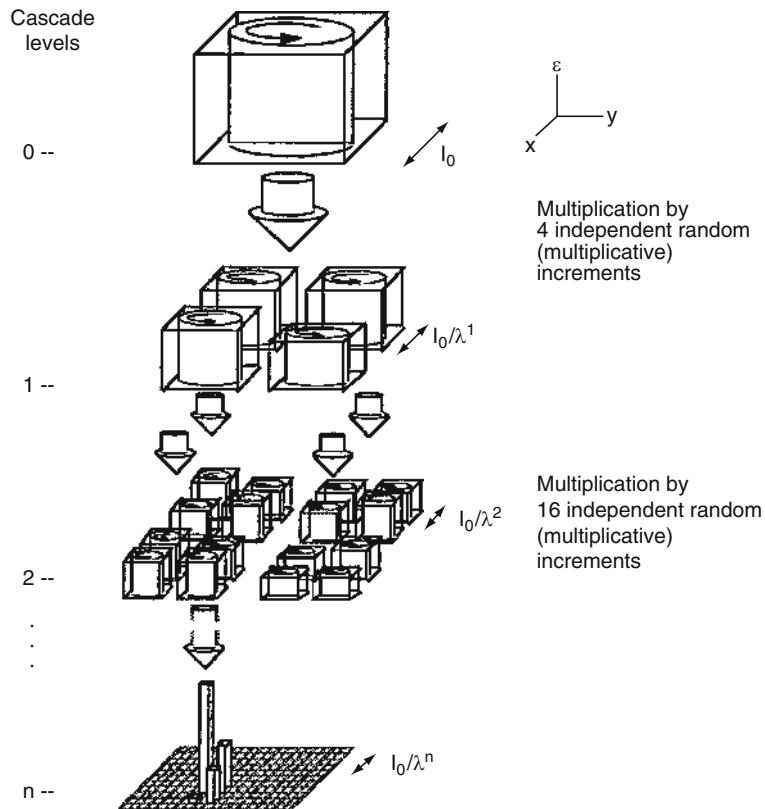

Physical processes resulting in fractal scaling in agrophysics

Many physical processes have been shown to generate fractal scaling (Pachepsky et al., 2000; Senesi and Wilkinson, 2008). Some of them are relevant to soil and biota development and functioning, and the correspondent fractal models are being applied in agrophysics. One example is the scale-invariant fragmentation (Turcotte, 1986) that leads to dependence between the number of fragments and their size:

$$N_r = kr^{-D_F} \quad (3)$$

Fractal Analysis in Agrophysics, Figure 2 Examples of fractal Brownian noises for three values of the Hurst exponent H . (From Kravchenko and Pachepsky, 2004. With permission.)

Fractal Analysis in Agrophysics, Figure 3 Schematic diagram of a multiplicative cascade. (From Schertzer and Lovejoy, 1991, p. 49. With permission.)

where r is the fragment radius, N_r is the number of fragments having radii less than r , k is a constant, and D_F is the fragmentation fractal dimension. The incomplete fragmentation process has the fractal dimension that can be related to density-size scaling of soil aggregates and appears to be the mass fractal dimension.

Agglomeration on a substrate can generate fractal structures (Witten and Sanders, 1981; Chen and Wilkinson, 1985). Particles may arrive to the surface by random diffusion or with ballistic energy. They may either just stick together or there is a chemical reaction involved which may change the local concentration gradient and sticking probability. Allowing particles to walk randomly until they strike the surface or another particle, which is already motionless, builds the fractal coating.

Various mechanisms were proposed to explain fractal branching networks that are omnipresent in nature. Such networks in living organisms have been suggested to evolve as the means of maximizing metabolic capacity, namely, the rate at which energy and material resources are taken up from the environment and allocated to some combination of survival and reproduction. On the other hand, it was argued that inherent randomness is a sufficient condition for the generation of tree patterns under evolutionary dynamics, and the decrease of energy

expenditure is not the cause but a consequent signature (West et al., 1999; Paik and Kumar, 2008).

Instability and chaotic behavior were shown to generate fractal structures. For example, the finger flow in soils can evolve as the result of soil layering, causing the instability in the wetting front boundary (Posadas et al., 2009). Atmospheric turbulence within canopies can cause fractal scaling of micrometeorological parameters (Chester et al., 2007). The superposition of processes of different nature acting simultaneously over a range of scales can generate multifractal patterns revealed in spatial and temporal variability of soil properties (Burrough, 1983).

Purposes and methods of fractal analysis

Fractal analysis aims to see if the data obtained at different scales can be related with scale-independent relationship consistent with one of the fractal models.

Purposes of fractal analysis depend on the overall goal of the research where such analysis is applied. Here are some of the purposes:

1. Find the relationships between system properties obtained at different scales; this is useful if measurements on some scales are more difficult than at others. This type of analysis has been used, for example, to

- estimate soil hydraulic properties that are difficult to measure.
2. Compress data obtained at different scales; fractal models have relatively smaller number of parameters and allow relating parameters of irregularity at different scales with simple relationships.
 3. Use fractal parameters as the indicator of change in environmental conditions or management.
 4. Infer the underlying physical and biological processes that cause the observed scale independence.
 5. Determine cutoffs in fractal scaling. Cutoffs can serve as indicators of the change in control processes at some scale.
 6. Generate synthetic examples of fractal media. Such examples provide a realistic representation of multiscale hierarchy in conduits and storages and are used in simulation of transport processes.
 7. Identify scale-related changes in relationships between soil properties that show fractal and multifractal features.
 8. Select an appropriate interpolation method for the development of soil property distribution maps.

Fractal analysis is applied to geometric objects – lines, surfaces, and three-dimensional shapes. These objects are either actually observed or obtained from other measurements by graphing observations or presenting them as an image.

Fractal analysis consists of:

1. Measuring the property of interest on an observed geometric shape or on a graphic representation of spatial or temporal series or imagery
2. Fitting a fractal model to the observed dependence of a property on scale

Measurement of scale dependence

Both direct and indirect measurements of geometric quantities are in use in agrophysics. Indirect, or proxy, geometrical measurements are very common. Nongeometrical values are converted into a geometrical value using a physical model. For example, capillary pressures in soils are converted in radii using capillary models. Then, different pressures correspond to different scales of measurement, and the dependence of filled pore volume on the scale can be investigated to reveal fractal pore structure. Similarly, masses of adsorbed molecules are converted in area values using molecular monolayer model, then the change in molecule size is equivalent to change in the measurement scale, and the dependence of monolayer area on the scale can be researched to establish fractal scaling of the adsorbing surface. X-ray computed tomography data provides information about the density differences of the soil components based on the radiation attenuation. Remote sensing of canopies presents spatial distribution of soil–plant–atmosphere systems as reflected in the images of radiance or irradiance. [Table 1](#) presents some

examples of measurements and relationships used in agrophysical studies to reveal fractal scaling.

Fitting a fractal model to data

A common way to reveal a fractal scaling law is to plot the measurement scale versus the property of interest in double logarithmic, or log–log, scale. The presence of a linear relationship indicates that fractal model may be appropriate to simulate the scale dependence in the property. The fractal dimension then can be found from the slope of the regression line. For example, the relationship (2) in log–log scale can be transformed into:

$$\log V = \log V_0 + (3 - D_{ss}) \log R \quad (4)$$

and the fractal dimension D_{ss} equals three minus slope. A similar transformation is applicable to all scaling relationships in [Table 1](#).

While it is true that natural objects are not made up of spheres and straight lines, it is also true that soil, plant, or atmospheric fields are far from being precisely fractal. Therefore, relationships of fractal geometry can be only approximately true in agrophysics. Different measurement methods lead to different results even for ideal geometric fractals. Values of fractal parameters obtained by different methods should never be compared for soils. Using proxy measurements creates additional uncertainty, since ideal shapes are assumed to convert nongeometrical to geometrical measures.

Uncertainty also exists in selecting the range of measurement scales in which the fractal scaling is valid. One way to decrease this uncertainty is to include cutoff values in the list of estimated parameters along with the slope and the intercept of the linear regression used to estimate the fractal dimension and the initiator measure.

To find parameters of the multifractal model, the mass fractions μ_i have to be defined at each available measurement scale ε , which is usually defined by the size of measurement cell in one, two, or three dimensions. Mass fractions have to be skewed using the series of values of q that typically range from -10 to 10 according to the equation:

$$\mu_i(q, \varepsilon) = \frac{\mu_i(\varepsilon)^q}{\sum_{i=1}^{n(\varepsilon)} \mu_i(\varepsilon)^q}. \quad (5)$$

Finally, values

$$\alpha_q = \frac{\sum_{i=1}^{n(\varepsilon)} \mu_i(q, \varepsilon) \log \mu_i(\varepsilon)}{\log \varepsilon} \quad (6)$$

and

$$f(\alpha_q) = \frac{\sum_{i=1}^{n(\varepsilon)} \mu_i(q, \varepsilon) \log \mu_i(q, \varepsilon)}{\log \varepsilon} \quad (7)$$

are computed for each q . Values α_q are the Hölder exponents and values $f(\alpha_q)$ form the singularity spectrum.

Fractal Analysis in Agrophysics, Table 1 Examples of measurements and relationships to perform fractal analysis in agrophysics

Method, reference to an example of application	Measurement scale or proxy measurement	Measured value	Scaling relationship	Fractal dimension
Box counting (Feder, 1988)	Δ – mesh size of a grid covering a line	N_L – number of grid cells where the line is present	$N_L \propto \Delta^{-D_K}$	D_K – Kolmogorov dimension ^a
Erosion-dilation (Russ, 1994)	M – number of times when erosion or dilation are applied	N_a – number of pixels that are affected by the erosion and dilation	$N_a \propto M^{-D_M}$	D_M – Minkowski dimension
Image coarsening (Stoyan and Stoyan 1994)	Δ – Pixel size	N_L – Number of cells where the line is present	$N_L \propto \Delta^{-D_K}$	D_K – Kolmogorov dimension ^a
Semivariogram (Burrough, 1983)	h – Distance between observation points	Semivariogram $\gamma(h) = \frac{1}{2m_h} \sum [Z(x) - Z(x+h)]^2$ Z is the observed point on the self-affine line, m_h is the total number of points separated by the distance h .	$\gamma \propto h^{2(2-D_L)}$	Fractal dimension of the self-affine line
Power spectrum (Turcotte, 1992)	f – Frequencies in Fourier expansion of the data series	a^2 – squared coefficients of the Fourier expansion	$a^2 \propto f^\beta$	$D_L = 2 + \beta/2$ – Fractal dimension of the self-affine line; $D_S = 3 + \beta/2$ – Fractal dimension of the self-affine surface
Roughness based (Pachepsky et al., 1997)	w – Size of windows over the data series	Root-mean squared deviations from the linear trend within the window $RMS = \frac{1}{n_w} \sum_{i=1}^{n_w} \sqrt{\frac{1}{m_i-2} \sum_{j=1}^{m_i} \varepsilon_{ij}^2}$ where n_w is the total number of windows of length w in the data, m_i is the number of points in the i th window, ε_{ij} is the residual of the linear regression in the j th data point in the i th window	$RMS \propto w^q$	$D_L = 2 + q$ – Fractal dimension of the self-affine line; $D_L = 3 + q$ – Fractal dimension of the self-affine surface
Area-perimeter (Lovejoy, 1982)	A – Outline area	P – Outline perimeter	$P \propto A^{\frac{D_L}{2}}$	D_L – Fractal dimension of the outline
Circle counting (Feder, 1988)	r – Pore radius	N_c – Number of circles with radii larger than r	$N_m \propto r^{-D_m}$	D_m – Mass fractal dimension
Adsorption of molecules of different sizes (Avnir et al., 1985)	r – Molecule radius	N_m – Number of molecules in monomolecular coverage	$N_m \propto r^{-D_s}$	D_s – Surface fractal dimension
Single adsorbate isotherm (Sokolowska, 1989)	$\frac{p}{p_0}$ – Relative pressure	n – Adsorption	$n \propto \left(-\ln \frac{p}{p_0}\right)^{D_s-3}$	D_s – Surface fractal dimension
Single adsorbate isotherm (Hajnos et al., 2000)	$\frac{p}{p_0}$ – Relative pressure	A_e – Area of the condensed adsorbate–vapor interface	$A_e \propto \left(-\ln \frac{p}{p_0}\right)^{D_s-2}$	D_s – Surface fractal dimension
Mercury or water porosimetry (Bartoli et al. 1999)	p – Capillary pressure	$\frac{dV}{dr}$ – Rate of the volume change at the pore radius obtained from the capillary law $r = \frac{\text{const}}{p}$	$\frac{dV}{dr} \propto r^{2-D}$	D is the mass fractal dimension D_m if the object is the mass fractal, the surface fractal dimension if the object of the study is the surface fractal
Light scattering (Gouyet, 1994)	I – Intensity of the scattered radiation	Q – Scattering vector	$I \propto Q^{-s}$	s is the mass fractal dimension D_m if the object is the mass fractal, and $s = 6 - D_s$ if the object of the study is the surface fractal

^aApproximates the fractal dimension of line

In general, this spectrum has a parabolically shaped concave down shape. The degree on concaveness and the asymmetry of the parabolic shape provide information about the heterogeneity in the system under study (e.g., Caniego et al., 2005).

Conclusions

The major contribution that fractal geometry makes in agrophysics is a general, simple, and succinct representation of complex structures by a small number of fractal parameters. Fractal parameters are complementary to other agrophysical parameters.

Fractals should never be considered an ultimate model of heterogeneity in the soil-plant-atmosphere system. Rather, they provide a balance between accuracy and clarity that may aid us in gaining insight into sources and consequences of the observed complexity. Eventually, once a greater insight into key processes is obtained, we expect causes of the apparent fractal scaling to be revealed and quantified.

FRACTURE

The characteristic appearance of the surface of a broken material (e.g., minerals, grains).

FRAGIPAN

A dense, natural subsurface layer of hard soil with relatively slow permeability to water, mostly because of its extreme density or compactness rather than its high clay content or cementation <http://encyclopedia2.thefreedictionary.com/fragipan>.

FRICTION

The resistive force that occurs when two surfaces move along each other when forced together. It results in physical deformation and heat buildup.

FRICTION PHENOMENA IN SOILS

Rainer Horn
 Institute for Plant Nutrition and Soil Science, Christian-Albrechts-University zu Kiel, Kiel, Germany

Introduction

The determination of interparticle, inter-aggregate, or intra-aggregate forces allows a more complete insight in the soil strength and the bindings forces and can be also applied to even predict the soil strength on various scales using PDF or related equations (as shown in ID 00144). The values for the cohesion and angle of internal friction strongly depend not only on soil texture but also to a much greater extent on soil structure apart from a slight increase of the cohesive forces with bulk density. The values strongly depend on the matric potential and can be quantified both under laboratory and also under in situ conditions.

Definition

In between single particles, aggregates, or at the root soil interface frictional forces occur, which prevent the particles from direct sliding. The coarser the particles or aggregates, the rougher the surfaces; the denser these particles are packed, the higher is the strength which must be exceeded by the applied stresses in order to rearrange or to move them. In general, the shear strength parameters:

cohesion (c) and angle of internal friction (φ) are defined by the Mohr–Coulomb failure line and described by:

$$\tau = \sigma_n \tan \varphi + c,$$

whereby

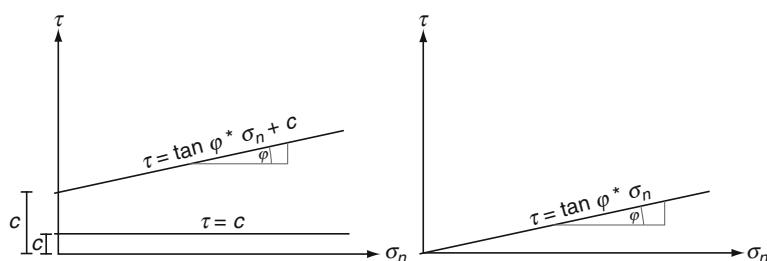

φ is the angle of internal friction, c defines the cohesion, and σ_n is the applied vertical stress.

Cohesion and angle of internal friction are additionally influenced by shear speed and drainage conditions for a given soil. The shear test can be carried out by the direct shear approach, whereby the type and direction of the shear plane, which is assumed to be affected only by normal and shear stresses, are fixed. Normal stress is applied to the specimen in the vertical and shear stress in the horizontal direction. To determine the Mohr–Coulomb failure line, at least four to five samples need to be tested, each with a different normal stress. The maximum shear resistance (τ_{\max}) is determined from a shear stress-displacement curve and plotted against the corresponding normal stress (σ_n) (Figure 1).

The determination of the shear strength of single aggregates or even only of soil crust surfaces (against the wind erosion) requires more sensitive and smaller shear devices like the crushing test (in order to determine the aggregate strength) or rheometrical approaches (like oscillation rheometer). For both tests approximately 20–30 aggregates or soil specimen must be measured at a given predrying intensity (matric potential) in order to get statistically reliable results (Horn and Baumgartl, 2002; Horn and Dexter, 1989; Markgraf and Horn, 2006).

The third approach is triaxial tests, where the stress path applied resembles more the in situ conditions (For more details see Hartge and Horn, 1999, 2009; McCarthy, 2007; Zhang et al., 2001).

Table 1 sums up the texture and structure-dependent values for φ and c as a function of the predrying intensity Ψ_m . At a given texture, the more rigid the soil, the more pronounced the aggregation and the drier the soil samples. Values for the angle of internal friction for a single aggregate ($>45^\circ$) are even higher than for the bulk soils. However, aggregated bulk soil reveals higher friction angles than the homogenized soil at the same bulk density (Figure 2). This shear strength gain is, however, lost again

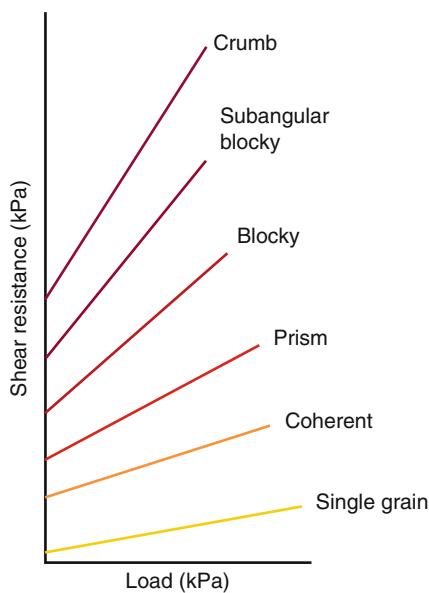

Friction Phenomena in Soils, Figure 1 The Mohr–Coulomb failure line for water saturated systems ($\tau = c$), structured unsaturated soils ($\tau = \tan \varphi * \sigma_n + c$; left) and dry sand ($\tau = \tan \varphi * \sigma_n$; right).

Friction Phenomena in Soils, Figure 2 Mohr–Coulomb failure line as a function of soil aggregation.

when stresses exceed the overall stability of the aggregated sample, leading to a reduction of the angle of internal friction to values similar for homogenized soil. When the maximum value of stress exceeds the maximum strength such that structure is homogenized only texture-dependent properties remain.

Conclusions

The analysis of the shear resistance parameters: angle of internal friction and cohesion allows the quantification of the soil strength and can be also applied to define the various processes and physical, chemical, and biological reasons of soil strengthening.

FRUITS, MECHANICAL PROPERTIES AND BRUISE SUSCEPTIBILITY

Margarita Ruiz-Altisent, Guillermo P. Moreda
 Laboratorio de Propiedades Físicas y Tecnologías Avanzadas en Agro-Alimentación (LPF-TAGRALIA), Universidad Politécnica de Madrid, Madrid, Spain

Definitions

Bruise. Subcutaneous mechanical damage without rupture of the skin caused to a fruit by an impact, a quasi-static compression, or a vibration. It consists of the local degradation of the flesh tissue, combined with intracellular water extravasation and browning (oxidation) of phenolic compounds from released intracellular water.

Bruise Susceptibility. Degree of ease or difficulty by which a fruit bruises. Besides of species and cultivar, bruise susceptibility depends on the physical condition or physiological status of each individual fruit, which can be assessed, among others, based on *mechanical properties*. The point at which fruits start to show symptoms of bruising is called *bruise threshold*. When this threshold is exceeded, mechanical load-induced stress exceeds flesh tissue failure stress, and a bruise results.

Mechanical Properties of Fruits. Properties related to the response of the fruit to mechanical loads such as impacts and quasi-static compressions. A major aim of determining the mechanical properties of a given specimen is to assess its physical condition. This includes aspects like firmness and turgidity. Another objective of quasi-static

compression testing is to determine maximum allowable static load for minimizing mechanical damage. Mechanical properties can be measured as stresses and deformations (strains), using appropriate instruments (see *Stress–Strain Relations*). For example, elastic modulus (Young's modulus) is often used by engineers as an index of product firmness. Another index relating stress and strain, considered a reference measurement of fruit firmness, is obtained through the Magness-Taylor test. This is an invasive or destructive procedure consisting of penetrating the flesh of a fruit with an 8 mm diameter cylindrical plunger at a constant loading rate, typically 20 mm min⁻¹, with the purpose of measuring the so-called Magness-Taylor firmness.

Introduction

Texture is one of the primary quality attributes of fruits and vegetables. It is determined by the mechanical properties of the tissue, which are affected by factors such as ripening stage and water status (Oey et al., 2007). Serious textural damage can occur to fruit pulp tissue on slow or quasi-static compression (as in bulk storage) or impact compression (as in drop on handling). Tissue failure leading to textural damage can occur as cleavage (i.e., cracking) caused by normal stresses and as slip or bruising caused by shear stress (Taub and Singh, 1998).

Bruising lowers the fruit grade (see *Quality of Agricultural Products in Relation to Physical Conditions*), increases decay, and ultimately results in lost revenue which affects packers, producers, and the industry as a whole (Guyer et al., 1991). In most fruit species, paradigmatically apples, flesh tissue is more easily bruised by impact compression than by slow compression; however, for strawberries the opposite applies (Holt and Schoorl, 1982). The amount of impact bruising that occurs to a fruit depends upon the number and severity of impacts that it experiences (see *Mechanical Impacts at Harvest and After Harvest Technologies*), and upon the *bruise susceptibility* of the fruit.

Susceptibility of fruits to mechanical damage

It is important to determine to what extent fruits are damaged when static or quasi-static (slow compression) and dynamic (impact compression, vibration) loads are applied on them. According to Stroshine and Hamann (1996), the mechanical properties of fruits determine the distribution of applied forces within them. Fruit bruises generally develop somewhere below the skin surface, where the shear stress is maximum (Schulte et al., 1994). Bruises are caused by three types of loading: impact, compression, and vibration. Bruising can result from a short sudden force: impact onto another fruit, tree, ground, or hard surface (Mohsenin, 1986). It can also result from vibration during transportation and handling, or a long term steady force such as packing box pressure.

The knowledge of how, why, and in what measure fruits are damaged when mechanical loads are applied on them is of big interest in order to:

- Determine optimum harvest time
- Select and breed cultivars according to their intended use: fresh consumption, processing
- Study ways to reduce or avoid the incidence of mechanical damage at harvest and postharvest

Damage susceptibility studies provide a useful experimental tool in this subject. The general objective of any susceptibility test is to determine how fruits respond to application of loads of different nature and intensity. The particular objective is to determine the point at which fruits start to show symptoms of mechanical damage. This point is called *bruise threshold*. According to García (2000), most susceptibility tests consist of the following stages:

1. Application of a controlled load on homogeneous samples of fruits of one or more cultivars, along with measurement and registration of load intensity.
2. Visual inspection of the fruit zone where the load has been applied. If damage is observed, measurement of the affected zone's size.
3. Analysis of results. Determination of the relationship between load applied and damage inflicted to the fruit. Identification of the bruise threshold.

When bruise appears, the variables measured to quantify it are the bruise diameter and depth, as well as the contact area corresponding to the load application. From these variables, some researchers adopt the *bruise area* as the main indicator of damage, whereas others use the *bruise volume* (V).

There are two traditional ways of applying an impact load on a fruit: to strike the fruit with a pendulum, or to drop the fruit from a given height onto a flat surface called *impact surface*. Hereinafter we refer to the second possibility. Bruise severity depends on the amount of energy absorbed or dissipated by the fruit. For an impact surface of a given hardness, the *absorbed energy* (E') increases with *impact energy* (E). In the case of a fruit dropped from a given height, [Equation 1](#) yields the value of E :

$$E = mgh \quad (1)$$

where E , impact energy (J); m , fruit mass (kg); g , acceleration of gravity (m s^{-2}); h , drop height (m).

An interesting index to quantify bruise susceptibility is the ratio of V to E (Bollen, 2005). This index makes comparisons among results obtained by different researchers easier. Nevertheless, for fully comparable results, the hardness of the impact surface should be constant among the different research works. Otherwise a same E can translate into different values of E' , which is ultimately the energy determining the severity of the bruise. In regards to the characteristics of the impact surface, Hyde (1997) reported that cushioning reduces the effective

severity of an impact in two ways: by absorbing energy and by spreading the load.

Although the ideal form of determining the bruise threshold is through direct ad hoc testing (susceptibility study), if circumstances recommend it, an analytic approach may be adopted. Thus, Baritelle and Hyde (2001) proposed an equation for estimating impact bruise threshold in apples, pears, and potatoes, based on tissue failure properties (see [Stress–Strain Relations](#)), Poisson's ratio, and specimen mass and radius of curvature, [Equation 2](#):

$$h = \frac{C\sigma_f(\varepsilon_f)^4(1 - \mu^2)^4 R^3}{mg} \quad (2)$$

where h , bruise threshold drop height (mm); C , constant (dimensionless); σ_f , failure stress (Pa); ε_f , failure strain (dimensionless); μ , Poisson's ratio (dimensionless); R , radius of curvature (m); m , mass (kg); g , acceleration of gravity (m s^{-2}).

For using [Equation 2](#) on a given fruit species and cultivar, it is necessary to know parameters such as σ_f , ε_f , or μ , which can be eventually found in literature; otherwise they would have to be measured. The value of C depends on the hardness of the impact surface.

Bruise susceptibility of pome fruit

Bruise damage is a major cause of quality loss for apples, and many studies have identified factors that have an effect on bruise susceptibility (Bollen, 2005; Pang et al., 1996; García et al., 1995). Most bruising occurs as a result of impacts, and several researchers have shown that bruising is linearly related to E (E') (Chen and Sun, 1981; Pang et al., 1992).

Fruit turgidity has an effect on impact bruise susceptibility in apples and pears. García et al. (1995) concluded that fruits with high turgidity are more susceptible to bruising. On the other hand, these authors submitted that deformation at skin puncture was shown to be the physical parameter most related to fruit turgidity.

With regard to the relation between bruise susceptibility and fruit firmness, García et al. (1995) found that fruits harvested early in the season, i.e., firmer fruit, were less susceptible to bruising than those harvested later in the season, i.e., softer fruit.

For apples, the risk of bruising is generally accepted to be higher at lower temperatures (Donati et al., 2005), but Saltveit (1984) also noted an increased tendency to bruising at higher than ambient temperatures (30°C).

Finally, bruise susceptibility depends on the cultivar. For example, *Stark Delicious* apples are more susceptible to bruise than *Golden Delicious* apples (Ragni and Berardinelli, 2001).

Bruise susceptibility of stone fruit

Brusewitz et al. (1991) investigated the impact bruise resistance of peaches. They concluded that ripeness was highly correlated with the percentage of fruit bruised and

bruise volume. Schulte et al. (1994) dropped peaches onto several impact surfaces to determine impact conditions that initiated bruising. After impact, the peaches were tested for flesh firmness and sorted into firm, soft, and very soft groups for bruise analysis. They obtained that the drop height that did not bruise decreased as fruit softened. This result agrees with that obtained by Brusewitz et al. (1991), since ripe peaches are softer than unripe ones.

Blahovec (1999) compressed individual cherries between two plates in the quasi-static compression test of *loading-unloading* (see *Rheology in Agricultural Products and Foods*), to determine the energy absorbed (E'') by the fruit during the test. After compression, he determined the bruise volume of the deformed fruit. He obtained that the index V/E'' increased with increasing values of E'' , as it occurs on apples, although for the cherries, up from a given value of E'' , the index V/E'' decreased.

Susceptibility of citrus fruits to mechanical damage

Mechanical damage in citrus fruits does not become visible after a few hours as it occurs with apples; instead several days must elapse to detect affected areas. The critical aspect in citrus fruits is not the mechanical damage itself, but its consequences. Any injury on the fruit, regardless of its size, is an invitation for pathogens, mainly fungi, to colonize the whole fruit.

Oleocellosis, also known as “oil spotting,” is an unattractive surface blemish on citrus fruits, directly related to mechanical damage. According to Wardowski et al. (1976), spots of oleocellosis are the result of the rupture of glands in the flavedo – the outermost layer of the citrus peel – which provokes the extravasation of the essential oils in the glands. This extravasation collapses the subcuticular cells, due to phytotoxicity, and gradually begins to darken and depress the affected tissue, finally turning it brown. The rupture of the glands containing the essential oils can be provoked by impacts, quasi-static compressions and abrasions. According to Ahmed et al. (1973), the resistance to rupture of lemon glands is approximately three times that of orange or tangerine. Susceptibility to oleocellosis damage depends on:

- The degree of turgidity of the fruit: Susceptibility increases with increasing turgidity.
- Environmental conditions: For example, susceptibility increases with increasing air relative humidity.
- Ripeness degree of the fruit: Susceptibility decreases with increasing ripeness. This effect is different to what happens in products such as pome or stone fruit. Pears, peaches, and many other fruits are harvested early in the season, partly because the bruise susceptibility of these products increases with maturity. Therefore, from this point of view, it is preferable to harvest citruses late in the season – and more considering their condition of non-climacteric fruits. However, it is reasonable to harvest stone and pome fruits early, because being climacteric fruits they will continue their ripening after harvest. On the other hand, optimum organoleptic

features are achieved when the fruit, whatever its type, is left to ripe in the tree. In conclusion, for climacteric fruits such as stone or pome fruit, a trade-off must be adopted between bruise susceptibility and flavor.

Bruise susceptibility of tomato and kiwifruit

In the case of tomato, it is almost impossible to measure the diameter and length of the bruise. Therefore, the only way to quantify bruise damage is through E' . The results obtained by Van Zeebroeck et al. (2007) suggest a lower bruise susceptibility of warmer tomatoes (tomatoes at 20°C vs. tomatoes at 15°C). These authors also found that E' , hence V , increases with increasing ripeness of tomato.

Hasey (1994), studying the bruising of kiwifruit during transport, reported that softer fruits were more easily damaged by vibration than firmer fruits. She also obtained that vibration bruising of kiwifruit usually results in only minor signs of surface injury, but can cause severe internal flesh injury.

Summary

Loss of commercially valuable fruits as a result of mechanical damage continues to be an issue for postharvest operators. For most fruit types, bruising is the most common type of postharvest mechanical injury, other types of mechanical damage being abrasions and open injuries (e.g., punctures). Not only a direct effect of fruit bruising affecting the quality appreciation by the consumer exists, but bruises, even small ones, can open the way for pathogen attack (Van Zeebroeck et al., 2006). By understanding the fruit susceptibility to bruising it is possible to identify when to adopt techniques which will reduce the chances of sustaining high levels of damage, or identify cultivars that require additional care when handling (Bollen, 2005). Baritelle and Hyde (2001) suggested that reducing relative turgor through slight dehydration can reduce tissue elastic modulus, which can in turn make the fruit more “self-cushioning,” by distributing a given force over a larger area of the fruit’s curved surface. This distribution effect also occurs in padding materials for reducing the aggressiveness of packing-line machinery (see *Mechanical Impacts at Harvest and After Harvest Technologies*). The result is reduced impact-induced stress, and thereby reduced probability of bruise occurrence. For most fruits, bruise susceptibility increases with maturity. This is partly responsible for the early-harvesting typical of our days often criticized by many consumers. Consumers argue that nowadays a fruit is not as tasty as it was some decades ago, when it was harvested later in the season. But this is a side effect of our days, when fruits have to travel long distances from the production to the consumption centers.

See [Greenhouse Gases Sink in Soils](#)

GEOLOGIC EROSION

A process that changes soil into sediment. It relates to movement and resistance of soil to the forces of water and wind that lead to detachment and transportation of soil particles, sedimentary rocks and various land formations.

GEOSTATISTICS

Applies the theories of stochastic processes and statistical inference to geographic phenomena. Geostatistics is a branch of statistics focusing on spatial or spatiotemporal datasets. Developed originally to predict probability distributions of ore grades for mining operations, it is currently applied in diverse disciplines including petroleum geology, hydrogeology, hydrology, meteorology, oceanography, geochemistry, metallurgy, geography, forestry, environmental control, landscape ecology, soil science, and agriculture (esp. in precision farming).

GIBBS FREE ENERGY

The thermodynamic potential for a system whose independent variables are the absolute temperature, applied pressure, mass variables, and other independent, extensive variables. The change in Gibbs free energy, as a system passes reversibly from one state to another at constant temperature and pressure, is a measure of the work available in that change of state.

Synonyms

Grains; Kernel; Seeds

Definitions

Kernel. Kernel is the cereal fruit (botanically called *caryopsis*). It consists of three components: bran, germ,

and endosperm. The fruit can play role as a grain or a seed depending on its utilization.

Grain. This term includes cereals, pulses, and oilseeds. Grain, according to its economical utilization, is divided into food grain crops, feed (fodder) crops, and industrial crops. Grains are also divided on three groups depending on type of main component: cereal fruits (polysaccharides), legumes (proteins), and oil plants (lipids).

Seed. Seed is a reproductive material of the cultivated plants. It is applied to obtain a new plant generation on a generative way.

Introduction

Crops cultivation started ages ago at the time when *Homo sapiens*, who lived in tropical and subtropical forests, changed gathering the gifts of nature (leaves, fruits, and roots) for primitive hoeing. Archeologists found fossils from the first cultivated plants dated back to Early Neolithic Period (10,000–12,000 years ago). A hypothesis that people had started plowing in the Upper Paleolithic Period (40,000–50,000 years ago) was proven by the recent archeological studies (Gordeev and Butkovsky, 2005).

Wide range of cultivated grain species including cereals, pulses (grain legumes), and oil plants (oilseeds) are exploited all over the world. Among different types of cultivated plants cereals are basic part of the human diet from ages. The word “daily bread,” the most common product obtained from grain, has become synonymous with food. Grain and grain products are vital for human activities since the proverb says: “Bread is beyond everything.” One of the grain products is a whole grain which is usually called “kernel.” If the kernel has been cracked, crushed, or flaked, then in order to be called whole grain, it must retain nearly the same relative proportions of bran, germ, and endosperm as the original grain.

Wrigley et al. (2004) describe a lot of cultivated plant species, especially cereals and pseudocereals. The cereal group consists of a few species such as wheat, rye, triticale, barley, oats, and corn, whereas buckwheat, millet, rice, and sorghum are included to pseudocereals. This division is connected with the fact that pseudocereal kernels are gluminous. It means that the buckwheat grain is covered with fruit glumes, while wheat grain is covered with flower glumes. Another group of cultivated plants are legumes that consist of ten crop species depending on specification. In Europe large-seeded annual plants (pea, soy, broad beans, lentil, pea-vine, haricot, chick-pea, spring vetch, feed lupine, etc.) are grown. Soy is referred both to leguminous and oil grain. Oil-bearing crops as a canola, sunflower, flax, etc., from which oils are produced and used mainly as oil for food and industrial purposes.

Physical properties of grain

Physical properties of grain are considered as features that are measured by instrumental methods. The properties are applying for estimation of grain quality depending on its destination. Using methods cannot change structure of

the grain, thus they must be nondestructive. Grain physical properties depend on size and structure of a studied object or amount of matter in it. Grain is regarded as an anisotropic center since some of its physical properties are linked with the direction of observation.

Grain is also considered to be viscoelastic material as many other biological materials. This kind of materials has interesting properties that exhibit viscous behavior as the gradual deformation of molasses and latex. For example, wheat with 9.3% moisture showed high elastic behavior compared with wheat tempered at 22.5% moisture that showed a plastic behavior (Ponce-Garcia et al., 2008) as well as elasticity (like a rubber band or monocrystal that stretches instantaneously and quickly returns to its original state once a load is removed). Various materials exhibit viscoelasticity with the deformation depending on load, time, temperature, and humidity.

Since there is a necessity for continuous estimation of grain quality, the physical properties are divided into the following groups:

- Mechanical: Young's modulus, ductility, moment of inertia, weight, specific gravity, hardness, density, mass, porosity, viscosity, volume, moisture, etc.
- Thermal: thermal transfer, heat conductivity, etc.
- Acoustic: velocity, emission, damping, etc.
- Optical: reflectance, refraction, luminance, refractive index, chromaticity, absorption, color, etc.
- Electrical: electric potential, capacitance, resistance, conductance, impedance, permeability of storage grain, etc.
- Magnetic: magnetic permeability, inductance

The grain has undergone handling and processing by using various means such as mechanical, thermal, electrical, spectral, and sonic techniques. For this reason, some information about basic physical properties of grain will be presented. Knowledge of these properties should construct the base of essential engineering data for designing of machines, determining of its efficiency control of processes or operation during food or feed production. Such basic information should have a sufficient meaning not only to engineers but also to other scientists who may exploit these properties and find new applications for final grain products.

To better understand some terms a few examples are given below. Grain mechanical damage that has not resulted from damage during development of the crop may be due to problems encountered at harvest, transport, subsequent storage, and processing. Grain mechanical damage is considered as a state of interruption of tissue continuity. It can be caused by external static, impact loading, or internal strain during intensive drying of wet grain or intensive wetting of dry ones. Mechanical damage of grain, which occurs in harvesting, threshing, and handling, can seriously affect viability and germination power of seeds, growth vigor, insect and fungi attack, and utility value of the final product. Decrease of viability is due to mechanical damage of the seed embryo,

especially during harvesting of cereals in the wetted region of cultivation, for example, in Scandinavian Countries.

Grain damage can be also caused by insect and/or fungus activity. Therefore, it is important to be familiar with normal, healthy cereal grains before trying to recognize physical defects of damaged ones. Causes of physical defects are not always obvious. Many of them result from pest infestation or disease infection that appeared earlier in the growing season.

All physical properties of grains/seeds originating from cultivated plants depend mainly on their humidity and temperature, which are very important. In fact, each biological material and the majority of its properties depend on temperature and water content inside the object and in its surrounding. Having acquaintance with the above-mentioned features provides insights into the physical structure of the cereal at both macroscopic and microscopic levels. Mechanical damage occurs wherever grain is subjected to the destructive action of internal or external forces, commonly in the form of impact, causing internal or surface cracks. One of the most often used properties of grain is hardness. Hardness of grain has been a subject of interest to millers, livestock feeders, breeders, and other agricultural scientists. According to literature (Mohsenin, 1978) biting and cutting the grain has provided a qualitative evaluation of grain hardness. A number of attempts have been made to find an objective and a qualitative method of the individual kernel hardness determination. One of these methods can be the SKCS apparatus (Single Kernel Characterization System, type 4100) made by Perten Instruments in Illinois (USA).

Mechanical properties such as strength, impact, and shear resistance are crucial for agricultural engineering to become acquainted with seed resistance to cracking during harvesting and handling conditions. The internal cracks in grain are caused very often by external forces (as impact), acting on grains during harvesting or handling processes. The second main reason of internal cracks originating are internal forces arising inside kernel as consequence of the fast changes of field conditions, temperature, and humidity of climate mainly, not the grains. The internal cracks are studied using soft X-ray and/or colorimetric techniques. X-ray investigations are carried out mainly in the Institute of Agrophysics of Polish Academy of Science (PAS) in Lublin, Poland, in Agrophysical Research Institute of Russian Academy of Agricultural Sciences (RAAS), St Petersburg, Russia, and in Czech University of Life Science (CULS) in Prague, Czech Republic. X-ray detection makes it possible to analyze position of cracks and also to quantify them inside the kernel. This method allows evaluating the physical state of the grain endosperm (Grundas et al., 1999). Studies, carried out in the above-mentioned institutes, have shown that moisture content influences on grain resistance to cracking. Natural processes like rain or dew cause sudden increase of grain moisture and it is a main reason of cracks formation in the endosperm.

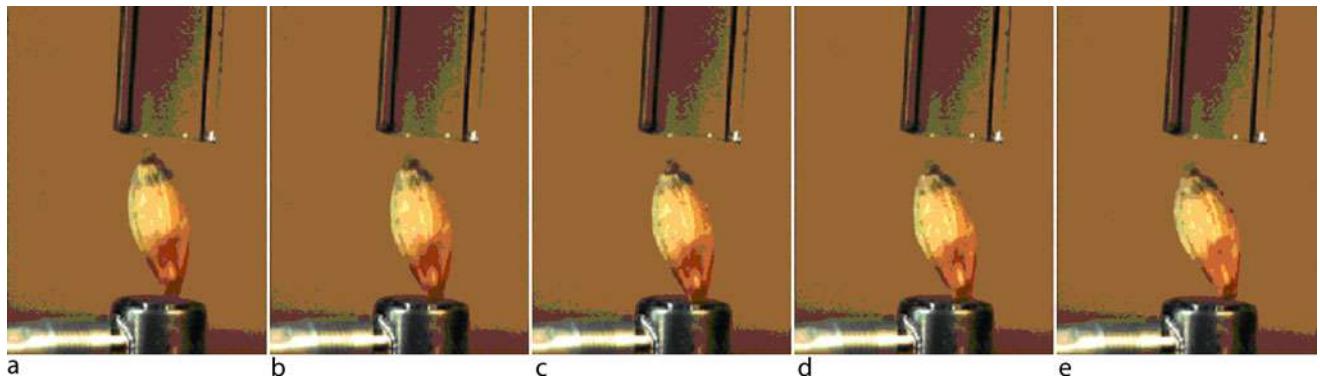

Results of research carried out by using X-ray methods showed also a significant difference in grain endosperm cracks between common wheat varieties. Natural wetting of dry grain (below 14% of moisture content) during rainfall, when wheat is standing in the field, is one of the reasons of cracking. Intensive drying of wet grain (above 15% of moisture content) in field or industry or in laboratory conditions is also the reason of cracking. In drier climate, premature ripening may occur due to stress connected with drought. In these conditions, grains are unlikely to reach full potential. The susceptibility of grain to mechanical damage is determined by genetic factors (e.g., grain hardness), environmental effects (climatic condition during pre-harvest period), and by the condition of grain storage (especially excessive humidity). The combination of these properties determines the utility value of grain material. The big effect of kernel humidity on its behavior is shown in next two literature examples: Al-Mahasneh and Rababah (2007) and Mohoric et al. (2009). Furthermore, mechanical properties of grain also change under biological factors, for example, insect pest infestation (Nawrocka et al., 2010) and fungi.

Shape, size, volume, surface area, density, porosity, color, and appearance are some of the physical characteristics of grain that are important in some problems connected with design of specific machines for harvesting and processing of raw materials or analysis of grain behavior during handling. What shape should be assumed for single grain in bulk material and which dimension should be employed in calculations are basic questions that have to be answered before selection of healthy grain or seeds from undesirable materials by preferred pneumatic or electrostatic devices. Knowledge about shape and size is also important for stress distribution in bulk material under load. Contact area is also vital for effective and safety transport of bulk material.

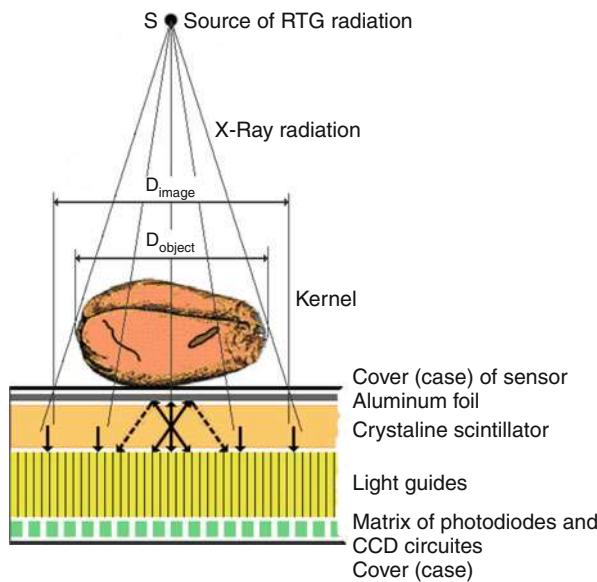

Knowledge of density and specific gravity of grains or seeds is needed, for example, in calculation of thermal diffusivity, in heat transfer, and in pneumatic and hydraulic handling. The irregular shape and porous nature of grains make problems in volume and density measurements.

Figure 1 shows the examples of grain impact. From a mechanical point of view, mechanism and the conditions of the running impact on grain play a big role in its damage (Stronge, 2000). The velocity of impact is not too high and the collision objects are rigid or viscoelastic bodies and very often is running noncollinear configuration of acting bodies. After rebound the kernel starts its rotation. An incidence of kernel is not on the center of the force transducer. This fact and the inclination of longitudinal axis of kernel are main reasons of a kernel rotation about a perpendicular axis.

Figure 2 shows the principle of scintillation sensor work, which is used for direct making of digital roentgenograms (Del Guera, 2004). The figure explains simultaneously a reason of “fuzzy contours” of roentgenogram. This phenomenon is caused by the difference in dimensions of image (D_{image}) and object (D_{object}), which depend

Grain Physics, Figure 1 A visualization of kernel deformation during its acting onto the force transducer is shown. The periodicity of the snaps is 200 μ s. The kernel of barley is falling onto the force transducer. The snaps (a) and (b) are before the impact, (c) during the impact and (d) and (e) are after the impact of kernel (Pecen et al., 2007).

Grain Physics, Figure 2 A basic principle and structure of scintillation sensor for direct making of digital roentgenograms.

Grain Physics, Figure 3 The example of real scintillation sensor (on the left) with active field of 9 cm^2 and dimensions 2.6 \times 3.5 cm. Matrix consists of two billion photodiodes with pitch about 25 μm . There is also X-ray image of *Ricin Castor* on the right.

on the geometrical arrangement of X-ray apparatus. A strong influence on “fuzzy contours” and X-ray image resolution has thickness and properties of the sensor scintillation layer. This type of sensor is widely used in practice and its properties depend mainly on properties of the sensor scintillation layer. This type of sensor is used in the laboratory of CULS, Prague. An image of this kind of sensor and a roentgenogram made by it are depicted on Figure 3.

Near-infrared hyperspectral imaging (NIR HSI) is another method used to determine the physical properties of grain. It integrates conventional imaging and spectroscopy to attain both spatial and spectral information from an object. Hyperspectral images (hypercubes) are three-dimensional blocks of data, comprising two spatial and one wavelength dimension. It allows for the visualization of biochemical constituents of a sample, separated into particular areas of the image, since regions of a sample with similar spectral properties have similar chemical composition. It is currently unfeasible to obtain information in all three dimensions of a hypercube simultaneously (Gowen et al., 2007).

The NIR technique can be applied to determine moisture, protein, lipid and starch content, wet and dry gluten, and alveograph parameters of whole wheat in the laboratory (Miralbes, 2003) as well as on the field during harvesting (Maertens et al., 2004). It also allows for detection of single wheat kernels containing insects (Maghirang et al., 2003) and classification of healthy and fungal-damaged soybean seeds (Wang et al., 2003).

TD-NMR technology (time-domain nuclear magnetic resonance) is widely used for various process and quality control, and R&D applications. Moisture and protein content of bulk cereal grain samples can be measured very quickly by a TD-NMR benchtop instrument at the harvest point. The same technique can be used to implement rapid quality control of incoming cereal grains at the food processing plant. TD-NMR can contribute significantly

toward quality improvement and can be a powerful tool for rapid analysis (Ghosh and Tombokan, 2009).

Conclusions

Physical measures to prevent some of the main causes for rejected grain samples are suggested. The physical condition of grain, which travels from field crop to commodity, is described. The simple method, used in the past to measure these quantities, have improved over time and nowadays that measure methods provide more information about studied objects. These methods are often noninvasive. Development of field measurement was caused mainly by a progress in information technologies and by the use of new physical principles. Nowadays more sophisticated and very sensitive methods for measuring individual properties of grain and seed are used. Very often optical properties of studied materials are preferred for their better characterization. These methods bring better knowledge about a material behavior on a cell level, and obtained results allow better utilization of studied materials.

GRAINS, AERODYNAMIC AND GEOMETRIC FEATURES

Bronisława Barbara Kram
Institute of Agricultural Engineering, University of Environmental and Life Sciences, Wrocław, Poland

Definition

Grains include cereals, pulses, and oilseeds. They are often referred to seeds that are reproductive materials of the cultivated plants (see [Grain Physics](#)).

Aerodynamics is a field of dynamics that deals with the problems of gas flow and forces produced by the phenomena.

Introduction

The forces affect a solid during its movement in gaseous environment. The magnitude of the force is affected by the parameters of the solid (length l [m], air density ρ [kg m^{-3}], coefficient of internal friction μ [$\text{kg m}^{-1} \text{s}^{-1}$]) as well as air stream velocity v [m s^{-1}]. Combination of above-mentioned components yields the Reynolds number

$Re = (v \cdot l) = (\mu/\rho)[-]$ which is very important in the theoretical aerodynamic calculations.

In practice, air acts as a carrier both during transport, classification, as well as cleaning. The most usual is a system, where particles (grains) are transferred in a moving stream of air. Grain parameters like weight, size, and shape as well as moisture have an essential influence on its aerodynamic characteristics like critical velocity v_k , coefficient of aerodynamic resistance k_x , and coefficient of fineness k_0 .

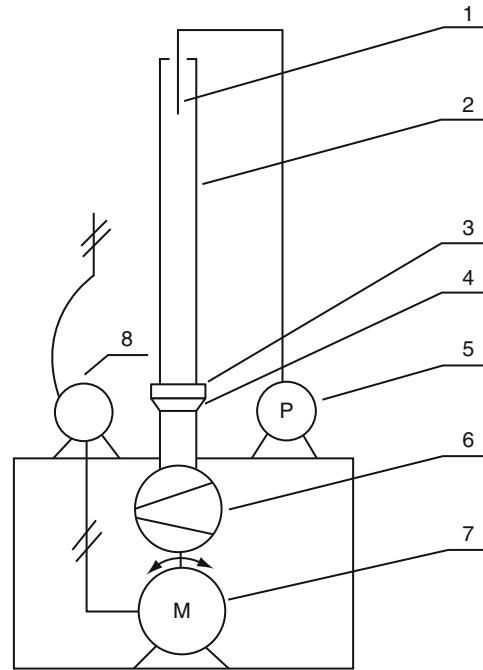

Survey of literature

Agricultural engineering has forced the investigation on the aerodynamic properties of the vegetables. Letoshnev (1949) considered in detail the problem of the aerodynamic properties in his textbook on the construction of agricultural machines. He referred there to Bezruckin (1936), who as early as in the 1930s, reported the numerical values of the properties for the basic seeds. In his very important for agricultural physicists textbook, Mohsenin (1970) devoted a lot of attention to the problem of aerodynamics; he presented two methods of estimation of the aerodynamic properties of agricultural products: in a vertical air tunnel for terminal velocity determination in air and in vertical water tunnel for determining terminal velocity in water. He included also the results of investigations of the aerodynamic properties by Bilanski et al. (1962). The method of critical velocity estimation in the vertical air tunnel is commonly employed with various constructional modifications. Bogaczyński (1975) measured a dynamic pressure in a vertical air tunnel and estimated the coefficient of resistance and then the critical velocity for wheat, barley, and rye. Coates and Yazici (1990) announced the aerodynamic properties of sorghum and jojoba seeds, respectively. Tabak and Wolf (1998) described in detail a vertical wind tunnel used to determine the critical velocity and coefficient of resistance of cotton-seeds. The aerodynamic properties of grain and straw materials were examined by Gorial and O'Callaghan (1990) and Zewdu (2007); weed seeds were investigated by Kahrs (1994). Jha and Kachru (1998) dealt with testing of the properties of makhana while Omobuwajo et al. (1999) examined African breadfruit seeds. In the following years the aerodynamic properties of pine nuts were studied by Faruk Ozguven and Kubilay Vursavus (2005), sunflower seeds were investigated by Gupta et al. (2007). A test stand and results of investigations on various coffee beans were presented in detail by Alfonso Junior et al. (2007).

Methodology

The method of estimation of a particle (grain) critical velocity v_k consists in a placement of the particle in a vertical air stream (Figure 1) and keeping it in an equilibrium state.

A glass pipe 2 equipped with a charging mechanism 3.4 for grain supply at its bottom part, a supporting sieve and air inlet is used for observation of the grain behavior. The

Grains, Aerodynamic and Geometric Features,

Figure 1 Scheme of the stand for determination of the grain aerodynamic properties: 1, Pitot tube; 2, glass tube; 3, charging mechanism; 4, screen; 5, compensating micromanometer; 6, fan; 7, electric motor; 8, autotransformer.

air stream is generated by a fan 6, driven by an electric motor 7. The yield of the fan is controlled by the change of rotational speed of the motor (by autotransformer 8). Pitot tube 1, arranged in the upper part of the glass pipe 2, is connected with a compensating micromanometer 5, measuring dynamic pressure in H_2O . The system composed of the devices (Figure 1) is employed for the measurement of pressure of the flowing air within accuracy $h = 0.01 \text{ mmH}_2\text{O}$. When the tested grain is in an equilibrium state, dynamic pressure p_{dyn} , described by Equation 1 can be measured:

$$p_{dyn} = \frac{v^2 \cdot \gamma}{2 \cdot g} \quad [\text{Pa}], \quad (1)$$

where

- v , air velocity $[\text{ms}^{-1}]$,
- γ , specific gravity of air $[\text{Nm}^{-3}]$,
- g , acceleration gravity $[\text{ms}^{-2}]$.

After transformation of the equation, critical velocity v_k may be evaluated:

$$v_k = \sqrt{\frac{2 \cdot g \cdot p_{dyn}}{\gamma}} \quad [\text{m s}^{-1}]. \quad (2)$$

In the equilibrium state, the weight of grain G [N] located in the vertical air stream is compensated by the resistance force R [N], expressed by Newton equation:

$$R = k_x \cdot S \cdot p_{dyn} \quad [N], \quad (3)$$

where

k_x coefficient of aerodynamic resistance [—],
 S lifting surface [mm^2].

From the equation, the coefficient of aerodynamic resistance k_x can be assessed:

$$k_x = \frac{G}{S \cdot p_{dyn}}. \quad (4)$$

The ability of a particle to resist against air stream is defined by the coefficient of fineness. It can be derived from the dependence between the resistance force, weight of particle, and its acceleration:

$$a = \frac{R}{m} = \frac{k_x \cdot S \cdot p_{dyn}}{m} = \frac{k_x \cdot S \cdot \rho}{2 \cdot m} \cdot v_k^2 \quad [\text{m s}^{-2}], \quad (5)$$

where

a , acceleration [m s^{-2}],
 m , mass of grain [mg],
 ρ , air density [kg m^{-3}].

The quantity $k_x \cdot S \cdot \rho / 2 \cdot m$ is called a coefficient of fineness k_0 :

$$k_0 = \frac{k_x \cdot S \cdot \rho}{2 \cdot m} \quad [\text{m}^{-1}]. \quad (6)$$

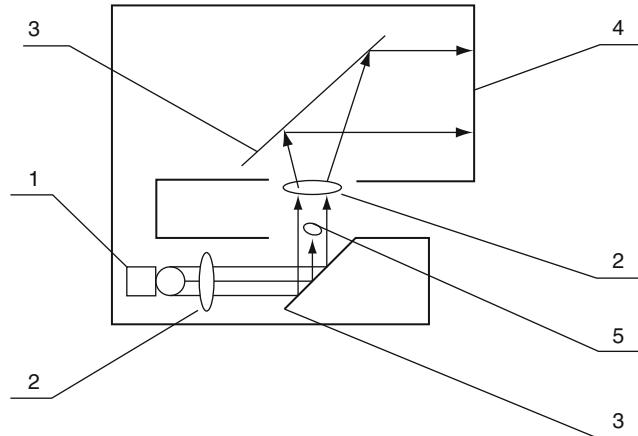

A lifting surface, necessary for the calculations is determined with an optical device (Figure 2) consisting of light sources (1), set of lenses (2), set of flat mirrors (3), screen with scale (4) enabling magnification of perpendicular projection of a tested grain (5) by the factor of 29.7. When we have the outlines of three perpendicular projections, we can measure and estimate the length, width, and thickness of a grain.

The method of setting of grain and the exemplary contours of three orthogonal projections presents Figure 3.

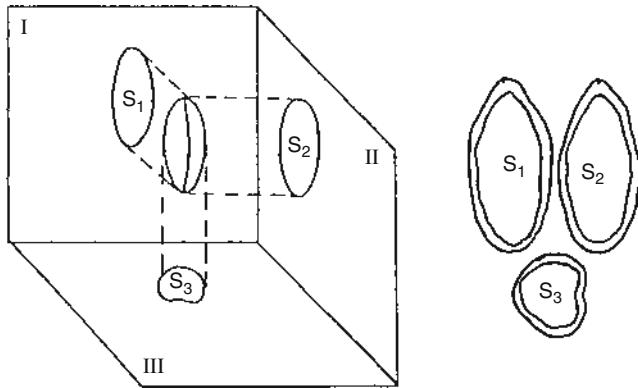

The largest of the three perpendicular projections is assumed as the lifting surface. After planimetry of the obtained outline of measured surface, its size can be estimated with a high accuracy. Size and shape of the lifting surface depend on the species and variety of tested grain. Some examples of lifting surfaces of tested grains are shown in Figure 4.

Aerodynamic characteristics

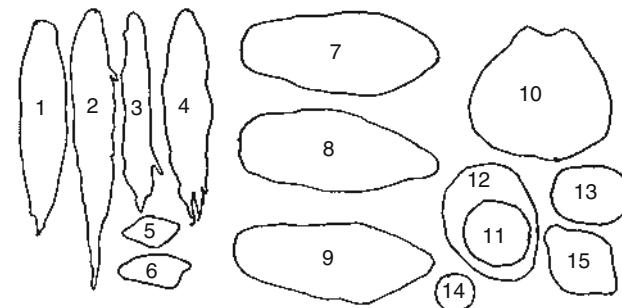

Aerodynamic characteristics were developed for the basic grains including: rape, seeds of chosen leguminous plants, maize, buckwheat, amaranth, and grass seeds.

Grains, Aerodynamic and Geometric Features,
Figure 2 Optical system of the device for determination of the grain lifting surface: 1, light sources; 2, set of lenses; 3, set of flat mirrors; 4, screen with scale; 5, grain.

Grains, Aerodynamic and Geometric Features,
Figure 3 Importing grain during determination of orthogonal projections, example contours of three orthogonal projections.

Grains, Aerodynamic and Geometric Features,
Figure 4 Lifting surface of seeds and grains: 1, Meadow Fescue; 2, Cocksfoot; 3, Smooth Brome-grass; 4, Westerwolds Ryegrass; 5, Timothy grass without glume; 6, Timothy grass with glume; 7, wheat; 8, rye; 9, triticale; 10, maize; 11, soya bean (dry); 12, soya bean of moistening; 13, horse bean; 14, amaranth; 15, buckwheat.

Lifting surface, weight, and length of a tested dry grain affect both critical velocity and coefficient of fineness. In all investigated cases high regularity has occurred. The critical velocity increased with growing weight, lifting surface and length of tested grain according to power or exponential relationship. On the other hand, the coefficient of aerodynamic resistance did not depend on any property of tested grain and therefore its average value was assumed as a characteristic property for a considered variety ([Table 1](#)).

Additionally, the investigation of horse bean and buckwheat was carried out for grain without seed cover due to technological requirements ([Table 2](#)).

In the case of maize, the grains for investigation were collected from three different zones of the cob. The first part of the cob (ca. one third of cob length from its rachis) called later A zone has the grains in the shape resembling a cone; the middle part, called B zone, has the grains in shape of disks with extended lifting surface; and the shape of grains from C zone (upper part of the cob) resembles spheres. The obtained results confirmed the influence of the shape of tested grains on their aerodynamic characteristics ([Table 2](#)).

To determine the effect of humidity on the aerodynamic characteristics, individual grains should be artificially moisturized. From dry grains with a defined humidity, one grain with a weight m is selected. When the weight m and humidity W of the grain are known, its dry matter m_s can be evaluated.

After immersing the grain in distilled water (for the time following from previously considered moisturizing dynamics), its weight rises to m_1 and humidity to W_1 , which can be easily estimated from the following equations:

$$W = \frac{m - m_s}{m} \cdot 100\%, \quad (7)$$

$$m_s = \frac{m(100 - W)}{100}, \quad (8)$$

$$W_1 = \frac{m_1 - m_s}{m_1} 100\% \quad [\%] \quad (9)$$

where:

W , moisture of grain [%],

m , mass of grain [mg],

m_1 , mass of moisturizing grain [mg],

m_s , dry substance [mg],

W_1 , moisture of moisturizing grain [%].

After the first moisturizing, the lifting surface is evaluated and the grain is placed in the vertical air stream. When the grain is in an equilibrium state, the dynamic pressure is measured. The procedure is repeated several times for an individual grain.

After numerical elaboration of the experiment it has been stated that the humidity affects critical velocity in a

high degree (Table 3). Generally, with an increase in grain humidity, its weight and lifting surface as well as critical velocity increase. Consequently, with the increase in critical velocity, both the coefficient of fineness and coefficient of aerodynamic resistance decrease (in case of moisturized

grain, its coefficient of aerodynamic resistance also depends on humidity). There is however one exception. It is the soya bean (Table 3). With an increase in the grain humidity the critical velocity decreases and in consequence the other coefficients rise. It follows probably from the fact

that a dry soya bean is almost a regular sphere which changes its shape after moisturizing into the shape of flat bean with an extended lifting surface. However, all considered aerodynamic characteristics versus humidity can be described by the simple power or exponential equations.

Summary

The investigations on aerodynamic properties are very time consuming and laborious, thus they require numerous repetitions. For the estimation of the coefficient of aerodynamic resistance the value of lifting surface

is necessary. The last can be assessed in several ways. The measurements of critical velocity are carried out in various measuring stands but since the main idea consisting in keeping the grain in a vertical air stream is maintained, their results are comparable. The values of critical velocity for various seeds, obtained over several years by different authors are collected in Table 4.

GRASS FIBERS, PHYSICAL PROPERTIES

Majda Sfiligoj Smole, Silvo Hribenik

Department of Textile Materials and Design, University of Maribor, Maribor, Slovenia

Definition

Grass fibers are sclerenchyma elongated cells which occur in different parts of plants, mainly in the stems and leaves. They can be found in ground and vascular tissues for mechanical support, but sometimes they occur in dermal tissues as well (Langer et al., 1991; Pazourek et al., 1997). This type of cell is of particular importance for the production of bast textile fibers as flax, hemp, etc.

Origin

Grasses (Poaceae) form one of the largest plant families consisting of some 650–785 genera and about 10,000 species (Petersen, 1981; Holmes, 1989; Leslie et al., 1992; Moser et al., 1996). Members of this family occur abundantly in every climatic region and certain possibilities for their nontraditional application are evident, e.g., production of pulp and paper (e.g., Pahkala, 2001). Perennial Ryegrass (*Lolium perenne*), Italian Ryegrass (*L. multiflorum*), Hybrid Ryegrasses (*L. perenne* × *multiflorum*), Timothy (*Phleum pratense*), Fescues (Meadow fescue – *Festuca pratensis*, Tall Fescue – *F. arundinacea*) are some of the most important representatives in this group of grasses, while legumes are presented by white clover (*Trifolium repens*), red clover (*Trifolium pratense*), and lucerne (*Medicago sativa*).

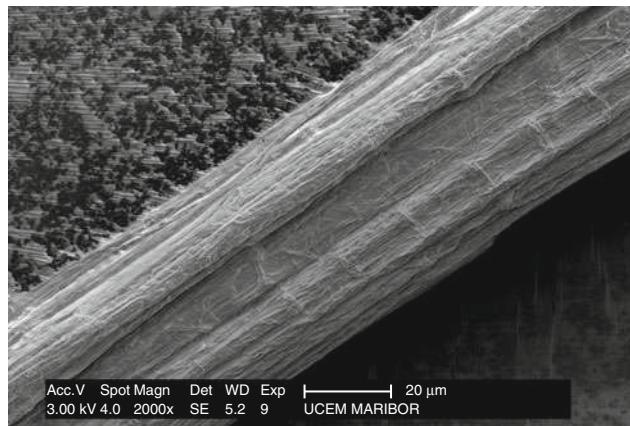

Isolation: The biological and chemical procedures for leaves and stems retting (i.e., separation of the fibers from the rest of the plant), respectively can be used to obtain technical grass fibers in the form of fiber bundles. However, mechanical separation of the fiber bundles is additionally needed (Sfiligoj Smole et al., 2004). The fiber bundles are mainly inhomogeneous and sclerenchyma cells are often accompanied by tracheary elements. Fiber content in stems is higher when compared to that in leaves (e.g., fiber content in hybrid ryegrass stems is 39.5% and in leaves it is 7.9%).

Fibers morphology

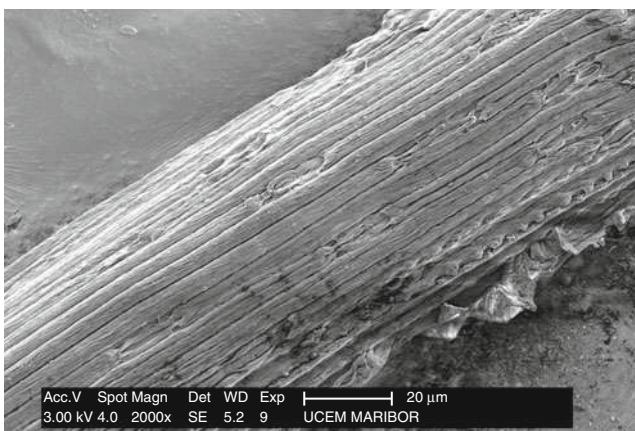

Scanning electron microscope images of the longitudinal views of the fibers isolated from hybrid ryegrasses by alkaline procedure are given in Figures 1 and 2.

Properties

The length of the elementary cells in grasses and legumes is between 0.5 and 3 mm; slightly shorter fiber cells are present in leaves when compared to the cells from stems. The diameter of the isolated cells is approximately 10–18 µm. Due to the history of the grasses (deformation and damage caused by the treatment of grasses, maturity grade, and conditions during grass growth), the plant

Grass Fibers, Physical Properties, Figure 1 Longitudinal view of fibers from a leaf of an ensiled ryegrass.

Grass Fibers, Physical Properties, Figure 2 Longitudinal view of fibers from a stem of an ensiled ryegrass.

structures vary considerably in their properties. Nevertheless, the mechanical properties of fiber bundles of the grass leaves in the axial direction are lower in comparison to the mechanical properties of fiber bundles of the stems, although the differences are insignificant. The stress-strain behavior of fiber structures indicates a rigid character. Elongations of samples at break are rather low, but higher than in the case of whole stems or leaves. The elongations vary between 1.5% and 5.5% and tenacities from 7.5 to 21 cN tex⁻¹. The obtained values are comparable with the mechanical properties of some textile bast fibers, e.g., jute, hemp, or coir.

GRAVIMETRIC WATER CONTENT

The ratio of water mass to dry matter mass.

GRAVITATIONAL POTENTIAL

The gravitational potential at a point is equal to the work by the exterior force as a particle of unit mass is brought from infinity to its position in the gravitational field.

GRAVITY HEAD (GRAVITY POTENTIAL)

The amount of work required to raise a body a specified height in a gravity field. Gravity head is expressed as energy per weight and is equal to the distance Z , of a measurement point in the soil above an arbitrary reference height (z). Gravity potential is expressed as energy per volume and is equal to the product of the distance raised, Z , the water density, ρ and the gravitation constant, g ($\rho g Z$).

GRAZING-INDUCED CHANGES OF SOIL MECHANICAL AND HYDRAULIC PROPERTIES

Synonyms

The influence of grazing on soil physical properties

Definition

Grazing. The activity of wild or domestic herbivores (e.g., deer, sheep, cattle) walking around and feeding on plants (mainly grasses and herbs).

Introduction

Soils that are grazed by animals undergo mechanical stresses, partly normal forces (load) and partly shearing forces (slip). The amount of loads and shearing forces depends on the kind of grazing animals and is sometimes comparable to agricultural machinery (Greenwood and McKenzie, 2001). Grazing and treading animals affect the (top) soil due to mechanical damage of the sod and the uppermost soil layers and due to soil deformation (Greenwood and McKenzie, 2001; Krümmelbein et al., 2006). Trampling by grazing animals results in the deformation and compaction of particularly the top soil (Zhang and Horn, 1996; Villamil et al., 2001; Greenwood and McKenzie, 2001; Martinez and Zinck, 2004; Krümmelbein et al., 2006; Tian et al., 2007). Grazing also influences the amount and composition of soil organic matter by the export of biomass and its return as excrements. This in turn influences biological activity and thus natural regeneration of soil structure by root activity (Angers and Caron, 1998; Greenwood and McKenzie, 2001).

Compressive and shearing soil deformation by grazing animals

The intensity and amount of deformation depends on the soil water content and the amount of pressure exerted on the soil; it becomes more distinct and more visible the higher the water content, and the stress exerted on the soil is, in comparison to the internal soil strength (Horn and Rostek, 2000; Arvidsson et al., 2003). The trampling effect of grazing animals is depending on their weight, hoof size, and kinetic energy. The pressure exerted on the soil becomes higher when the grazing animal is moving. While an animal is moving, only three or two and in extreme situations (e.g., while escaping) only one hoof touches the ground, meaning that the whole body mass is transferred by a reduced hoof area. Scholefield et al. (1985) measured that the pressure of a walking cow is twice as high as the pressure of a standing cow. Shearing forces due to grazing have widely been ignored although they are transmitted on the soil surface by all moving and scrabbling animals. We have to consider that such dynamic shearing movements modify soil structure and thus decrease soil stability (Peth, 2004; Krümmelbein et al., 2006). With increasing soil water content this effect becomes more pronounced, shearing occurs more frequently and it particularly occurs in the upper soil layer. Grazing leads to increasing values of precompression stress. This indicates a grazing-induced compaction of the soil, along with increasing soil strength against compressive forces and an increasing bulk density (Peth, 2004; Krümmelbein et al., 2006). Cyclic loading experiments have shown that with increasing grazing intensity the soil becomes less sensitive to repeated loading (Krümmelbein, 2007). The soil structure deterioration due to grazing is not only pointed out by increasing strength against compressive forces but also by decreasing

angles of internal friction with increasing grazing intensity (Krümmelbein et al., 2006; Krümmelbein, 2007). The angle of internal friction is one component of shear strength and a measure for the structural development of a soil; the greater the angle of internal friction, the further advanced is the structural formation of the soil (Silva et al., 2004).

Effects of soil deformation

Pore system

Soil compaction is characterized by a volume decrease, particularly of the coarse pore volume, accompanied by an increase of the fraction of smaller pores. The structural change due to grazing is also reflected by decreasing values of vertically oriented saturated hydraulic conductivity with increasing grazing intensity and particularly by the anisotropy of the saturated hydraulic conductivity (Krümmelbein et al., 2006). The total pore volume decreases, the pore size distribution shifts showing a decrease of coarse pores and an increase of medium and fine pores (Greenwood and McKenzie, 2001; Peth, 2004; Krümmelbein, 2007). Due to grazing, there is not only a modification in the total pore volume and the pore size distribution, but also a decrease in the pore continuity. The decrease of pore volume and pore continuity and the changed pore size distribution affect soil functions, e.g., air and water conductivity, which are decreased in deformed soils (Vogeler et al., 2006; Krümmelbein et al., 2006), water retention (Kutílek et al., 2006; Krümmelbein, 2007), and soil biological processes (Whalley et al., 1995).

Infiltration and saturated hydraulic conductivity and its anisotropy

Even more sensitive to compaction than the pore volume is the pore continuity (Ball and Robertson, 1994). Pore continuity in turn determines saturated hydraulic conductivity and air permeability. In general, the saturated hydraulic conductivity is not only decreased due to a grazing-induced formation of a platy structure, but also becomes higher in the horizontal compared to the vertical direction and results in anisotropic flow conditions (Dörner Fernández, 2005; Krümmelbein et al., 2006).

The alterations in flow direction and pore continuity by grazing also reduce the water infiltration into the soil because of the loss of macropores open to the surface. Removal of vegetation also decreases the number of root channels that are important for water infiltration into the soil (Pietola et al., 2005; Kennedy and Schillinger, 2006).

Water repellency

Infiltration can also be decreased by changes in water repellency. Soils of higher grazing intensities mostly show decreased water repellency at comparable soil water contents because less soil organic matter accumulates which enhances the potential water repellency (Krümmelbein, 2007). Because of the high amounts of living and dead

biomass on ungrazed sites, the soil water content of those sites mostly is higher than on grazed sites (Zhao et al., 2007). In turn, water repellency increases with decreasing water contents, accordingly the actual water repellency is often higher on grazed than on ungrazed sites (Zhao et al., 2007). The higher the water repellency, the lower is the amount of water infiltrating into the soil (Lamparter et al., 2006). Water repellency also affects capillary rise negatively (Bachmann et al., 2001). The combination of effects of soil compaction, shearing, water repellency, etc. leads to higher runoff rates on grazed compared to ungrazed sites (Greenwood and McKenzie, 2001).

Interrelation between mechanical and hydraulic properties

The mechanical and hydraulic changes described above are interlinked with each other. They commonly have negative effects for the productivity of grassland soils and their ecological functioning (Greenwood and McKenzie, 2001). Poor physical quality of soils due to soil compaction can, apart from the negative economical impact due to productivity losses, sometimes lead to drastic environmental consequences, such as flood disasters as, e.g., encountered lately in areas of Central Europe(Akkermann, 2004) and landslides in hilly or mountainous areas. Soil compaction deteriorates the pore system and induces increasing intra-aggregate bulk density and a reduced interaggregate macropore system, followed by an even more intense shear-induced deterioration of soil structure. Thus, as the final stage even a complete aggregate homogenization due to shear forces can occur on grazed soils, which results in lower infiltration rates, higher run off and greater probability for water erosion events (Pietola et al., 2005; Peth and Horn, 2006). Thus, structure degradation and sparse vegetation enhance not only water but also wind erosion (Hesse and Simpson, 2006; Zhao et al., 2007). In many semiarid areas, compaction and structural degradation of the top soil resulting from intense grazing has led to widespread degradation processes (Krümmelbein et al., 2006; Krümmelbein, 2007), such as wind erosion resulting in heavy dust emissions (Li et al., 2003). It is well known that on intensely grazed grassland soils also water erosion is a common phenomenon during strong rainfall events, partly accompanied by severe gully development (Arnaez et al., 2007; Wei et al., 2007).

Soil recovery from structure degradation

Soils have a limited ability to structurally recover from former mechanical deterioration such as compaction (Drewry, 2006; Krümmelbein, 2007). In general it is known that due to wetting and drying cycles and, consequently, swelling and shrinkage, soil structure is able to recover from a compacted or even homogenized state by forming new aggregates. Because these aggregates are surrounded by the interaggregate pore space, wetting and drying may also be able to improve the aeration and water

infiltration as well as the thermal properties of the soil in dependence of the number and intensity of these swell-shrink processes (Horn, 1994). Especially, soils with a clay content of more than 12% show intense swelling and shrinkage processes (Horn, 2002). Structure homogenizing processes, e.g., mechanical disturbance of the soil, lead to normal shrinkage accompanied by crack formation and separation of the soil into smaller parts (Janssen et al., 2006). Wetting and drying of homogenized soils create planes of weakness, along which the soil breaks into aggregates (Utomo and Dexter, 1982). A formerly disturbed soil can partly regain its strength over a period of time. When the original strength is regained, it is called thixotropy (Utomo and Dexter, 1982; Markgraf et al., 2006).

Wiermann and Horn (2000) showed that a loess-derived Luvisol exhibited distinct signs of regeneration after a single compaction event, e.g., in terms of increasing macroporosity and gas permeability at 10 cm depth. North Ethiopian soils degraded by grazing show distinct signs of regeneration after 5 years (Mekuria et al., 2007). Biological activity of soil fauna and flora can further enhance structure formation and remediation due to various mechanisms (Horn and Dexter, 1989). Soil fauna influences structure due to its grubbing and digging actions in the soil, leaving loosened zones (channels) surrounded by compacted areas (channel walls) (Schrader et al., 2007). Bossuyt et al. (2006) and Pulleman et al. (2005) describe the important contribution of earthworms to microaggregate formation and incorporation and protection of organic matter in these aggregates. The saprophagous macrofauna can furthermore enhance microbial respiration and biomass and increase the water retention of the soil due to litter fragmentation and soil mixing, thus increasing organic matter accumulation and relocation (Frouz et al., 2007).

Plant roots can also influence the recovery of soil structure in various ways. They form continuous vertical pores and therefore disrupt and reaggregate homogenous soils into smaller units. This is due not only to the shearing and compressive forces roots exert on the soil, but also to the water uptake of the roots, followed by more intense and frequent wetting and drying cycles close to the roots, creating more negative pore water pressure, which induces crack formation and age hardening of existing soil aggregates as mentioned above. Roots furthermore increase the structural soil stability with fine roots and root hairs growing around soil aggregates; fungal hyphae can be associated to plant roots and further enhance the binding of soil aggregates as well as plant residues (Greenwood and McKenzie, 2001). Former studies revealed a positive correlation between root mass and porosity in pastures and an increased infiltration due to macropores created by living roots (Greenwood and McKenzie, 2001). Even when the roots are dead, the continuity of the old root channels and the cracks induced by shrinkage due to root water uptake persisted and kept the infiltration rate at a high level (Priksat et al., 1994). Czarnes et al. (2005) showed

that the exudates of plant roots and microbes in the rhizosphere together with intense wetting and drying cycles improve soil structure. Recently advanced x-ray microtomographies of soil aggregates allow to show the complexity of intra-aggregate pore systems (Schrader et al., 2007; Peth et al., 2008) and prove that soil micro organisms significantly contribute to the processes of aggregate formation by improving their habitat (Feeney et al., 2006), inducing crack formation in the soil (Preston et al., 2001) and by rearranging clay particles adjacent to them (Chenu, 1993, 2001). Micro organisms can also influence the amount and distribution of water repellency; carbon in turn influences soil wettability (Hallett et al., 2004) and mechanical stability (Horn, 1994; Chenu et al., 2000; Mataix-Solera and Doerr, 2003). Herrick and Lal (1995) pointed out the importance of excretal return to tropical pastures to keep soil organisms active and maintain good physical pasture properties. Recapitulating it can be stated that soil flora and fauna, including micro organisms and, accordingly, carbon content and composition and mechanical as well as hydraulic processes are closely interlinked with each other and with external factors such as climate and management.

Summary and conclusions

Grazing affects the physical conditions of soils. The effects which can be attributed to grazing are limited to the upper 10–15 cm below surface. Most of the changes are unfavorable in terms of productivity and ecosystem services of grassland ecosystems. Grazing induced changes of soil mechanical and hydraulic properties are strongly interrelated with each other and lead to an increased sensitivity to wind and water erosion. The susceptibility of soils to structural deterioration increases with increasing water content. Repeated mechanical loading combined with shearing forces as applied by grazing animals adversely affect soil structure along with diminishing angles of internal friction and a decrease of the total and coarse pore volume. This in turn affects the pore water pressure and the occurrence and orientation of water menisci, which in dry states are concave, thus stabilizing. If due to the compression of coarse pores the hydraulic conductivity of the soil becomes too low to remove excess soil water from the pore system during loading, soil compaction leads to less negative and sometimes even positive pore water pressure during loading, resulting in convex, thus mechanically destabilizing menisci according to the effective stress equation (Nuth and Laloui, 2008). With incomplete drainage of excess soil water, soil strength can be severely decreased. Soil mechanical changes are interconnected with changes in the pore system; accordingly, soil functions such as hydraulic conductivity and air conductivity are influenced by grazing. Water infiltration and saturated hydraulic conductivity, which are highly depending on the pore diameter and pore continuity, are also highly sensitive to deformations induced by mechanical stresses exerted by grazing animals.

Natural soil recovery due to wetting and drying cycles, soil fauna, root growth, and decay occurs but takes several years to decades. It is also not proofed that recovery will ever lead back to the state before being influenced by grazing.

Synonyms

Optimization of greenhouse parameters

Definition

Climate control refers to keep the desired value of the greenhouse inside parameters as temperature, light, humidity, and CO₂ concentration in order to provide optimal conditions for the plants.

With respect to the energy cost, the temperature in greenhouse should keep around a desired level. Lower accuracy requires higher set point in temperature, which results in more energy consumption (Tantau, 1997). The temperature can be increased by heating of the air and, at the same time, the use of thermal screens may decrease the energy consumption during nighttime periods.

The light control is mainly based on the requirement of the plant growing age.

The control of humidity provides to avoid the extremely high or low air humidity values. Concerning to energy saving avoiding the high humidity is more important. The control of humidity can be achieved by heating and/or by ventilation.

CO_2 concentration can be controlled by opening the top window in the greenhouse.

In order to assess appropriate control strategies, the productivity and quality of the plant should be provided duration of growing. The set-points are based on the practical experiments, but it is aimed to modify them according to the plant responses, which can be reached via leaf conductivity, CO_2 consumption, or nutrient uptake. The set-point for control variables has a strong influence on the energy consumption of greenhouses. The climate control computer has got a feeding control extension, which provides nutrients in solution to plants (van Henten, 1994).

GREENHOUSE EFFECT

Inhibition of the atmospheric transmission of outgoing thermal radiation from the earth, due to the presence of certain gases in the atmosphere. The principal “greenhouse gas” is water vapor. Another important one is carbon dioxide, the concentration of which has been increasing due to forest clearing, cultivation of formerly virgin soils, and – especially – the burning of fossil fuels (coal, petroleum, natural gas).

GREENHOUSE GAS FLUXES: EFFECTS OF PHYSICAL CONDITIONS

Ryusuke Hatano

Laboratory of Soil Science, Graduate School of Agriculture, Hokkaido University Kita-Ku, Sapporo, Hokkaido, Japan

Definition

Physical conditions: Soil moisture, soil temperature, air pressure, rainfall, snowfall, flooding, drainage, aeration, freezing, and thawing affecting plant roots, soil fauna, and soil microbial activities, producing and consuming greenhouse gases in soil.

Greenhouse gases: Including carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O) produced and consumed in soil and absorbing and emitting radiation within the thermal infrared range in the atmosphere.

Carbon dioxide (CO_2): Colorless and odorless gas (mol weight 44.010 g mol⁻¹; density 1.977 g L⁻¹ at 1 atm and 0°C; solubility in water 0.47 g CO_2 –C L⁻¹ at 1 atm and 20°C), consumed by plants during photosynthesis to make organic matter, and produced by respiration of animals, plants, and microorganisms to obtain energy through decomposition of organic matter.

Methane (CH_4): Colorless, odorless gas (mol weight 16.042 g mol⁻¹; density 0.717 g L⁻¹ at 1 atm and 0°C; solubility in water 0.018 g CH_4 –C L⁻¹ at 1 atm and 20°C), oxidized by photochemical reaction in the atmosphere and consumed by methanotrophic bacteria in dry soil, and produced by methanogenic bacteria in wet soil.

Nitrous oxide (N_2O): Colorless and odorless gas (mol weight 44.013 g mol⁻¹; density 1.977 g L⁻¹ at 1 atm and 0°C; solubility in water 0.79 g N_2O –NL⁻¹ at 1 atm and 20°C), consumed by denitrifying bacteria and produced by nitrifying and denitrifying bacteria.

Gas flux: Amount of gas flowing through a unit area per unit time.

Introduction

An increase in the concentrations of greenhouse gases (GHG; carbon dioxide [CO_2], methane [CH_4] and nitrous oxide [N_2O]) in the troposphere causes global warming (Prather et al., 2001). The global atmospheric concentrations of CO_2 , CH_4 , and N_2O have increased from a pre-industrial value of about 280 ppm, 715 ppb, and 270 ppb, respectively, to 379 ppm, 1,774 ppb, and 319 ppb in 2005 (Forster et al., 2007). Increase of GHG emissions increases radiative forcing warming the earth. Contribution of CO_2 , CH_4 , and N_2O to total radiative forcing in 2005 is 63%, 18%, and 6%, respectively, and chlorofluorocarbons (CFCs) and others account for the rest of 13% (Forster et al., 2007). Global warming potential (GWP), which is the index in order to compare the relative radiative forcing of different GHGs and GWP in 100-year

time horizon is 1 for CO₂, 25 for CH₄, and 298 for N₂O (Forster et al., 2007). N₂O is a long-lived gas and contributes to stratospheric ozone destruction (Cicerone, 1987).

Soil is the major source of GHG emissions into the atmosphere. Land use change contributes 20% of total CO₂ emission into the atmosphere (7.9 Gt C year⁻¹ in the 1990s); rice paddy, and wetland soils contribute 34% of total CH₄ emission (515 Mt CH₄ year⁻¹); and agricultural soils contribute 24% of total N₂O emission (16.2 Mt N year⁻¹) (Prather et al., 2001).

CO₂, CH₄, and N₂O are produced and consumed in soil by mainly microbial activities, which changes the concentrations of these gases in soil. Soil microbial activities are influenced by soil environment factors, which are soil temperature; soil moisture; available carbon; nutrients; acidity; redox potential, which are affected by the factors of climate, topography, soil texture, soil structure, vegetation, and land use. Change in soil gas concentration varies concentration gradients between the soil and the atmosphere, regulating gas diffusion fluxes through the soil. Slower flux provides the opportunity for further microbial reaction in the soil. Also, the gas flux is influenced by the pressure gradient. Some of the gases dissolved in soil water leach into groundwater and secondarily emitted after drainage water is discharged to the ground surface. The rates of production and consumption of GHGs, diffusion, mass flow, and dissolved gas leaching in soil are the main factors controlling GHG exchange between the soil and the atmosphere. This paper provides the information about the effect of soil physical conditions on the controlling factors for soil CO₂, CH₄, and N₂O fluxes.

CO₂

CO₂ is produced in soil through heterotrophic respiration (organic matter decomposition by heterotrophic organisms) and plant root respiration. The emission of CO₂ is called soil respiration (Raich and Schlesinger, 1992). Increase of heterotrophic respiration in soil decreases soil

organic carbon. Supplying oxygen molecule from the atmosphere into soil through aeration proceeds soil heterotrophic respiration. Tillage stimulates the heterotrophic respiration and reduces soil organic carbon (Jarecki and Lal, 2003). Increase of soil temperature increases soil microbial activity. There is a relationship between soil temperature (*T*) and CO₂ emission (*F_c*) from soil as follows:

$$F_c = a \exp(b T) \quad (1)$$

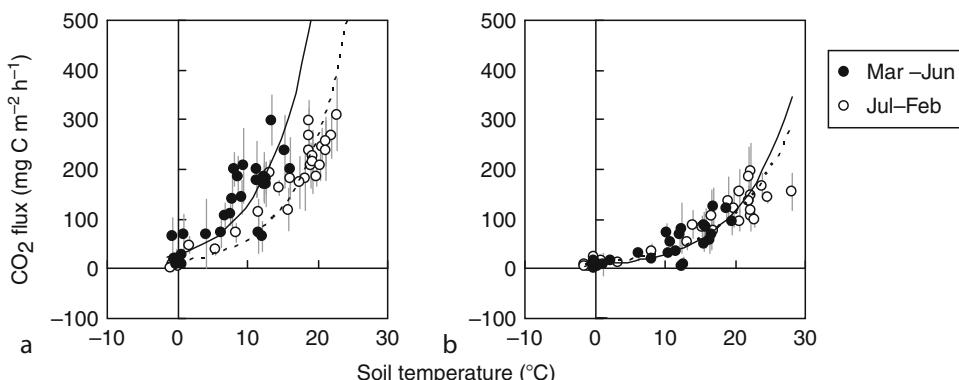

where *a* and *b* are fitted constants.

Figure 1 shows an example of the relationship between soil temperature at a depth of 5 cm and CO₂ fluxes measured by chamber method at the root-included plot and root-excluded plot in a Japanese grassland (Shimizu et al., 2009). The CO₂ fluxes were higher in spring (beginning of March to end of June) than in other seasons (beginning of July to end of February) at the same temperature due to the decomposition of litter supplied into soil during the winter, resulting in being divided into two groups at each plot. The relationship between the CO₂ flux and the soil temperature in each plot was well explained by Equation 1 for each season. There was a significant difference in the regression between the seasons (*P* < .001) in root-included plot, while there was no significant difference between the season in the regressions for the root-excluded plot (Table 1).

The *Q*₁₀ value is the rate of increase in CO₂ emission with 10°C of increase in soil temperature along with the exponential relationship between them. It was calculated by applying the fitted constant (*b*) obtained from Equation 1 to Equation 2.

$$Q_{10} = \exp(10 b) \quad (2)$$

The *Q*₁₀ value of CO₂ fluxes of the Japanese grassland was higher in root-included plot (4.50) than in root-excluded plot (3.61) (Table 1). The *Q*₁₀ values of CO₂ fluxes derived from plant root respiration and soil organic

Greenhouse Gas Fluxes: Effects of Physical Conditions, Figure 1 Relationship between CO₂ flux and soil temperature in root-included plot (a) and root-excluded plot (b) (From Shimizu et al., 2009). Data represent mean \pm SD (*n*=6). The lines indicate the exponential regression models for each season (solid line, from the beginning of March to the end of June; dashed line, from the beginning of July to the end of February), and the models are described in Table 1.

Greenhouse Gas Fluxes: Effects of Physical Conditions,
Table 1 The exponential regression models using soil
 temperature at 5 cm depth to predict the CO₂ flux and Q₁₀
 (From Shimizu et al., 2009)

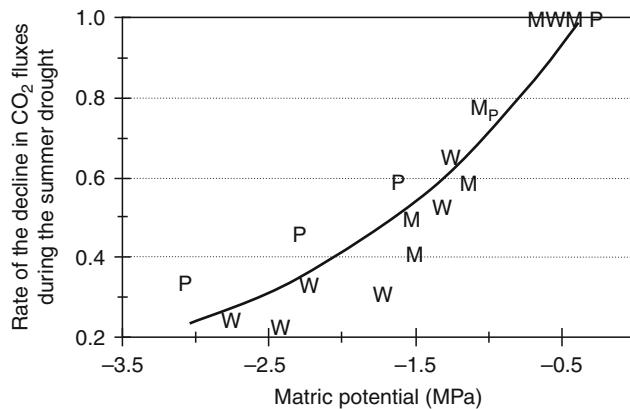

Treatment	Equation	R ²	P value	Q ₁₀
Root-included fertilizer plot				
March–June	F=27.6 exp (0.151 T)	0.65	<.001	4.53
July–February	F=12.8 exp (0.150 T)	0.85	<.001	4.50
Root-excluded control plot				
March–June	F=7.6 exp (0.136 T)	0.61	<.001	3.90
July–February	F=10.0 exp (0.120 T)	0.90	<.001	3.31

The model is $F=a \exp (bT)$, where F is the CO₂ flux (mg C m⁻² h⁻¹) and T is the soil temperature at 5 cm depth (°C)

matter decomposition in mixed-hardwood forest soil of temperate zone were 4.6 and 2.5, respectively (Boone et al., 1998). Also, the Q_{10} value of CO₂ fluxes at an intact site of Siberian larch forest was 4.35, while it decreased to 1.69 and 2.09 at the burnt and cutover sites, respectively (Takakai et al., 2008a). These findings suggest that Q_{10} value of CO₂ flux is higher in root respiration than in soil organic matter decomposition.

There is an optimal water filled pore space (WFPS) for soil CO₂ production, which is around 60% (Linn and Doran, 1984). However, in actual field there is an interaction between soil moisture and soil temperature, and there is a tendency that temperature increases with decreases of soil moisture. Therefore, sometimes CO₂ fluxes correlated with not only soil temperature positively but also soil moisture negatively. Soil temperature is a better predictor for CO₂ fluxes, and a Q_{10} function can predict reasonably annual CO₂ fluxes. However, rapid decline in CO₂ fluxes caused by significant drought was found in the Harvard Forest in central Massachusetts. Figure 2 shows that the rate of the decline in CO₂ fluxes correlated exponentially with decreasing soil matric potential (the rate of the decline in CO₂ fluxes = $1.21 \times e^{(0.553 \times \text{matric potential})}$, $R^2=0.83$, $P<.01$). Combining this function of the decline in CO₂ fluxes to the soil matric potential and Q_{10} function can provide better prediction of CO₂ fluxes (Davidson et al., 1998). However, CO₂ fluxes in crop fields in tropical dryland correlated better with soil moisture content than with soil temperature (Singh et al., 2009).

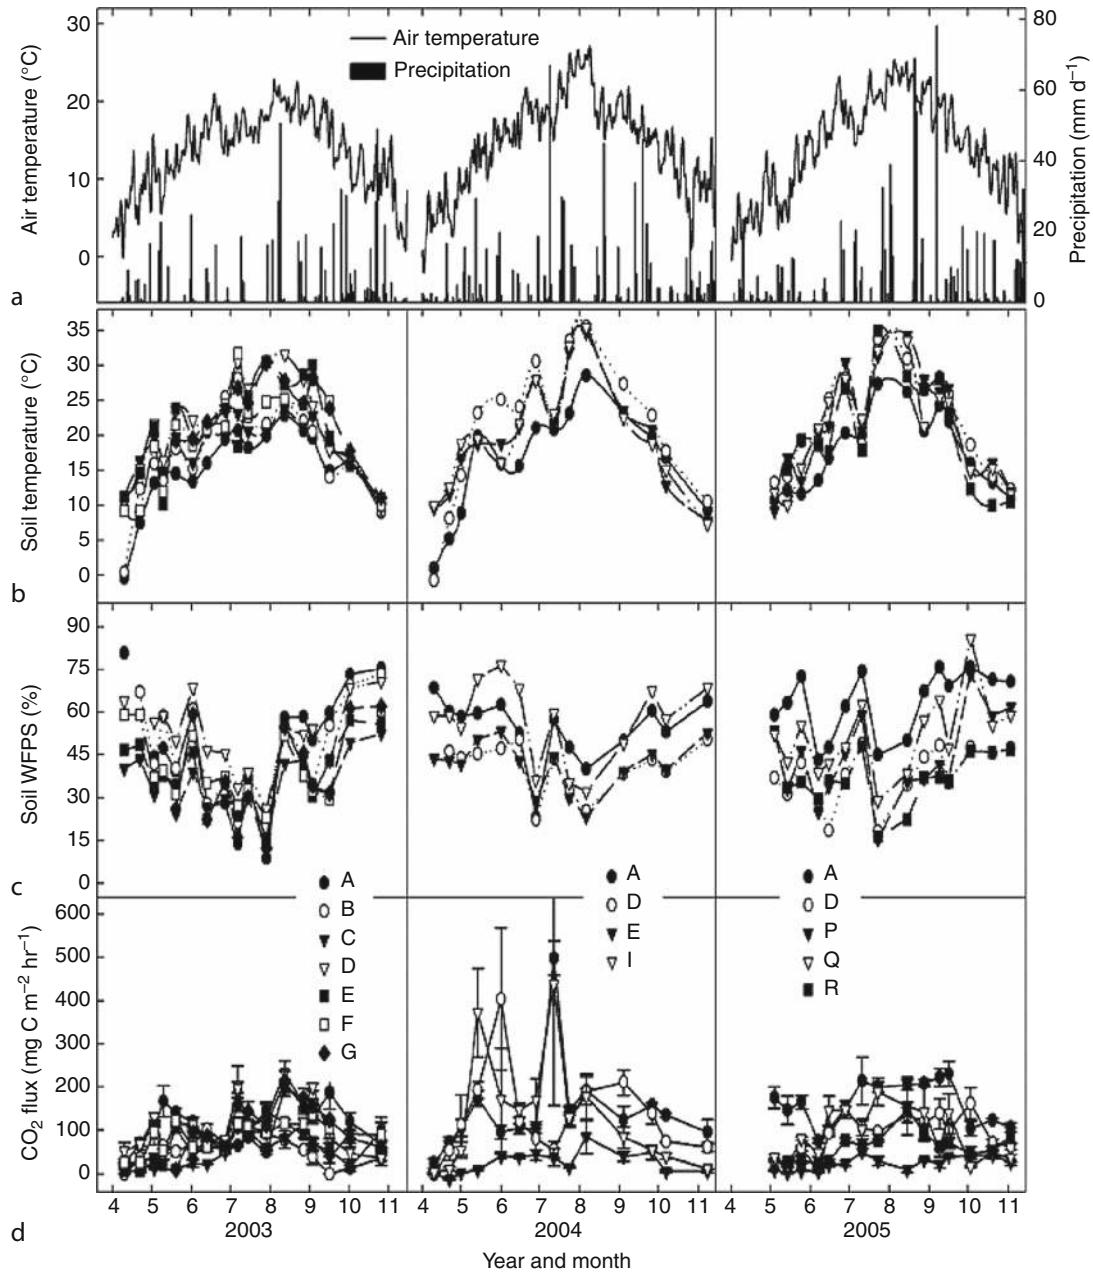

Figure 3 shows the CO₂ fluxes derived from soil organic matter decomposition measured at the root-excluded plots established in the 11 upland crop fields with different types of soil (Brown Forest soils, Brown Lowland soils, Gray Lowland soils, Psedogleys) with various texture (18.4–51.6% of sand content) in Mikasa city, central Hokkaido, Japan, over the no snow cover months (mid-April to early November) from 2003 to 2005 (Mu et al., 2008). The seasonal pattern of soil CO₂ fluxes mainly followed the seasonal changes in soil temperature but was occasionally interrupted by soil moisture

Greenhouse Gas Fluxes: Effects of Physical Conditions,
Figure 2 Effect of soil matric potential on the rate of decline in CO₂ fluxes (normalized soil respiration) during the summer drought (Davidson et al., 1998). The plotting symbols refer to the site drainage classes (V, very poorly drained, P, poorly drained, M, moderately well drained, W, well drained).

fluctuation. Soil CO₂ fluxes increased with increasing soil temperature prior to June. Large fluctuation in soil CO₂ fluxes was observed from June to August, which was coincided with drying/rewetting events occurring during this period. After August, soil CO₂ fluxes declined with decreasing soil temperature. The instantaneous CO₂ fluxes ranged from 0.1 to 234 mg C m⁻² h⁻¹ for 2003 and from 2.6 to 231 mg C m⁻² h⁻¹ for 2005. Several significantly high emission episodes (300–500 mg C m⁻² h⁻¹) were recorded at the sites investigated following heavy rainfall within the previous week (amounting to 33–82 mm) in 2004.

Multiple regression analysis for correlation of logarithmic value of the CO₂ flux to soil temperature and WFPS showed that soil temperature alone or together with WFPS, clay content, and CN ratio could explain 27–76% of the temporal variation in the instantaneous soil CO₂ fluxes at the sites. Furthermore, there was a significant quadratic relationship between mean CO₂ flux or cumulative CO₂ emission and clay plus silt content (Figure 4). In contrast, mean CO₂ flux and cumulative CO₂ emission had no significant relationship with the mean values of soil temperature and moisture ($P > .2$). This suggests that soil texture is important for explaining spatial variability in soil CO₂ flux between sites within the same climate region. According to the quadratic function in Figure 4, soil mean or cumulative CO₂ flux will increase with increasing clay plus silt content at a clay plus silt content to 63%, but a further increase in clay plus silt content will lead to a decrease in soil CO₂ flux. Soil clay and silt facilitate soil aggregation and increase the stability of soil aggregates, which can reduce fluctuation in temperature and water content and can protect microorganisms from predation by soil fauna (Hassink et al., 1993). As a result, soil microbial biomass and microbial activity appeared to increase with increasing clay and silt content.

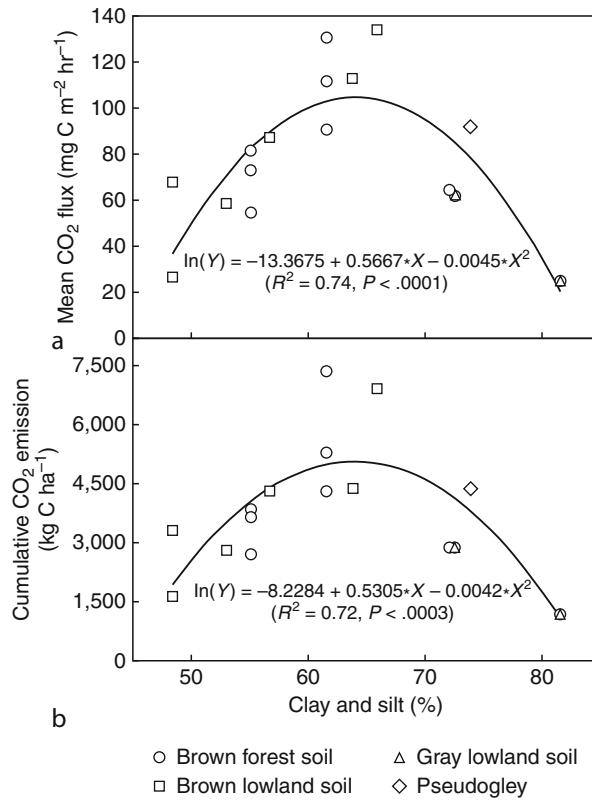

Greenhouse Gas Fluxes: Effects of Physical Conditions, Figure 3 Seasonal patterns in (a) local weather conditions, (b) soil temperature, (c) moisture, and (d) soil CO₂ fluxes derived from soil organic matter decomposition in the 11 upland crop fields with different types of soil in Mikasa city, central Hokkaido, Japan. WFPS, water-filled pore space. Error bars indicate the standard error ($n=3$). A is grassland soil, others are cropland bare soils (Mu et al., 2008).

This might be a reason for the increase in soil CO₂ flux at the lower contents of clay and silt. In contrast, it is well known that soil clay and silt can absorb organic matter and stop it from being decomposed by microorganisms (Hassink et al., 1993). When the content of clay and silt exceeds a certain level (in this case 63%), the organic matter available for the decomposition might become limited and leads to a decrease in soil CO₂ flux. As a consequence

of the negative relationship between soil CO₂ flux and higher fine particle content in soils, soil carbon content might be expected to increase with increasing fine particle content.

Indirect CO₂ emission through the subsurface drainage in an onion field of Gray Lowland soil in central Hokkaido, Japan, increased with increase of discharge rate during snowmelt season and rainfall events, and annual

Greenhouse Gas Fluxes: Effects of Physical Conditions,
Figure 4 Correlation of clay and silt content with (a) annual mean CO_2 flux and (b) cumulative CO_2 emission (Mu et al., 2008).

indirect CO_2 emission was $13.2 \text{ g C m}^{-2} \text{ year}^{-1}$, which corresponds to 2.5% of the direct CO_2 emission from soil to the atmosphere (Sawamoto et al., 2003). Indirect CO_2 emissions observed at different land uses of a well-permeable loamy soil varied with the land use. It was higher in a paddy rice field (33.4 and $36.7 \text{ g C m}^{-2} \text{ year}^{-1}$) than in upland fields (7.62 and $8.01 \text{ g C m}^{-2} \text{ year}^{-1}$ in a soybean field and 11.7 and $10.5 \text{ g C m}^{-2} \text{ year}^{-1}$ in a upland rice field) (Minamikawa et al., 2009). Flooding was the most influential factor determining the indirect emission in the paddy rice plots, because flooding substantially increased the drainage volume and thus increased the indirect emission.

CH_4

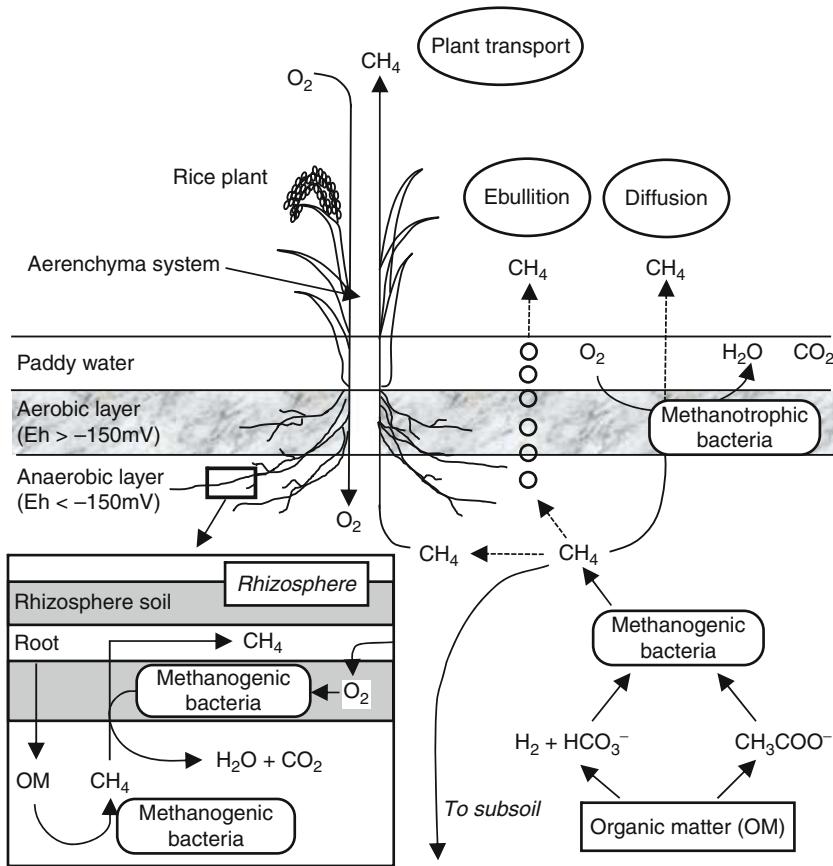

CH_4 is produced by methanogenic bacteria and consumed by methanotrophic bacteria (Mer and Roger, 2001). When the soil redox potential (Eh) is below -200 mV after flooding, methanogenic bacteria produce CH_4 using acetate and $\text{CO}_2 + \text{H}_2$, which are produced by fermenting and syntrophic bacteria under anaerobic condition (Yamane and Sato, 1964; Conrad, 1999). In general, contribution of acetate and $\text{CO}_2 + \text{H}_2$ to CH_4 production is 67% and 33%, respectively. However, excess CO_2 production occurs when some of the soil organic acids act

as electron acceptor (Yao and Conrad, 2000). Most methanogenic bacteria have their optimum pH at 7 (Goodwin and Zeikus, 1987). CH_4 production in soil is influenced by soil temperature. CH_4 production in various wetlands increases with increasing temperature from 2°C to 39°C (Bergman et al., 1998). CH_4 production is also influenced by the substrate. Significantly low CH_4 production was found in ombrotrophic bogs composed of acid and fibric peat in temperate region (Moore and Knowles, 1990).

Methanotrophic bacteria oxidized CH_4 in aerobic spot in soil (Hanson and Hanson, 1996). Measurements in flooded rice fields indicated that 80% of the methane produced was oxidized at the soil surface (Conrad and Rothfus, 1991). CH_4 uptake by aerobic soil decreases with an increase of water-filled pore space (WFPS) (Nesbit and Breitenbeck, 1992; Sitaula et al., 1995). Also, CH_4 uptake rate is decreased by the addition of NH_4^+ (Steudler et al., 1989) due to both a competitive inhibition of the CH_4 mono-oxygenase (MMO) enzyme as well as a noncompetitive (toxic) inhibition by hydroxylamine (NH_2OH) or nitrite (NO_2^-) produced by NH_4^+ oxidation (King and Schnell, 1994). Less temperature dependence of CH_4 consumption was found compared to that of CH_4 production in peat soil (Dunfield et al., 1993).

CH_4 fluxes between the soil and the atmosphere are determined by the balance of CH_4 production and CH_4 consumption in soil (Conrad, 1995) and strongly influenced by water table position (Moore and Knowles, 1990). Measurements in three ecosystems of forest, oil palm and sago plum in tropical peatland, Sarawak, Malaysia, showed that CH_4 was emitted at forest and sago plum with high groundwater table and it was taken up at oil palm with low groundwater table (Melling et al., 2005). CH_4 emission from the grassland of permafrost in Yakutsk was observed when the grassland was flooded with snow melting and permafrost thawing (Takakai et al., 2008b).

Figure 5 shows the processes involving CH_4 emission from rice paddy field. CH_4 is emitted mostly through rice aerenchyma and, at a lower level, through diffusion and ebullition after CH_4 was produced by methanogenic bacteria in anaerobic soil through organic matter decomposition, and CH_4 was consumed by methanotrophs in oxidized zones (rhizosphere, lower part of culms, soil–water interface, and submersion water) (Schütz et al., 1989). Once soil is flooded and water logged, anoxic and anaerobic conditions quickly develop in rice paddy soils due to decreasing aeration, resulting in the sequential utilization of a series of electron acceptors such as oxygen, NO_3^- , Mn(IV), Fe(III), and SO_4^{2-} . CH_4 production starts under highly reductive conditions after alternative electron acceptors have been depleted (Takai, 1970). CH_4 produced in rice paddy soils is emitted to the atmosphere by three pathways: molecular diffusion, ebullition as gas bubbles, and rice aerenchyma transport. Contributions from individual pathways vary over time and space, and rice aerenchyma is the major pathway accounting for more than 90% of the total CH_4 emitted from soils over the

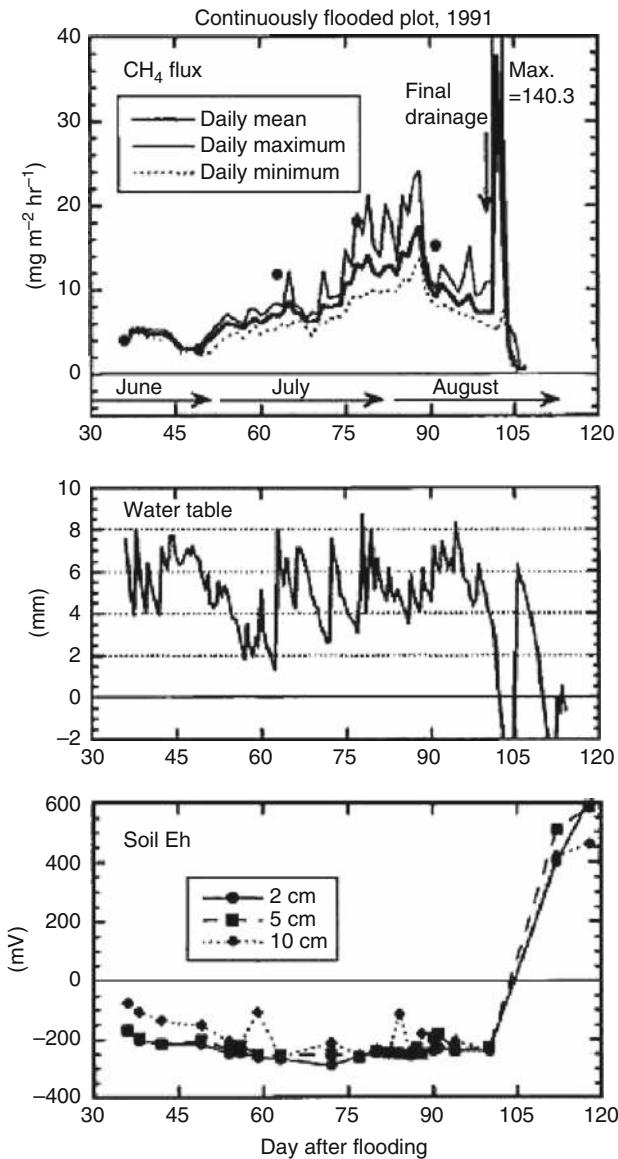

Greenhouse Gas Fluxes: Effects of Physical Conditions, Figure 5 Scheme of production, reoxidation, and emission of CH_4 in a paddy field. (Modified from Schütz et al., 1989 by Yagi, 1994.)

growing season due to inhibition of upward gas diffusion by flooding. A fraction of CH_4 produced in soils is oxidized in the rhizosphere, either aerobically by oxygen released from plant roots or anaerobically by other electron acceptors such as $\text{Fe}(\text{III})$ and SO_4^{2-} .

Figure 6 shows an example of CH_4 flux from the continuous flooded rice paddy field in Japan (Yagi et al., 1996). The CH_4 flux gradually increased until the beginning of August and decreased thereafter until the final drainage, with minimum flux occurring in the early morning and the maximum flux in the early afternoon. The mean CH_4 flux ranged from 2 to 16 $\text{mg CH}_4 \text{ m}^{-2} \text{ h}^{-1}$ during the period of flooding, but the CH_4 flush of 140 $\text{mg CH}_4 \text{ m}^{-2} \text{ h}^{-1}$ in maximum was observed at 8 h after water table dropped below the soil surface associated with final drainage for harvest. The CH_4 emission decreased below 1 $\text{mg CH}_4 \text{ m}^{-2} \text{ h}^{-1}$ at 3 days after the final drainage. Soil Eh at 2 and 5 cm depths were between -288 and -165 mV during the flooding period, indicating that the redox potential in the surface layer of the paddy soil was low enough for active methanogenesis. However, after final drainage, the soil Eh increased significantly. The large CH_4 flush after final drainage was possibly caused by a direct diffusion of CH_4 entrapped in soil through

macropores and cracks in soil after the removal of the water seal by final drainage, followed by a rapid decrease in the CH_4 emission. Total CH_4 emission during the cultivation period was 14.8 $\text{g CH}_4 \text{ m}^{-2}$, and the CH_4 flush after final drainage accounted for 7% of the total CH_4 emission.

CH_4 emissions from paddy fields are also influenced by agricultural management practices, mainly drainage practices and residue incorporation into soil. Total CH_4 emission during a rice cultivation period was reduced from 42% to 45% by two 3-day and 6-day short-term draining practices in the midseason of rice cultivation compared to the CH_4 emissions in a continuous flooded field (Yagi et al., 1996). In a Texas rice paddy field, a 6-day draining practice and three 2- to 3-day draining practices reduced total CH_4 emission by 48% and 88%, respectively (Sass et al., 1992). There was a significant correlation between rice straw carbon application rate (0–219 g C m^{-2}) and total CH_4 emission during cultivation period (4.04–40.8 g C m^{-2} per cultivation period) in continuously flooded paddy fields in central Hokkaido, Japan (Naser et al., 2007). Similar trends have also been observed in rice paddy fields in Italy (Schütz et al., 1989), Texas, USA (Sass et al., 1990), Japan (Yagi and Minami, 1990), the Philippines (Wassmann et al., 1996),

Greenhouse Gas Fluxes: Effects of Physical Conditions,
Figure 6 Seasonal variation of CH_4 flux, water table, and soil redox potential (Eh) at depths of 2, 5, and 10 cm measured at the continuous flooded plot in a Japanese rice paddy field. Solid dot indicates the flux data obtained by the manual measurements (Yagi et al., 1996).

and Louisiana, USA (Kongchum et al., 2006). However, CH_4 emission per unit dry matter of rice straw applied during the rice growing period season was significantly higher in the snowy temperate region than in other regions because of deep snow cover, low temperature, and unplowed conditions which might have retarded the decomposition of rice straw over the winter fallow (Naser et al., 2007).

Contribution of ebullition with falling atmospheric pressure has been less than 10% of total annual CH_4

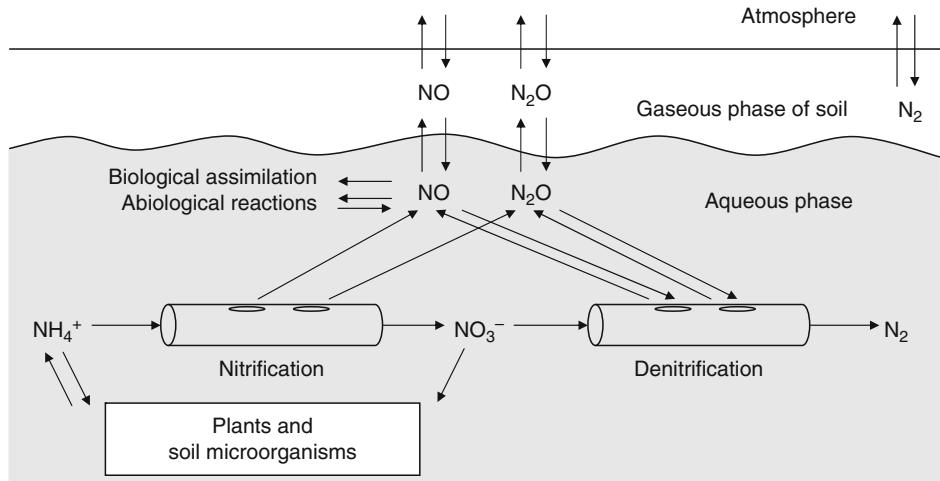

emission (Schütz et al., 1989), but abrupt CH_4 flux from a Japanese wetland, which can change by two orders of magnitude within several tens of minutes was recently found due to the release of free-phase CH_4 triggered by a drop in air pressure (Tokida et al., 2007).

Indirect CH_4 emission through subsurface drainage in an onion field of Gray Lowland soil in central Hokkaido, Japan, increased with increase of drainage rate during snowmelt season and rainfall events (Sawamoto et al., 2003). Annual indirect CH_4 emission was $11.5 \text{ mg C m}^{-2} \text{ year}^{-1}$, which corresponds to 58% of the direct CH_4 emission from soil to the atmosphere. This high contribution suggests subsoil CH_4 production. On the other hand, in a well-permeable loamy soil, indirect CH_4 emissions were considerably low even in paddy field (Minamikawa et al., 2009). The values were 2.20 and $0.964 \text{ mg C m}^{-2} \text{ year}^{-1}$ in a paddy rice field, 0.145 and $0.159 \text{ mg C m}^{-2} \text{ year}^{-1}$ in a soybean field, 0.238 and $1.28 \text{ mg C m}^{-2} \text{ year}^{-1}$ in an upland rice field, and the proportion of the indirect CH_4 emission to the direct CH_4 emission from the soil to the atmosphere was only 0.05% and 0.03% , $0.30\text{--}0.22\%$ and $0.46\text{--}2.64\%$, respectively.

N₂O

N_2O is mainly formed as a by-product of nitrification and as an intermediary of denitrification (Bremner, 1997). In aerobic condition, autotrophic nitrification is the main source of N_2O , but heterotrophic nitrification is generally regarded as a minor source of N_2O (Inubushi et al., 1996; Wrage et al., 2001). However, at low pH, N_2O is formed by chemodenitrification, which is the chemical decomposition of HNO_2 , following reaction with organic (e.g., amines) or inorganic (e.g., Fe^{2+}) compounds (van Cleempunt, 1998). At low O_2 concentration around 1 kPa dissolved O_2 , N_2O is produced through nitrifier-denitrification process, which is a biological process proceeding NH_4^+ oxidation using NO_2^- reduction simultaneously (Muller et al., 1995). Under anaerobic condition, N_2O is produced as an intermediary mainly through denitrification and anaerobic ammonium oxidation (Anammox). Heterotrophic denitrification, in which NO_3^- is converted to N_2 with organic matter decomposition, is the significant process for N_2O production. Autotrophic denitrification in which NO_3^- is converted to N_2 with the oxidation of sulfide (Cardoso et al., 2006) or ion oxidation (Till et al., 1998). Anammox is also a biological process in which NH_4^+ is converted to N_2 gas with NO_2^- reduction as the electron acceptor (Strous et al., 1997; Kampschreur et al., 2008).

During nitrification and denitrification which are the major processes producing N_2O in soil, NO is also produced. **Figure 7** shows a conceptual “hole-in-the-pipe” model, using the analogy of a leaky pipe, which suggests three levels regulating N_2O and NO emission from the soil to the atmosphere (Firestone and Davidson, 1989; Davidson and Verchot, 2000). At first level, there are

Greenhouse Gas Fluxes: Effects of Physical Conditions, Figure 7 Diagram of the hole-in-the-pipe conceptual model (Davidson et al., 2000).

factors controlling the rates of nitrification and denitrification (the “flow through the pipe”), which are the amounts of raw material (soil mineral N), soil temperature, and soil moisture; at second level, there are factors regulating the proportions of N₂O and NO productions in nitrification and denitrification (the “size of the holes in the pipe”), which are acidity, concentrations of NO₃⁻, and available carbon in soil; and at third level, there are factors controlling the consumption of N₂O and NO within the soil matrix, which are diffusion and mass flow in soil depending on soil texture, soil structure, air-filled pore space, temperature, and air pressure. Increase of soil moisture decreases air-filled pore space, which decreases gas diffusivity in soil, increasing the opportunities for further microbial reaction in soil.

Optimal moisture condition for organic matter decomposition (mineralization) and nitrification is around 60% of water-filled pore space (WFPS), while the optimal condition for denitrification is at saturation of the WFPS, with sufficient presence of nitrate and available organic carbon (Linn and Doran, 1984). The ratio of N₂O–N/NO–N ranges from 0.2 to 1 during nitrification and is approximately 100 during denitrification (Lipschultz et al., 1981).

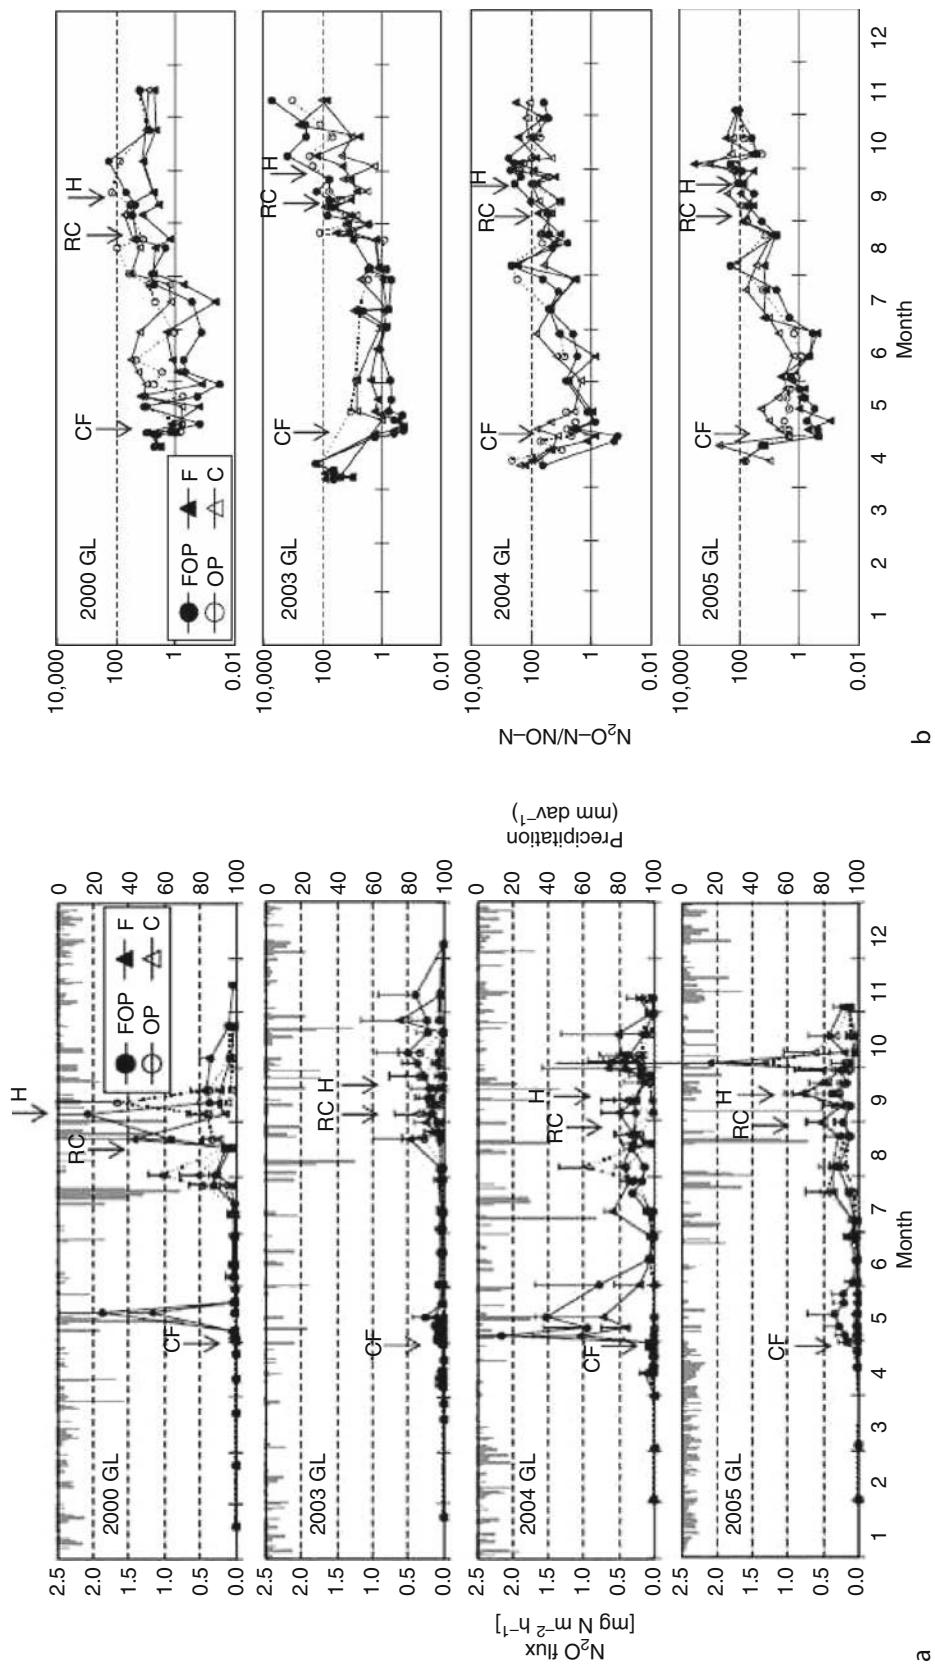

Figure 8 shows examples of the seasonal and yearly variation in N₂O fluxes (a) and N₂O–N/NO–N ratio (b) measured in an Onion field of Gray Lowland soil in central Hokkaido, Japan (Toma et al., 2007). The measurements were conducted in four treatments; chemical N fertilization and organic matter application, with plants (FOP); chemical N fertilization only, without plants (F); organic matter application only, with plants (OP); and control, no fertilization, or organic matter application, without plants (C). In chemical N fertilizer–applied treatments (FOP and F), there were two peaks in the periods from May to June and from late August to October (Figure 8a), and the N₂O–N/NO–N ratio decreased to less than 1 from May to June and increased to approximately

100 from September to October (Figure 8b). These indicate nitrification after spring N fertilization and denitrification with increase of rainfall. On the other hand, in no chemical N fertilizer–applied treatments (OP and C), only one peak was found in the period from August to October (Figure 8a), and the N₂O–N/NO–N remained above 1 from May to June (Figure 8b). There was a significant correlation between 2-month N₂O emission from May to June and mean temperature during these months ($n=8$, $r^2=0.53$, $P < .05$; Figure 9a). The N₂O production after spring fertilization resulting from the nitrification process may be affected by temperature. The 2-month N₂O emissions from September to October in the FOP and OP treatments, however, were positively correlated with the precipitation during these months ($n=8$, $r^2=0.39$, $P < .1$; Figure 9b).

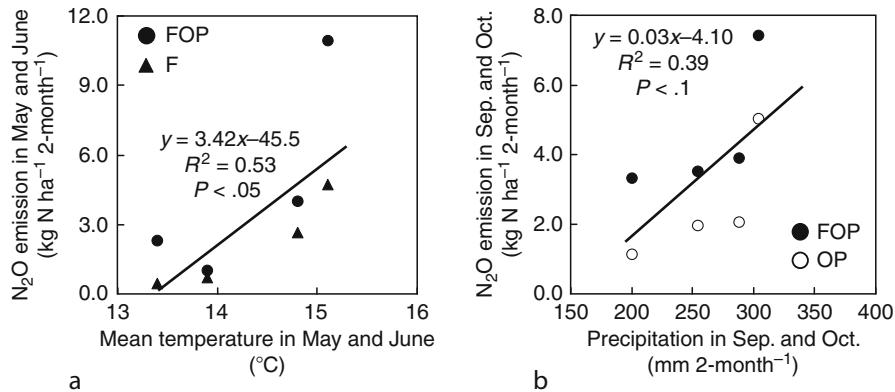

Figure 10 shows the relationship between total N application rate and N₂O emission from Japanese upland fields, with measurement period more than 90 days. N₂O emission increased with increase of N application rate and was generally higher in poorly drained soil than that in well-drained soil (Akiyama et al., 2006).

Huge amount of annual N₂O emission of 259 kg N ha⁻¹ year⁻¹ in maximum was found at the croplands of tropical peatland in Palangka Raya, central Kalimantan, Indonesia. During the rainy season, N₂O fluxes from the soil surface of the croplands increased with increase of NO₃⁻ content in the soil when water-filled pore space in the top soil exceeded 60–70% (Takakai et al., 2006). Acid-tolerant *Janthinobacterium* sp. as an N₂O emitter isolated from the cropland peat soil showed high ability of denitrification (NO₃⁻ reduction) but low activity of N₂O reductase (Hashidoko et al., 2008).

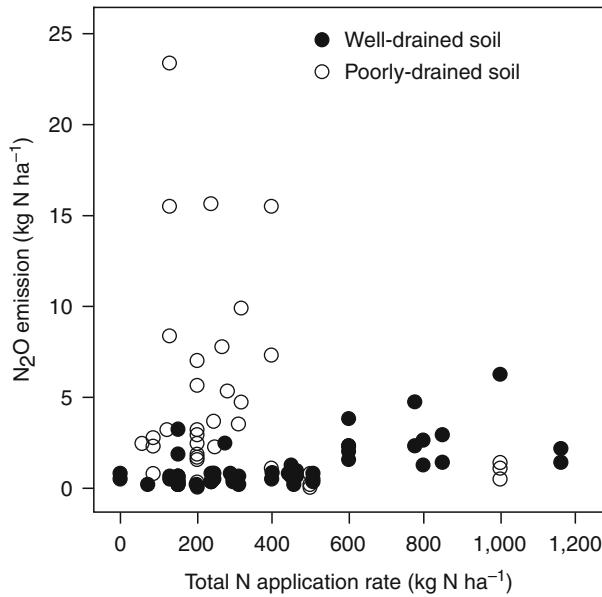

In temperate and boreal climates with periodic soil freezing and thawing, high N₂O emission from soil in the winter and early spring is usually observed (Christensen and Tiedje, 1990; Flessa et al., 1995).

Greenhouse Gas Fluxes: Effects of Physical Conditions. **Figure 8** Seasonal variation in N_2O flux (a) and $\text{N}_2\text{O-N}/\text{NO-N}$ ratio (b) at the onion fields of Gray Lowland soil (GL) in central Hokkaido, Japan (From Toma et al., 2007). The arrows indicate the time of chemical fertilizer application (CF), root cutting (RC), and harvest and residue application (H). The four treatments were: chemical nitrogen fertilization, with plants (FOP); chemical nitrogen fertilization only, without plants (F); organic matter application, with plants (OP); no fertilization or organic matter, and no plants (C). Error bars indicate standard deviation.

Greenhouse Gas Fluxes: Effects of Physical Conditions, Figure 9 Relationship between N_2O emission and mean temperature and precipitation at the onion field of Gray Lowland soil in central Hokkaido, Japan (From Toma et al., 2007). (a) Relationship between the 2-month N_2O emission and mean air temperature from May to June in 2000 and 2003–2005 in the chemical nitrogen fertilization and organic matter application, with plants (FOP) and the chemical nitrogen fertilization only, without plants (F) treatments; (b) relationship between the 2-month N_2O emission and precipitation from September to October in those years in the FOP and the organic matter application, with plants (OP) treatments.

Greenhouse Gas Fluxes: Effects of Physical Conditions, Figure 10 Relationship between total N input (kg N ha^{-1}) and N_2O emission (kg N ha^{-1}) from upland fields; measurement period more than 90 days (Akiyama et al., 2006).

Biological denitrification is the main process in N_2O production when soil is undergoing the process of freezing and thawing (Müller et al., 2002; Öquist et al., 2004). This might be caused by an imbalance of N_2O -producing and N_2O -reducing activities of denitrifying communities enhanced by the freeze–thaw cycles (Yanai et al., 2007).

Indirect N_2O emission through subsurface drainage in an Onion field of Gray Lowland soil in central Hokkaido, Japan, increased with increase of drainage rate during snowmelt season and rainfall events

(Sawamoto et al., 2003). Direct N_2O emission from the field increased significantly with increase in precipitation in the growing seasons (Kusa et al., 2002), and NO_3^- leaching increased with increase of precipitation in the same field (Hayashi and Hatano, 1999). Annual indirect N_2O emission was $74.7 \text{ mg N m}^{-2} \text{ year}^{-1}$ which corresponds to 4.6% of the direct N_2O emission from the soil to the atmosphere. The NO_3^- concentration in the drainage ranged from 8.5 to 25.5 mg N L^{-1} and the dissolved N_2O concentration ranged from 19.3 to $189 \mu\text{g N L}^{-1}$. But, there was no significant relationship between $\text{N}_2\text{O}-\text{N}$ and NO_3^--N concentration. The ratio of $\text{N}_2\text{O}-\text{N}/\text{NO}_3^--\text{N}$ (kg kg^{-1}) ranged from 0.00076 to 0.0105 (Sawamoto et al., 2003). The ratio has been estimated to be 0.0024 using 15 data sets of N_2O and NO_3^- concentrations in drainage water (Sawamoto et al., 2005). In a well-permeable loamy soil in Tsukuba, Japan, considerably different tendency in indirect N_2O emission was found.

Summary

Soil is the major source of CO_2 , CH_4 , and N_2O emissions into the atmosphere. Those gases are produced and consumed in soil by mainly microbial activities which are strongly influenced by soil environmental factors. This paper reviewed the relationship between the fluxes of those gases and soil environmental factors.

Soil temperature is the most important soil environmental factor for CO_2 flux from soil. However, significant drought declined soil CO_2 flux rapidly and heavy rain event induced episodic CO_2 flux from soil. Different soils within a watershed have different relationships between CO_2 flux and soil temperature and soil moisture. However, soil texture significantly influenced CO_2 emission from the soil during a growing season, and there was a critical clay and silt content for the CO_2 emission.

Soil moisture is the most important soil environmental factor for CH₄ flux from soil, because CH₄ is produced by methanogenic bacteria in anaerobic soil and consumed by methanotrophic bacteria in aerobic soil. In paddy field, rice aerenchyma is the major pathway during the growing season due to inhibition of upward gas diffusion by flooding. Final drainage at the end of growing season in paddy field often induced large CH₄ flush due to a direct diffusion of CH₄ entrapped in soil after the removal of the water seal by drainage. Short-term drainage practice during the growing season in paddy field reduced the CH₄ emission, but the increase of rice straw incorporation significantly increased CH₄ emissions.

Soil temperature and soil moisture are significant soil environmental factors for N₂O flux from soil, because N₂O is mainly formed as a by-product of nitrification and as an intermediary of denitrification. Long-term observation in an upland field indicated that N₂O emission induced by nitrification increases by the increase of soil temperature, and N₂O emission induced by denitrification increases by the increase of precipitation. Very high N₂O flux was found at the croplands of tropical peatland in Indonesia when water-filled pore space in the top soil exceeded 60–70%. This was ascribed to acid-tolerant bacterium with low activity of N₂O reductase. On the other hand, soil freezing and thawing in temperate and boreal climates enhances high N₂O flux from soil in the winter and early spring.

GREENHOUSE GASES SINK IN SOILS

Teresa Włodarczyk

Synonyms

Consumption; Uptake

Definition

Greenhouse gases sink in soils is defined as reducing their amount in the atmosphere and in the soils atmosphere or solution due to some biological processes. Carbon dioxide (CO₂) is naturally sequestered (sunk) in plants, soils, and in ocean life. Methane is oxidized by methane-oxidizing microorganisms (methanotrophs). A complete denitrification, at which N₂O is reduced to N₂, is assumed to be the main elimination or sink process of N₂O in the soils.

Introduction

The main greenhouse gases in the Earth's atmosphere are water vapor, carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O), which enhances the greenhouse effect. Since around the time of the Industrial Revolution in Western countries, concentrations of carbon dioxide, methane, and nitrous oxide have increased. Mitigation of greenhouse gases emission leads to minimizing the effects

of global warming. Very important is stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system.

Carbon sink

A carbon sink is a natural or manmade reservoir that accumulates and stores some carbon-containing chemical compound for an indefinite period. The main natural sinks are absorption of carbon dioxide by the oceans and photosynthesis by plants and algae. The main manmade sinks are landfills and carbon capture and storage proposals. Carbon dioxide sequestration (or carbon sequestration) is the term given for locking up CO₂ somewhere other than the atmosphere. In biological sequestration, carbon is naturally sequestered in plants, soils, and in ocean life. Soils represent a short to long-term carbon storage medium, and contain more carbon than all terrestrial vegetation and the atmosphere combined and are a major reservoir of carbon and an important sink. Because of the relatively long period of time that carbon spends within the soil and is thereby withheld from the atmosphere, it is often referred to as being sequestered (Swift, 2001). Plant litter and other biomass are accumulated as organic matter in soils especially in litter and soils of colder regions such as the boreal forests. The carbon sequestration potential of soils (by increasing soil organic matter) is substantial. Improving the humus levels of these soils would both improve soil quality and increase the amount of carbon sequestered in these soils. Decomposition rates can be slowed by reducing tillage and by growing crops with low residue quality that is more difficult for microbes to decompose. No tillage implants seeds without turning the soils reduce the loss of soil organic matter. Natural soils retain carbon in stable micro aggregates for up to hundreds of years unless environmental conditions are changed and the stable soil structure is damaged (Luo and Zhou, 2006). The C sequestration potential of a soil depends on the vegetation it supports, its mineralogical composition, the depth of the soil, soil drainage, the availability of water and air, the temperature of the soil environment, and the chemical characteristics of the soil organic matter and its ability to resist microbial decomposition (Swift, 2001). Conversion of the soil to pastureland, particularly with good management of grazing, can sequester more carbon. Thus, soil restoration and woodland regeneration, no-till farming, cover crops, nutrient management, manuring and sludge application, improved grazing, water conservation and harvesting, efficient irrigation, agroforestry practices, growing energy crops on spare lands, and pyrolyzing the biomass to biochar are recommended management practices to increase the soil carbon sequestration (Lal, 2004). The chemosynthetic autotrophs (chemolithotrophs) take carbon dioxide as their carbon source for growth and derive their energy from oxidation of inorganic materials like iron, sulfur, ammonia, and nitrite. *Grasslands* contribute

huge quantities of soil organic matter over time, mostly in the form of roots, and much of this organic matter can remain unoxidized for long periods. They also deposit carbon directly to the soil in the form of char that does not significantly degrade back to carbon dioxide. No-till pastureland, particularly with good management of grazing, can sequester even more carbon in the soil. The wetlands cover only 3% of land area but store nearly 37% of global terrestrial carbon. As a consequence of anoxic conditions, the rate of organic matter decomposition is slow and carbon tends to accumulate in wetland soils. Wetland soil carbon storage is sensitive to climatic changes, water table fluctuations, and human disturbances. Peat lands cover about 75% of the wetlands by area and are particularly important for storage of soil carbon (Luo and Zhou, 2006). Organic matter in peat bogs undergoes slow anaerobic decomposition below the surface and fixes more carbon from the atmosphere than is released. Peat bogs absorb approximately one-quarter of the carbon stored in land plants and soils. Forests are carbon stores, and they are carbon dioxide sinks when they are increasing in density or area. As part of photosynthesis, trees absorb carbon dioxide from the atmosphere and store it as carbon. Rapidly growing trees absorb a larger amount of carbon dioxide. The sink effect exists only when they grow in size. Mature trees grow less rapidly and thus have a lower intake of carbon dioxide. One ton of dry wood is equivalent to 1.8 tons of carbon dioxide. Upon harvesting, wood can be incorporated into construction or a range of other durable products, thus sequestering its carbon over years or even centuries. Management measures to improve carbon storage in forest include prolonging rotation, changing tree species, continuous cover forestry, fire control, combined water storage with peat swamp afforestation, fertilization, and reducing the rate of deforestation. (Luo and Zhou, 2006).

CH₄ sink

The atmospheric concentration of CH₄ has increased and more than doubled during the past 200 years (Mancinelli, 1995). Aerobic consumption of CH₄ is common in soils and aquatic environments. There are only two important sinks for atmospheric CH₄. The major sink is reaction of CH₄ with hydroxyl radical. Additionally, CH₄ is consumed by aerobic microbial activity in soils. The soil CH₄ sink is sensitive to nitrogen fertilization. Methanotrophs play a major role in the reduction of the release of methane into the atmosphere from environments such as rice paddies, landfills, bogs, and swamps where methane production is relatively high and from aquatic systems, soils, forest, tundra, and agricultural soils.

Aerobic methane oxidation

Methane-oxidizing microorganisms (methanotrophs) are found in variety of soil and aquatic environments and play an important role in regulating atmospheric methane

content. Oxidation of methane to carbon dioxide in soils occurs primarily as part of aerobic metabolism in methanotrophic bacteria. Methanotrophs are able to metabolize methane as their only source of carbon and energy mostly in soils, where methane is produced. Methanotrophs are often concentrated in a narrow band where methane diffusing away from its source (an anaerobic zone) meets oxygen from the air. Although nearly all methane oxidizers are obligate aerobes, they are microaerophilic, preferring oxygen level lower than atmospheric levels. The net reaction of methane oxidation under aerobic conditions can be described as CH₄ + O₂ → CO₂ + H₂O (Mancinelli, 1995).

Methane is oxidized in soil by methanotrophs with the use of a chain of enzymes such as methanol, formaldehyde, formate, and nonspecific aldehyde dehydrogenases (Large, 1983). It was found that during incubation of a Mollic Gleysol with methane in the headspace dehydrogenase activity of the soil significantly increased, compared to the control value, after 2 days to its maximum and decreased slowly during the next days (Brzezińska et al., 1998).

Methanotrophic bacteria possess both dissimilatory and assimilatory pathways of methane oxidation. In dissimilatory pathways, methane is oxidized completely to carbon dioxide, thereby producing cellular energy, and none of the carbon becomes cellular material, or biomass. In assimilatory pathways, methane is oxidized and converted to cellular biomass. In both pathways, methane is first oxidized to methanol by methane monooxygenase (MMO) using molecular oxygen, which is then oxidized to formaldehyde. The formaldehyde can be used as reducing power in the electron transport chain, oxidized to formate, or assimilated by the cell via the ribulose monophosphate pathway and/or the serine pathway. The cell then either oxidized the formate to carbon dioxide or uses it as reducing power to drive the electron-transport chain. Several physicochemical factors influence rates of methane oxidation in soil, including soil diffusivity, water potential, and levels of oxygen, methane, ammonium, nitrate, nitrite, and copper. Most of these factors exert influence through interactions with MMO (Mancinelli, 1995). In general, methanotrophic activity increased with increasing CH₄ addition in the different range of initial methane content. Soils are characterized by different requirements with respect to threshold methane concentration expressed as high- or low-affinity oxidation. The differences in methanotrophic activity mainly depend on differences in organic matter content and availability and methanotrophs existing in the soils (Włodarczyk et al., 2004).

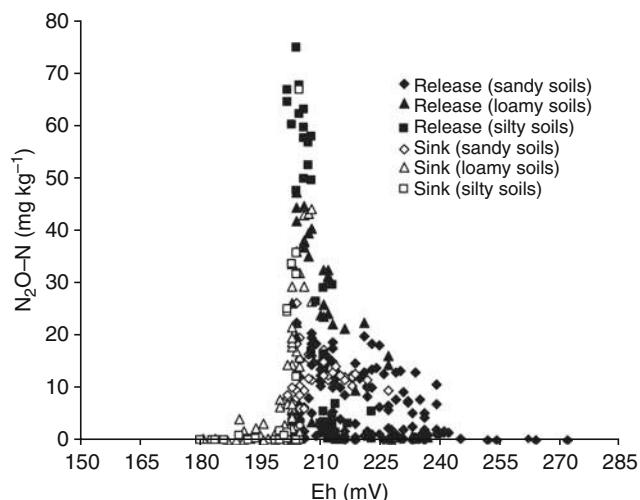

Anaerobic oxidation of methane

Anaerobic oxidation of methane (AOM) is a microbial process occurring mainly in anoxic marine sediments and reducing the emission of methane from the ocean into the atmosphere. During AOM, methane is oxidized with sulfate as the terminal electron acceptor: CH₄ + SO₄²⁻ → HCO₃⁻ + HS- + H₂O. AOM is mediated by

a syntrophic consortium of methanotrophic archaea and sulfate-reducing bacteria. Recent investigations have shown that some consortia of archaea and bacteria are also able to oxidize methane with nitrate instead of sulfate (Raghoebarsing et al., 2006). But recent findings suggest that this nitrate-reducing process coupled to methane oxidation can also be performed by a single bacterium without the need for an archaeal partner.

N₂O sink

Natural production and emission to the atmosphere of nitrous oxide is from microbial activity in soils and in the aquatic systems. N₂O is greenhouse gas that increased by 16% over the last 200 years. N₂O uptake has been observed in soils, aquatic systems, and riparian zones. A complete denitrification, at which N₂O is reduced to N₂, is assumed to be the main elimination or sink process of N₂O in the soils, beside dissolution in water. However, other types of N₂O sink were observed, for example, N₂O fixation with following transforming to NH₃. Only 1% of the microbes in soils have the ability to produce the enzyme N₂O reductase that reduces N₂O to N₂. The production of the enzyme is controlled by environmental influences like oxygen concentration and the concentration of the denitrification intermediate products. The potential of this process depends highly on the N₂O and O₂ concentrations, and aggregate sizes in the soil (Vieten, 2008). Next factors affecting N₂O uptake by soils are nitrogen availability, soil wetness, temperature, soil drainage conditions, and soil pH. Maximum N₂O reduction was measured at pH 6 and 7 (Smith et al., 1983). Agricultural soils are usually fertilized and therefore not likely to be sinks for N₂O, some studies report on N₂O uptake in fertilized fields; several studies report on considerable N₂O uptake in forest soils, which may potentially be important sinks for atmospheric N₂O; riparian zones depending on local conditions may be potential sinks for N₂O; N₂O uptake may occur in the open ocean (Kroeze et al., 2007). Because the N₂O emission at the soil surface is the result of production and consumption processes, some research has concentrated on net N₂O production. However, there are some reports of net negative fluxes of N₂O (i.e., fluxes from the atmosphere to the soil). Low mineral N and large moisture contents have sometimes been found to favor N₂O consumption. Denitrification is the responsible process, reducing N₂O to N₂. However, it has also been reported that nitrifiers consume N₂O in nitrifier denitrification. The wide range of conditions found to allow N₂O consumption, ranging from low to high temperatures, wet to dry soils, and fertilized to unfertilized plots. Generally, conditions interfering with N₂O diffusion in the soil seem to enhance N₂O consumption. Soil sink could help account for the current imbalance in estimated global budgets of N₂O (Chapuis-Lardy et al., 2007). N₂O emission and consumption is regulated within a narrow redox potential range +120 to +250 mV (Yu et al., 2001) and +200 to 230 mV (Włodarczyk et al., 2005).

Greenhouse Gases Sink in Soils, Figure 1 Relationship between the N₂O-N content and the redox potential of the releasing and consumption phases. (From Włodarczyk et al., 2005.)

et al., 2005) due to the balance of N₂O production and its further reduction to N₂. The interval of redox potentials allowing the existence of gaseous nitrous oxide in the equilibrium or “quasi-equilibrium” with the soil is very narrow and does not exceed 50 mV (Figure 1). Soils texture and particle size distribution significantly differentiated soil ability to N₂O consumption. Nitrous oxide sink showed a significant positive correlation with the fraction 0.05–0.002 mm and a negative one with the fractions >0.05 mm (Włodarczyk et al., 2005).

Summary

Sink of the main greenhouse gases in the Earth’s atmosphere such as CO₂, CH₄ and N₂O were viewed. Mitigation of greenhouse gases emission leads to minimizing the effects of global warming. The main natural carbon sinks are absorption of carbon dioxide by the oceans and photosynthesis by plants and algae. The main manmade sinks are landfills and carbon capture and storage proposals. Methanotrophs play a major role in the reduction of the release of methane into the atmosphere from environments such as rice paddies, landfills, bogs, and swamps where methane production is relatively high. Anaerobic oxidation of methane is a microbial process reducing the emission of methane from the ocean into the atmosphere. A complete denitrification, at which N₂O is reduced to N₂, is assumed to be the main elimination or sink process of N₂O in the soils, besides dissolution in water. Forest soils and riparian zones may potentially be important sinks for atmospheric N₂O depending on local conditions.

GROUND-PENETRATING RADAR, SOIL EXPLORATION

Jim Doolittle
USDA-NRCS, National Soil Survey Center, Newtown Square, PA, USA

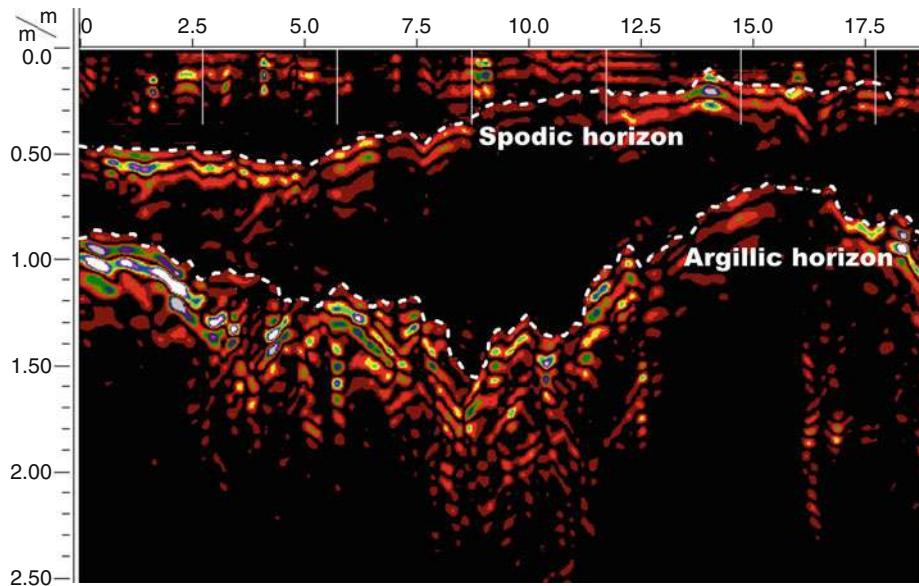

Ground-penetrating radar (GPR) is a noninvasive, high-resolution geophysical method used in soil exploration. Ground-penetrating radars transmit short pulses of high- to ultra-high frequency (center frequencies from 12.5 MHz to 2.6 GHz) electromagnetic energy into the ground to detect subsurface interfaces. A time-scaled system, GPR measures the time that it takes pulses of

electromagnetic energy to travel from an antenna to a subsurface interface and back. Interfaces often correspond to major soil, stratigraphic, and lithologic layers or features. Whenever a pulse contacts an interface separating layers with different relative dielectric permittivity (ϵ_r), a portion of the energy is reflected back to a receiving antenna. The more abrupt and contrasting the permittivity on opposing sides of an interface, the greater the amount of energy that is reflected back to the antenna and the greater the amplitude of the recorded signal. To convert the travel time into a depth scale, the velocity of pulse propagation or the depth to a reflector must be known.

A typical GPR system consists of a radar control unit with antenna (Figure 1). The control unit serves as a user interface and consists of a colored screen, microprocessor, and mass storage device. Choice of antenna is depth, target, and soil dependent. Higher frequency antennas provide greater resolution but do not penetrate as deeply as lower frequency antennas. Soils having high electrical

Ground-Penetrating Radar, Soil Exploration, Figure 1 Modern GPR systems are lightweight, highly mobile, and integrated with global positioning systems (GPS).

Ground-Penetrating Radar, Soil Exploration, Figure 2 Highlighted on this radar record of Pomona soils (sandy, siliceous, hyperthermic Ultic Alaquods) are the upper boundaries of the spodic and argillic horizons.

conductivity rapidly attenuate radar energy, restrict penetration depths, and severely limit the effectiveness of GPR (Daniels, 2004; Jol, 2009). The electrical conductivity of soils increases with increasing water, soluble salt, and/or clay contents.

Ground-penetrating radar provides spatially continuous records of the subsurface. Figure 2 is a representative radar record from an area of Pomona soils, which form in sandy over loamy marine sediments in Florida (USA). In Figure 2, the continuity and depths to both the spodic and argillic horizons are highlighted with segmented lines.

In soil exploration, GPR is principally used to document the presence, depth, lateral extent, and continuity of subsurface soil horizons, stratigraphic layers, and lithologic units (Collins, 2008; Daniels, 2004; Jol, 2009). It has also been used to: identify preferential flow pathways, animal burrows, and buried drainage tiles; assess root biomass and hydrocarbons in soils; study soil moisture dynamics, water table depths, and the movements of agrochemicals; predict groundwater flow patterns; and characterize near-surface hydrologic conditions.

Synonyms

Hard-layer soils; Management of hard-layered soils

Definition

Hardpan soil. A soil that has a layer whose physical characteristics limit root penetration and restrict water movement.

Penetration resistance. The penetration resistance (or soil strength) is usually measured as the force exerted on

*All rights reserved

a standardized implement (penetrometer) as it is pushed into the soil divided by the cross-sectional area of its tip.

Introduction

Hardpans, hard layers, or compacted horizons, either surface or subsurface, are widespread problems that limit crop production. Hard layers can be caused by traffic or soil genetic properties that result in horizons with high density or cemented soil particles (Hamza and Anderson, 2005); these horizons have elevated penetration resistances that limit root growth and reduce water and airflow. Limited root growth leads to limited crop water and nutrient uptake. Reduced water flow prevents rainfall or irrigation water from filtering into the soil profile where it can be stored for plant growth. Reduced airflow limits oxygen and carbon dioxide exchange with the atmosphere; exchange is needed for plant and microorganism respiration. These limitations reduce crop productivity.

Improving the hard layer consists of reducing its hardness or penetration resistance. When we reduce the layer's hardness, we assume that it and/or the layers below it have properties conducive to plant growth. As the hard layer softens, water and air are able to move into and/or through it and into the layers below, improving conditions for root growth and with its productivity. There are several ways to improve hard layers; the most common is tillage; but other solutions exist in the forms of water/crop management and soil amendments.

Tillage

Tillage has been and is the common method used to remediate hard-layer problems; it physically breaks up hard layers. Tillage by hand involves digging with a spade, broad fork, or U-fork. In large-scale mechanical agriculture, tillage involves using a tractor to pull any of a number of tines or shanks through the soil. In the mechanical method, shallow hard layers (<5 cm) can be

broken up with tines or cultivators that disrupt the surface soil. Deeper hard layers (>15 cm) can be broken up with shanks. Shanks are sized or adjusted so they are pulled through the soil at the depth of the hard layer shattering it and decreasing its resistance to root growth. Different shank designs that are manufactured by various tillage companies produce different results or work with different efficiencies depending on the type of hard layer and the type of soil. Consider the example seen in [Figure 1](#) where the hard layer was located in loamy sand between 20-cm and 40-cm depths. Tillage in this example was performed with an older 5-cm thick shank that produced wider zones of disruption and used more energy than narrower shanks. Also seen in [Figure 1](#), the process that reduced soil penetration resistance under the row increased it under the trafficked mid row because of the tractor weight.

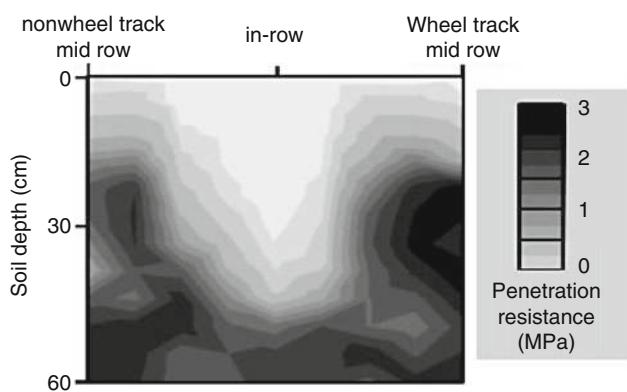

To meet conservation goals, deep tillage such as that shown in [Figure 1](#) can be performed in such a way that it does not invert soil; equipment companies have developed shanks that break up soil with minimal surface disruption. Non-inversion tillage leaves most crop residue on the soil surface protecting it from erosion, surface crusting/compaction, and excessive evaporation ([Raper, 2007](#)). Though early studies with non-inversion and reduced tillage demonstrated little or no yield advantage, improvements in planters, residue management, and soil/crop management practices increased the success of conservation systems by optimizing factors that affected seed germination and vigor.

The problem with tillage is that the reduction of penetration resistance is temporary. For some soils, temporary means a few to several years. For others, it can mean only a few months ([Raper et al., 2005a](#)). Most often it is effective for only months. In either case, over time, soil reconsolidates leading to reduced water/airflow, reduced root growth, and lower crop yields ([Håkansson and Lipiec, 2000](#)). Even if the reconsolidated soil's penetration resistance is not as high as it was originally, it can be high enough to limit growth. As a result, tillage has to be

performed repeatedly at prescribed frequencies, often seasonally or annually. Frequent tillage can be expensive because it often requires large tractors (14–20 kg weight per shank), 20–40 min ha^{-1} of labor, and 20–25 L ha^{-1} of fuel. Eventually, the producer has to make the decision whether or not to till based on the value of increased yield by tillage vs. the cost of tillage ([Bolliger et al., 2006](#)).

In an effort to save time, fuel, and production costs, deep tillage studies have included soil disruption on a multiple-year rotation. In many cases, not tilling every year reduces yield to levels that may (or may not) be acceptable given the increase in fuel costs. Additionally, annual deep tillage may not be needed for some crops, such as cotton, to maintain yields. Deep tilling every 2–3 years may be just as effective as deep tilling annually ([Busscher et al., 2010](#)). This will depend on the crop and variety grown, amount of re-compaction, and other crop management techniques such as row width and traffic/compaction patterns.

Another effort to save fuel and production costs involves varying the tillage depth. Deep tillage is often performed with implements set to a fixed depth. But depth to the compacted layer varies throughout a field. What depth should the implement have? On the one hand, if tillage depth is based on the deeper zones of the compacted layer, the implement disrupts too much soil where the compacted layer is shallow; this wastes fuel. On the other hand, if tillage depth is based on the shallower zones, the implement will not disrupt the whole compacted layer, leaving hard zones that limit root growth. Technologies are now available that allow tillage to vary with the depth of the compacted layer; this can be accomplished by mapping the hard layer of a field or placing sensors on the shanks. Shanks are then raised and lowered as needed. This action can save energy without sacrificing crop yields. Research has shown that this “site-specific tillage” produced yields equivalent to those of uniform deep tillage while reducing tractor draft forces, drawbar power, and fuel used ([Raper et al., 2005b](#)).

Hardpan Soils: Management, Figure 1 Soil penetration resistance for a loamy sand that has a hard layer at 20- to 40-cm depths. The soil was tilled to a depth of about 45 cm with shank that did not invert the soil.

Other solutions

Soil Organic Matter: For the past few decades, soil scientists and producers have been trying to increase organic matter levels in soils ([Carter, 2002](#)). This improves fertility, decreases strength in hard layers (especially those close to the surface), and increases yield ([Soane, 1990](#)). But with the increase in fuel prices comes the need for organic matter/residue in the form of cellulose. The same organic matter that scientists and producers were trying to increase in soils may be removed to produce ethanol. Both increased organic matter and removed cellulose might be attainable; but only after some research. Research on organic matter removal had started during the 1970s fuel crisis; but because the crisis did not continue, the research priority decreased as funding ceased. Results from the 1970s showed that some residue could be removed provided that nutrients were replaced with fertilizers. The problem with this finding is that fertilizer

production requires large amounts of energy. The previously unfinished research has resumed asking questions about the sustainability, economic efficiency, energy efficiency of residue removal, and the effect of the removal on soil properties such as penetration resistance.

To ameliorate hard layers, additions of organic matter need not come from crop residues. Another way to add it, especially to subsurface hard layers, is through root growth (Yunusa and Newton, 2003). In this method, cover crops are grown between growing seasons aimed at penetrating the hard layers with their roots. Cover crop roots are able to penetrate soil where production crops cannot either because conditions between growing seasons are different, for example, cold and wet, or because the cover crop has hearty roots but it is not an economic crop. For example, large rooted crops such as radish are grown to add both large holes and large amounts of organic matter to the hard layer. In another method, rye cover crop roots penetrate compacted layers softened because they are wet in winter; rye roots leave holes behind for summer row crop roots to follow. Success of these methods depends on whether the roots can grow deep enough to affect the hard layer and whether or not the holes left by the roots collapse.

Other management: Another way to soften hard layers that met with some success was to irrigate the soil with drip tubes buried just above the hard layer. In this method, irrigation water keeps the hard layer soft while supplying the crop's needs. However, tubes buried above a hard layer require careful management to avoid overwatering or under watering. Overwatering prevents roots from penetrating a flooded layer while under watering does not loosen the hard layer enough. It is likely that both types of irrigation will occur simultaneously between and at the buried tubes or between and at irrigation ports or emitters along the tubes. Water management needs to find a proper irrigation schedule that can satisfy all needs for each soil. Because water is not at the soil surface, this type of irrigation reduces evaporation saving water but a relatively dry surface can reduce germination and stand establishment during years with early dry seasons.

A long-term solution that reduces both compaction and energy demand is to add amendments to soil. The amendment chosen will have to reduce compaction much like the organic matter does and it should be effective for several years because it will be expensive to incorporate it into the soil. Potential amendments include polyacrylamide (PAM) and biochar. PAM was tried in the 1950s. Older formulations were used to stabilize aggregates in the surface 30-cm to 40-cm depths. Hundreds of kilograms of PAM per hectare were needed, limiting PAM-use to high value crops and nurseries. Since the 1950s, polymer formulations and purity have improved, making them more effective at lower concentrations. In the 1990s, environmentally safe PAM was found to be an effective erosion-preventing and infiltration-enhancing polymer when applied at 1–10 mg L⁻¹ in furrow irrigation water. This can affect the surfaces of irrigated soils; but if the hard layer is deep

in the profile, the amount of PAM and its mixing into the soil will cost several hundred euros per hectare. Given the high cost of fuel, this cost might be feasible if the PAM could last multiple years. Current estimates have the PAM breaking down at a rate of 10% per year.

Another amendment that has attracted attention in the past few years is biochar. Biochar captured the attention of the agricultural community as a result of archeological/agricultural findings of charcoal-amended soils in the Amazon and other historically old areas. Charcoal- or biochar-amended soils were found to have supported larger populations 500–1,000 years ago than previously estimated and today they are still more productive than expected. If biochar can be effective over time and if it improves productivity, it could be economically feasible to use it as a long-term soil amendment to eliminate or reduce hard-layer tillage (Busscher et al., 2010). More research needs to be performed before making a final decision; but preliminary results are favorable. Biochars vary based on their source material and production technique. Current work is underway to match biochar properties to the needs of the soil and its hard layer; then their effectiveness needs to be assessed.

Effects on individuals

Whether or not you work in tillage management or agrophysics, they affect you because of their impact on food, fiber, and energy production. As populations increase and as we make more demands on our resources, we will require tillage management and other areas of agriculture to produce more food for more people with a limited and dwindling soil base (Small, 2009). We can all become involved by being educated and active in conservation efforts to improve the lot of our soils, our environment, and our fellow men.

Cohesive soils or soils with a cohesive character

Definition

Hardsetting soils or soils exhibiting hardsetting behavior. Soils that have horizons that, when dried, harden significantly, constituting a mass without structure (apedal); this soil tilth is more difficult or even impossible. This impediment can be avoided by humidifying the soils (Mullins et al., 1990; Mullins, 1999).

Cohesive soils or soils with cohesive character. Soils with dense pedogenic subsurface horizons, which are very resistant to penetration of the knife or hammer and are very hard to extremely hard when dry, becoming friable or firm when moist. In natural conditions, they have

a weak structural organization, generally appearing solid or with some tendency to form blocks (Fabiola et al., 2003; Lima et al., 2006).

Introduction

Hardsetting is a phenomenon that occurs in many soils around the world in arid tropical, semiarid, and Mediterranean regions (Mullins, 1999) and covers more than 110 million ha of areas of agricultural exploitation. The term hardsetting was introduced by Northcote (1960) in binary textured soils of Western Australia, and was subsequently recognized in Africa, Asia, and South America (Mullins et al., 1987; Mullins et al., 1990; Chartres et al., 1990; Fabiola et al., 2003; Lima et al., 2006).

The Australians were pioneers in identifying and mapping hardsetting soils, as well as in incorporating these characteristics into a soil taxonomic classification system (Harper and Gilkes, 1994; Isbell, 1996). Nevertheless, the ambiguous nature of hardsetting behavior has limited the use of the term in other classification systems outside Australia and Brazil (Harper and Gilkes, 1994).

Many agricultural problems are associated with hardsetting soils, including a more restricted period for soil tillage and an increase in physical impediments to adequate root development (Mullins et al., 1987; Mullins et al., 1990). Hardsetting is normally associated with processes of soil degradation such as erosion, compaction, crusting, and acidification of the soil (Mullins, 1997). In these soils, the agricultural production is frequently frustrating due to low production and a high cost/benefit ratio.

Characteristics of hardsetting soils

Hardsetting soils present a pedogenetic densification in the surface horizons (A and AB) and the subsurface horizons (BA, B, E, EB, BE) (Mullins et al., 1990; Chartres et al., 1990; Fabiola et al., 2003). When dry, they present a lack of visible structural organization (they are massive), elevated resistance to penetration by a knife or auger, and a hard to very hard (at times extremely hard) consistency. The humid soil consistency varies from friable to firm, and a dry sample, when immersed in water, disintegrates rapidly (Mullins, 1997).

Hardsetting characteristics normally occur in deep soils, with a loamy-sandy-clay texture, clay-like or very clay-like, in a plain to gently undulating relief. Hardsetting horizons possess soil bulk density higher than the underlying horizons and tensile strength values ≥ 0.09 MPa (Fabiola et al., 2003). From a chemical point of view, they present a low base saturation ($V < 50\%$), organic material content $< 2.0\%$, Fe_2O_3 content (by H_2SO_4) < 8 g kg^{-1} , and an illitic or kaolinitic mineralogy (Mullins et al., 1990; Giarola et al., 2001).

It is important to distinguish between hardsetting and compacted soils. Soil compaction results from repeated or long-term movement of agricultural machinery and stock compacting the soil profile when it is moist, often remaining hard when wet. In many cases, this compaction

layer occurs at depth. Hardsetting affects the A1 horizon (Mullins et al., 1987), but the soil softens when moist.

The hardsetting horizons should not be confused with fragipan, which also presents high levels of cohesion, but presents diverse pedogenetics (chemical grouting), occurring at greater depths; fragipan has different implications in relation to soil management (Chartres et al., 1990).

Hardsetting processes

The hardsetting character can be associated with the following processes: (1) the precipitation of soluble salts in the contact zone between aggregates and/or soil particles (Mullins and Panayiotopoulos, 1984; Mullins et al., 1987; Mullins, 1999); (2) the dispersion of soil clay, associated or not with the presence of sodium (Mullins, 1999); (3) natural bulk density increases of the soil particles, which increase the effective stress and the water matrix potential in the soil as the soil dries (Fabiola et al., 2003) (Figure 1).

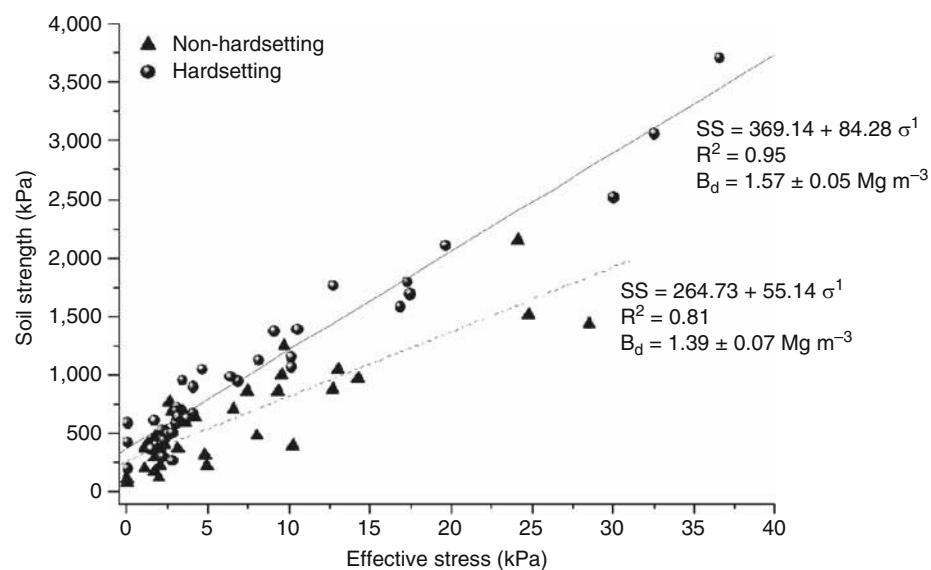

Other types of hardsetting soils have been distinguished in northern Cameroon (Lamotte, et al., 1997): (1) Soils with very hard sandy layers that usually occur under a more or less softer sandy layer. Some indications suggest that these properties could result from the gradual clogging of the pores between sand grains due to newly formed clay. Such a process may be favored by the succession of drying and wetting periods. (2) Soils with a very hard clay layer that are thought to be derived from Vertisols degraded by cultivation. These very hard layers, sandy or clayey, are not necessarily associated with a high sodium content but rather with a low iron content, as reflected by their pale color.

Physical behavior of hardsetting soils

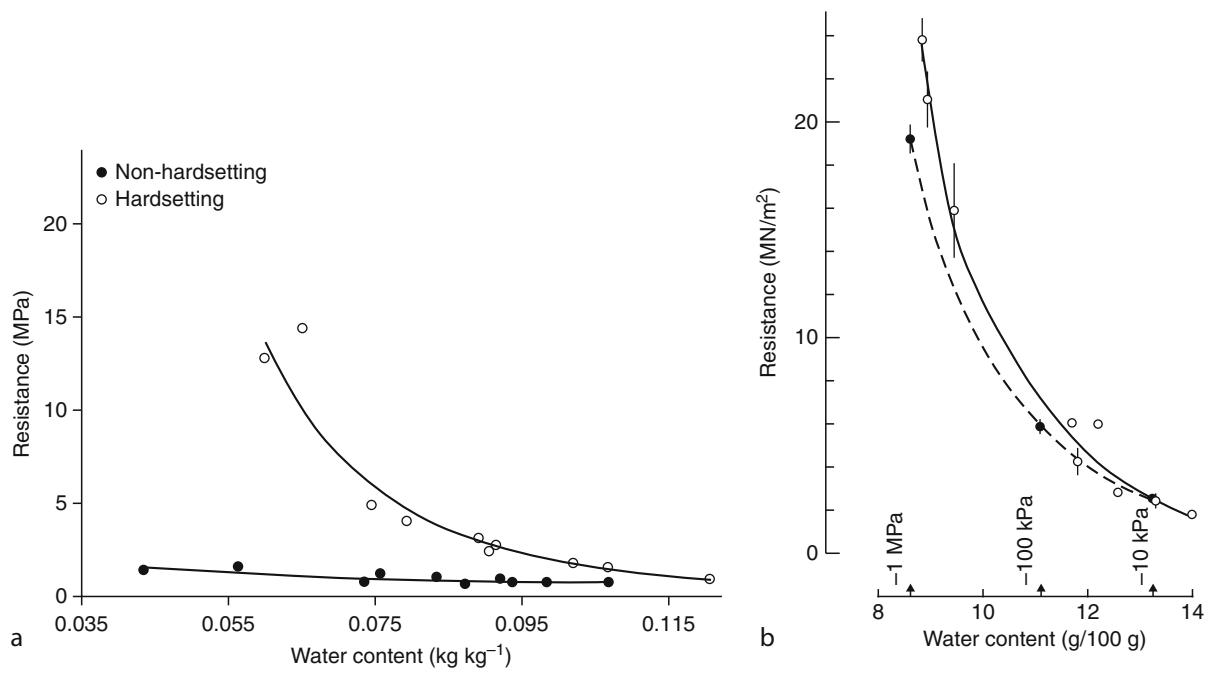

Once wet, the unstable hardsetting soil structure collapses and then shrinks as it dries. This leads to a “massive” soil layer with little or no cracks and greatly reduced pore space (Lima et al., 2006). This hard-set “massive” structure is associated with poor infiltration, a low water holding capacity, and a high soil strength (Figure 1). In many instances, this causes patchy establishment and poor crop and pasture growth. Naturally hardsetting soils are unable to develop water-stable aggregates (Mullins et al., 1990). This means that during wetting, soil aggregates start to swell and become soft. This occurs prior to “slumping” (also referred to as “slaking”) when the aggregates collapse and disintegrate.

Hardsetting can also occur in soil with a high exchangeable sodium percentage (ESP) through the “dispersion” of soil aggregates. This results in clay and silt becoming suspended in the soil solution and causing a breakdown of aggregates (Mullins et al., 1990). Other factors that influence the dispersion of soil aggregates include the soil electrical conductivity (EC), calcium/magnesium ratios, and the organic matter content. Soil types more prone to soil structure decline are sandy loams to clay loams (between 10% to 35% clay), particularly those low in organic matter (<2%) (Giarola et al., 2001).

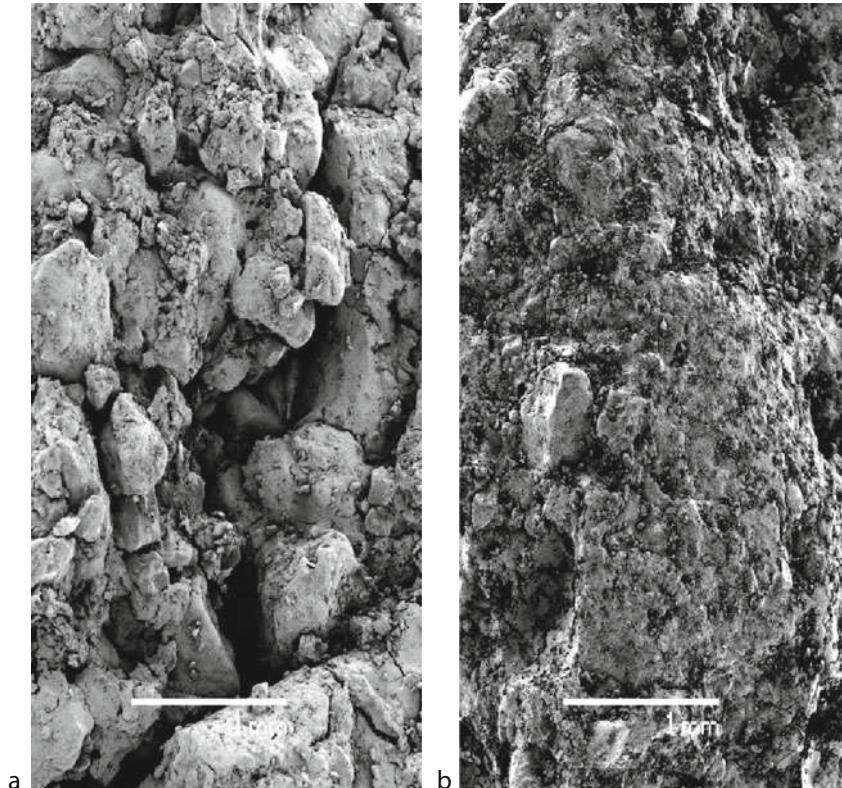

The soil resistance to penetration curve (RP) can be used to differentiate hardsetting from non-hardsetting soils. In soils with hardsetting horizons, in the same moisture range, the variation of soil resistance is much greater than in soils with stable structures (Figure 2). The soil resistance normally exceeds 3 MPa before the soil reaches the permanent wilting point (1,500 kPa of

Hardsetting Soils: Physical Properties, Figure 1 Soil strength (SS) versus effective stress (σ') for non-hardsetting (A1) and hardsetting (AB1) horizons. B_d is the bulk density.

Hardsetting Soils: Physical Properties, Figure 2 Curve of soil resistance to penetration for hardsetting and non-hardsetting soils from Brazil (a) and Australia (b). Source: adapted from (a) Giarola et al. (2001) and (b) Mullins et al. (1987).

Hardsetting Soils: Physical Properties, Figure 3 Structural arrangement of soil particles of (a) non-hardsetting and (b) hardsetting horizons from Cruz das Almas, Bahia, Brazil.

matrix potential). Some soils studied by Mullins et al. (1987) developed a resistance to penetration greater than 3 MN m^{-2} , before being dried to a potential of 100 kPa. Ley et al. (1995) found an RP equal to or greater than 2 MPa in some soils from Nigeria, when these soils were dried at a matrix potential of only 100 kPa. Similar results have been obtained for hardsetting soils from the United Kingdom (Young et al., 1991), Australia (Mullins et al. 1987), Tanzania (Mullins, 1997), and Brazil (Fabiola et al., 2003).

In addition to their high cohesion, the denser layers have higher bulk densities ($1.6\text{--}1.8$ compared to $1.4\text{--}1.5 \text{ Mg m}^{-3}$) and lower permeabilities compared to the softer upper layers (Fabiola et al., 2003; Lima et al., 2006) (Figure 3).

The decrease in total pore volume is another negative consequence of hardsetting behavior, as it affects the biological activity, the movement and capacity of water retention, and the availability of water for plants. The lower pore volume shows a marked effect on the increase of RP during soil drying, which can vary from close to zero to 25 MPa at the point of permanent wilt (matrix potential $[\psi_m] = 1.5 \text{ MPa}$). Values of RP = 3 MPa were also obtained for a dampness close to $0.15 \text{ cm}^3 \text{ cm}^{-3}$, which is sufficient to impede plant growth or emergence (Mullins, 1997).

The tensile strength (TS) of aggregates is another parameter used to recognize hardsetting behavior. Values of TS = 200 kPa were registered in materials from Australian hardsetting soils after air drying (Ley et al., 1989; Gusli et al., 1994). In Brazil, the TS varied from 37 to 76 kPa in hardsetting horizons with a loamy-sandy-clay texture (Fabiola et al., 2003; Lima et al., 2006).

Conclusions

Hardsetting soils are structurally unstable soils common in Oceania, Africa, Asia, and South America. Because of their instability to wetting, cultivated hardsetting soils become almost homogenous masses upon drying and present physical problems such as high soil strength, poor infiltration, and crusting, which tend to adversely affect crop performance and management. The latter includes losses in the timeliness of cultivation, as well as a requirement for more frequent irrigation and tillage, leading to further deterioration in soil structure. The lack of defined parameters that indicate the presence of hardsetting behavior and the different degrees of cohesion make it impossible to accurately and easily recognize this behavior in soils.

 Institute of Soil Science and Environment Management,
 University of Life Sciences, Lublin, Poland

Definition

Horticultural substrate. It is the life environment of the plant roots, isolated from the parent rock.

Structure. Form of spatial arrangement of the solid phase. Structural elements in the horticultural substrate are the primary particles of the solid phase, their complexes, or aggregates and pores, or the space between the solid phase particles and aggregates.

Physical property. Physical property is the attribute of a substance that can be observed and measured without changing one substance into another. The main physical parameters characterizing the physical condition of the

horticultural substrate are bulk density, total porosity, container water capacity, available water retention, air capacity, water, and air permeability.

Introduction

In the second half of the twentieth century, horticultural substrates made mainly from white peat were the most widely used. Now, the assortment of applied materials has increased considerably. Besides the commonly used organic substrates, some other materials are also being used. It is, first of all, the rockwool, produced from the melted diabase or basalt with addition of some dolomite as well as the artificial substrates such as superabsorbents. The physical condition of the applied materials definitely decides on the success of the cultivation. The suitable growth of the plants and their development can be assured, above all, by the proper proportions of the amount of water and air in the substrate (Verdonck et al., 1983). A very important problem in case of the determination of the physical properties of the horticultural substrates is the application of such standard methods, which make possible to receive the comparable results of the measurements (Gabriëls and Verdonck, 1991; Bohne and Günther, 1997).

Classification of the substrates

Taking into the consideration the materials, which can be used as substrates in horticulture, one can classify them, first of all, into the unary and multicomponent substrates. Among the unary substrates, one discerns the organic, mineral, and artificial ones. To the organic substrates belong white peat, black peat, brown coal, straw, coconut fiber and dust, tobacco, and wood waste. Gravel, sand, grit, keramsite, perlite, and rockwool are grouped among the mineral substrates, while the artificial substrates comprise the phenolic ones, the polyurethane, polyethylene, and polyvinylchloride foams as well as the superabsorbents composed of polyvinyl alcohol, polyoxyethylene, or polyacrylates. To the multicomponent substrates belong the traditional horticultural substrates produced from leaves, sod, heather, compost and garden soil; peat substrates, and standard soils. Standard soils are the substrates, prepared from the materials of defined properties and constant composition. To some of the first such universal horticultural substrates belong John Innes Composts, elaborated in the mid-thirties of the twentieth century in Great Britain. They are formed of the loam, peat, and grit-sand, completed by the addition of some mineral fertilizers. A well-known standard soil is "Einheitserde" elaborated by Anton Frühstorfer in Germany. It is made of white peat, black peat, and loam or clay (Turski et al., 1980).

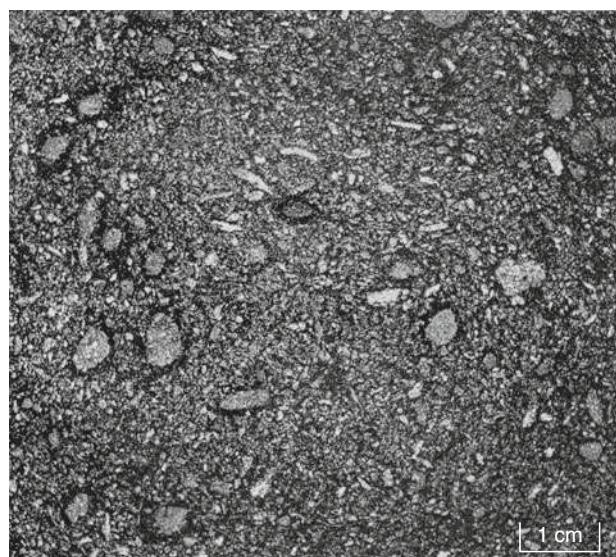

Structure

Structure considerably decides on such conditions of the plant growth and development, as supply in air and water as well as on the temperature in the root area. In the field conditions, the most suitable physical condition of the soil is guaranteed by the aggregate structure. It is characteristic

for the soils, in which there occur the aggregates – the clumps of the particles of the solid substance only in certain points loosely connected. There is air in the large interaggregate spaces, while the small internal pores of the aggregates keep water in them; this ensures that the plant roots have free access both to the water and to the oxygen. In the horticultural substrates, the aggregate structure is not as much essential as in the natural soils. The amount of water and air in the substrate highly depends on the way of hydration, on the regulating the water outflow, on the dimensions, and on the shape of the container, and not on the solid phase geometry, as it takes place in soil (Fonteno, 1989; Argo, 1998). Very good conditions of the growth and development of the plants, in spite of the lack of aggregate structure, is assured by the rockwool, in which the pressed concentrations of the fibers shape a characteristic sponge-like structure. In the horticultural substrates the aggregate structure occurs most often in case of the loosely heaped-up materials of a considerable contribution of the organic substance, while the structure of separated particles is characteristic for the mineral horticultural substrates (Słowińska-Jurkiewicz and Jaroszuk-Sierocińska, 2007). Very advantageous structure of horticultural substrates represents Figure 1.

Physical properties

Traditionally, such substrates were considered to be the most suitable for the cultivation of the garden plants in which one-half of the volume is occupied by the solid phase, and the other by the pores, just as in the mineral

soils (Penningsfeld and Kurzman, 1966). De Boodt (1965) stated that an ideal substrate should be characterized by a considerably larger total porosity, about $0.85 \text{ m}^3 \text{ m}^{-3}$ and a low bulk density, 0.215 Mg m^{-3} . Such conditions can be realized, first of all, in the soilless substrates, produced on the base of peat, as well as in the modern substrates, such as rockwool. Pores and their dimensions play an important part in the water and air conditions. In the pores there is either the water or the air. One admits that the large pores contain the air (except the situation of a complete saturation of substrate with water), while the small pores are filled with water. Drzal et al. (1999) introduced a classification on large pores (macropores), of dimensions $>416 \mu\text{m}$, from which the water flows out, quickly, under the influence of the gravitation force, middle-size pores (mesopores), of dimension from 416 up to $10 \mu\text{m}$, in which the water, available for the plants, is retained against the gravitation, as well as the small pores (micropores), covering the range from 10 up to $0.2 \mu\text{m}$. The micropores contain the water which is not used by the plants in case of a normal hydration, and being a reserve in the situation of a water stress. The pores of dimensions below $0.2 \mu\text{m}$ or the ultramicropores, keep the water unavailable for plants. To the dimension of pores $416 \mu\text{m}$ corresponds the water potential of -0.7 kPa , to the dimension $10 \mu\text{m}$, water potential -31 kPa , and to dimension of $0.2 \mu\text{m}$, water potential -1.5 MPa . According to White and Mastalerz (1966), De Boodt and Verdonck (1972), and Fonteno (1989, 1993) in case of characterizing the water properties of the horticultural substrates, as a basic parameter there should be named the container water capacity, defined as the amount of water, remained in the substrate after the free outflow of the gravitational water, but before the beginning of evaporation. This amount depends not only on the character of the substrate but considerably on the dimensions, and also on the shape of the container, in which the plant is

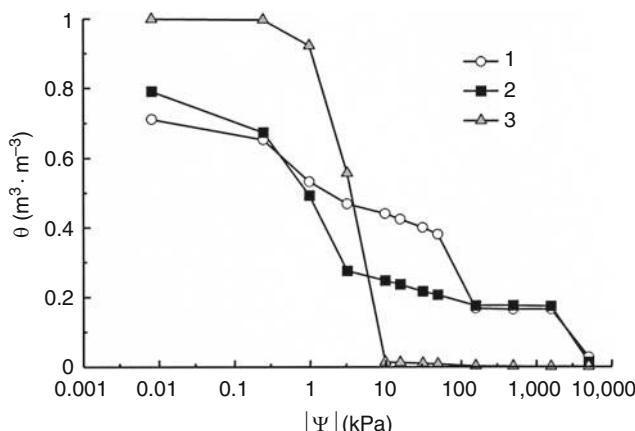

cultivated (Drzal et al., 1999). After the irrigation and outflow, the level of free water occurs on the bottom of the container. For every 1-cm increase of the height above the bottom of the container the water potential decreases by 0.1 kPa , and, this way, decreases the possibility of its keeping. For the container of 20-cm high, the average water potential corresponding to the container water capacity is equal to -1 kPa . In regard to the water retention in the substrates, De Boodt and Verdonck (1972) applied the concept of an easily available water in the range of water potential from -1 to -5 kPa and water buffering capacity from -5 to -10 kPa . Brückner (1997) made a difference between the light available water retention in the range of water potential from -1 to -10 kPa and the heavy available water retention in the range from -10 kPa to -1.5 MPa . Light available water retention is especially important for steering the irrigation. It should begin soon after its consumption by the plants, and thus in the case of water potential being -10 kPa . Aside of the characteristics determining a capability of the material to collecting the water, very important are the parameters determining its capability to water filtration, both in the saturated and in the unsaturated zone (Sławiński et al., 1996). In the condition of the saturation the movement of water is determined by the large pores. With the moisture decrease in the substrate, after the water outflow from the large pores, the movement of water takes place in the smaller pores also, which results in a more tortuous route of water outflow (Fonteno, 1993). In the substrate environment, aside of water, also the air plays an important part (Caron and Nkongolo, 1999). In an ideal environment of root growth of porosity $0.85 \text{ m}^3 \text{ m}^{-3}$ placed in the pot of 15-cm high, in state of container water capacity, the air should occupy $0.25 \text{ m}^3 \text{ m}^{-3}$ and water, $0.60 \text{ m}^3 \text{ m}^{-3}$ (De Boodt and Verdonck, 1972). It should be remembered that the change of the bulk density of substrates, related to their compaction during the transport

Horticulture Substrates, Structure and Physical Properties,
Figure 2 Water retention curves of three horticultural substrates: white peat – 1, coconut fiber – 2, and rockwool – 3. On the horizontal axis there are the absolute values of water potential ($|\Psi|$) in kPa and on vertical axis there are the values of moisture content (θ) in $\text{m}^3 \text{ m}^{-3}$ (Jaroszuk-Sierocińska and Słowińska-Jurkiewicz, 2009).

and performing various cultivating works, can result in a radical decrease in the air capacity (Brückner, 1997; Jaroszuk and Słowińska-Jurkiewicz, 2003). The values of the basic physical properties of most often used substrates are listed in Table 1 (Jaroszuk and Słowińska-Jurkiewicz, 2005).

Conclusions

Horticultural substrates show the most various physical properties, depending on the character of the materials used to their production. Among the actually used substrates, the best physical condition, from the point of view of the horticultural production, is characteristic for rockwool and coconut fiber (Figure 2). These substrates can certainly substitute the white peat in the process of horticultural production, what surely results in protections of the bogs under the menace of the excessive exploitation.

Hydraulic Properties of Unsaturated Soils. Properties reflecting the ability of a soil to retain or transmit water and its dissolved constituents.

Introduction

Many agrophysical applications require knowledge of the hydraulic properties of unsaturated soils. These properties reflect the ability of a soil to retain or transmit water and its dissolved constituents. For example, they affect the partitioning of rainfall and irrigation water into infiltration and runoff at the soil surface, the rate and amount of redistribution of water in a soil profile, available water in the soil root zone, and recharge to or capillary rise from the groundwater table, among many other processes in the unsaturated or vadose zone between the soil surface and the groundwater table. The hydraulic properties are also critical components of mathematical models for

studying or predicting site-specific water flow and solute transport processes in the subsurface. This includes using models as tools for designing, testing, or implementing soil, water, and crop management practices that optimize water use efficiency and minimize soil and water pollution by agricultural and other contaminants. Models are equally needed for designing or remediating industrial waste disposal sites and landfills, or assessing the long-term stewardship of nuclear waste repositories.

Predictive models for flow in variably saturated soils are generally based on the Richards equation, which combines the Darcy–Buckingham equation for the fluid flux with a mass conservation equation to give (Richards, 1931):

$$\frac{\partial \theta(h)}{\partial t} = \frac{\partial}{\partial z} \left[K(h) \frac{\partial h}{\partial z} - K(h) \right] \quad (1)$$

in which θ is the volumetric water content ($L^3 L^{-3}$), h is the pressure head (L), t is time (T), z is soil depth (positive down), and K is the hydraulic conductivity ($L T^{-1}$). Equation 1 holds for one-dimensional vertical flow; similar equations can be formulated for multidimensional flow problems. The Richards equation contains two constitutive relationships, the soil water retention curve, $\theta(h)$, and the unsaturated soil hydraulic conductivity function, $K(h)$. These hydraulic functions are both strongly nonlinear functions of h . They are discussed in detail below.

Water retention function

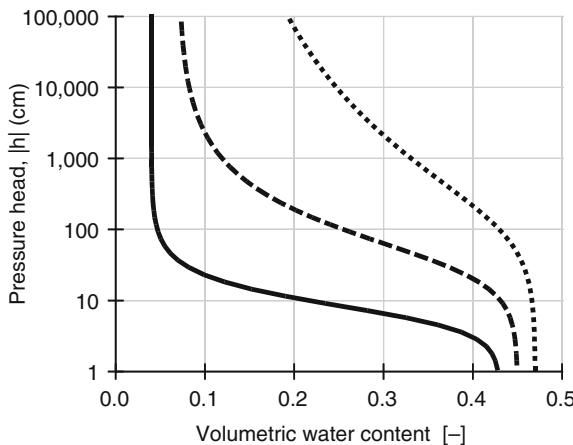

The soil water retention curve, $\theta(h)$, describes the relationship between the water content, θ , and the energy status of water at a given location in the soil. Many other names may be found in the literature, including soil moisture characteristic curve, the capillary pressure–saturation relationship, and the pF curve. The retention curve historically was often given in terms of pF, which is defined as the negative logarithm (base 10) of the absolute value of the pressure head measured in centimeters. In the unsaturated zone, water is subject to both capillary forces in soil pores and adsorption onto solid phase surfaces. This leads to negative values of the pressure head (or matric head) relative to free water, or a positive suction or tension. As opposed to unsaturated soils, the pressure head h is positive in a saturated system. More formally, the pressure head is defined as the difference between the pressures of the air phase and the liquid phase. Capillary forces are the result of a complex set of interactions between the solid and liquid phases involving the surface tension of the liquid phase, the contact angle between the solid and liquid phases, and the diameter of pores.

Knowledge of $\theta(h)$ is essential for the hydraulic characterization of a soil, since it relates an energy density (potential) to a capacity (water content). Rather than using the pressure head (energy per unit weight of water), many agrophysical applications use the pressure or matric potential (energy per unit volume of water, usually measured in Pascal, Pa), $\psi_m = \rho_w g h$, where ρ_w is the density of water (ML^{-3}) and g the acceleration of gravity (LT^{-2}).

Figure 1 shows typical soil water retention curves for relatively coarse-textured (e.g., sand and loamy sand), medium-textured (e.g., loam and sandy loam), and fine-textured (e.g., clay loam, silty loam, and clay) soils. The curves in **Figure 1** may be interpreted as showing the equilibrium water content distribution above a relatively deep water table where the pressure head is zero and the soil fully saturated. The plots in **Figure 1** show that coarse-textured soils lose their water relatively quickly (at small negative pressure heads) and abruptly above the water table, while fine-textured soils lose their water much more gradually. This reflects the particle or pore-size distribution of the medium involved. While the majority of pores in coarse-textured soils have larger diameters and thus drain at relatively small negative pressures, the majority of pores in fine-textured soils do not drain until very large tensions (negative pressures) are applied.

As indicated by the plots in **Figure 1**, the water content varies between some maximum value, the saturated water content, θ_s , and some small value, often referred to as the residual (or irreducible) water content, θ_r . As a first approximation and on intuitive ground, the saturated water content is equal to the porosity, and θ_r equal to zero. In reality, however, the saturated water content, θ_s , of soils is generally smaller than the porosity because of entrapped and dissolved air. The residual water content θ_r is likely to be larger than zero, especially for fine-textured soils with their large surface areas, because of the presence of adsorbed water. Most often θ_s and especially θ_r are treated as fitting parameters without much physical significance.

Soil water retention curves such as shown in **Figure 1** are not unique but depend on the history of wetting and drying. Most often, the soil water retention curve is determined by gradually desaturating an initially saturated soil by applying increasingly higher suctions, thus producing a main drying curve. One could similarly slowly wet an

Hydraulic Properties of Unsaturated Soils, Figure 1 Typical soil water retention curves for relatively coarse- (solid line), medium- (dashed line), and fine-textured (dotted line) soils. The curves were obtained using [Equation 6a](#) assuming hydraulic parameter values as listed in [Table 1](#).

initially very dry sample to produce the main wetting curve, which is generally displaced by a factor of 1.5–2.0 toward higher pressure heads closer to saturation. This phenomenon of having different wetting and drying curves, including primary and secondary scanning curves is referred to hysteresis. Hysteresis is caused by the fact that drainage is determined mostly by the smaller pore in a certain pore sequence, and wetting by the larger pores (this effect is often referred to as the ink bottle effect). Other factors contributing to hysteresis are the presence of different liquid–solid contact angles for advancing and receding water menisci, air entrapment during wetting, and possible shrink–swell phenomena of some soils.

Hydraulic conductivity function

The hydraulic conductivity characterizes the ability of a soil to transmit water. Its value depends on many factors such as the pore-size distribution of the medium, and the tortuosity, shape, roughness, and degree of interconnectedness of the pores. The hydraulic conductivity decreases considerably as soil becomes unsaturated since less pore space is filled with water, the flow paths become increasingly tortuous, and drag forces between the fluid and the solid phases increase.

The unsaturated hydraulic conductivity function gives the dependency of the hydraulic conductivity on the water content, $K(\theta)$, or pressure head, $K(h)$. **Figure 2** presents examples of typical $K(\theta)$ and $K(h)$ functions for relatively coarse-, medium-, and fine-textured soils. Notice that the hydraulic conductivity at saturation is significantly larger for coarse-textured soils than fine-textured soils. This difference is often several orders of magnitude. Also notice that the hydraulic conductivity decreases very significantly as the soil becomes unsaturated. This decrease, when expressed as a function of the pressure head (**Figure 2**; right), is much more dramatic for the coarse-textured soils. The decrease for coarse-textured soils is so large that at a certain pressure head the hydraulic conductivity becomes smaller than the conductivity of the fine-textured soil. The water content where the conductivity asymptotically becomes zero (**Figure 2**; left) is often used as an alternative working definition for the residual water content, θ_r .

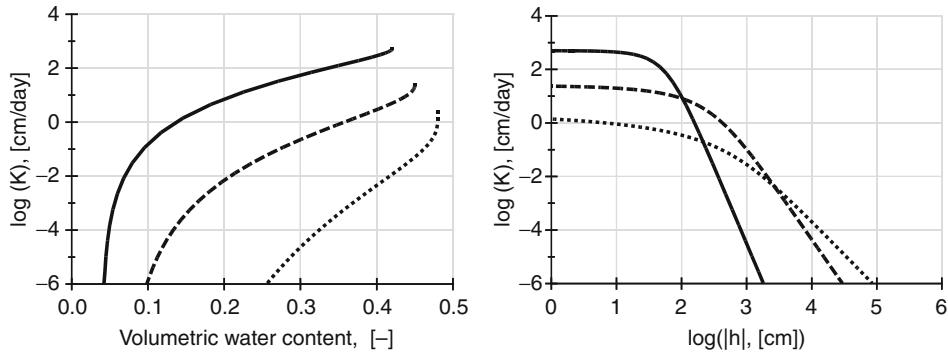

Soil water diffusivity

Another hydraulic function often used in theoretical and management application of unsaturated flow theories is the soil water diffusivity, $D(\theta)$, ($L^2 T^{-1}$), which is defined as

$$D(\theta) = K(\theta) \left| \frac{dh}{d\theta} \right|. \quad (2)$$

This function appears when [Equation 1](#) is transformed into a water-content-based equation in which θ is now the dependent variable:

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z} \left[D(\theta) \frac{\partial h}{\partial z} - K(\theta) \right]. \quad (3)$$

Hydraulic Properties of Unsaturated Soils, Figure 2 Typical curves of the hydraulic conductivity K , as a function of the pressure head (left) and water content (right) for coarse- (solid line), medium- (dashed line), and fine-textured (dotted line) soils. The curves were obtained using Equation 6b assuming hydraulic parameter values as listed in Table 1.

Equation 3 is very attractive for approximate analytical modeling of unsaturated flow processes, especially for modeling horizontal (without the $K(\theta)$ gravity term) and vertical infiltration (e.g., Philip, 1969; Parlange, 1980). However, the water-content-based equation is less attractive for more comprehensive numerical modeling of flow in layered media, flow in media that are partially saturated and partially unsaturated, and for highly transient flow problems.

Analytical representations

To enable their use in analytical or numerical models for unsaturated flow, the soil hydraulic properties are often expressed in terms of simplified analytical expressions. A large number of functions have been proposed over the years to describe the soil water retention curve, $\theta(h)$, and the hydraulic conductivity function, $K(h)$ or $K(\theta)$. A comprehensive review of the performance of some of many these models is given by Leij et al. (1997). The functions range from completely empirical equations to models based on the simplified conceptual picture that soils are made up of a bundle of equivalent capillary tubes that contain and transmit water.

While extremely simplistic as indicated by Tuller and Or (2001) among others, conceptual models that view a soil as a bundle of capillaries of different radii are still useful for explaining the shape of the water retention curve for different textures, as well as to provide a means for predicting the hydraulic conductivity function from soil water retention information. These models typically assume that pores at a given pressure head are either completely filled with water, or empty, depending upon the applied suction. Flow in each water-filled capillary tube is subsequently calculated using Poiseuille's law for flow in cylindrical pores. By adding the contribution of all capillaries that are still filled with water at a particular pressure head, making some assumption about how small and large capillaries connect to each other in sequence

(using a cut-and-paste concept of a cross-section of the medium containing different-sized pores), and then integrating over all water-filled capillaries leads to the hydraulic conductivity of the complete set of capillaries, and consequently of the soil itself. The approach allows information of the soil water retention curve to be translated in predictive equations for the unsaturated hydraulic conductivity. Many theories of this type, often referred to also as statistical pore-size distribution models, have been proposed in the past, including Childs and Collis-George (1950), Burdine (1953), Millington and Quirk (1961), and Mualem (1976). A review of the different approaches is given by Mualem (1992). Examples of analytical $\theta(h)$ and $K(h)$ equations resulting from this approach are the hydraulic functions of Brooks and Corey (1964), based on the approach by Burdine (1953), and equations by van Genuchten (1980) and Kosugi (1996), based on the theory of Mualem (1976).

The classical equations of Brooks and Corey (1964) for $\theta(h)$, $K(h)$, and $D(\theta)$ are given by

$$\theta = \begin{cases} \theta_r + (\theta_s - \theta_r) \left| \frac{h_e}{h} \right|^{\lambda} & h < h_e \\ \theta_s & h \geq h_e \end{cases} \quad (4a)$$

$$K(h) = K_s S_e^{2/\lambda+l+1} \quad (4b)$$

$$D(\theta) = \frac{K_s}{\alpha(\theta_s - \theta_r)} S_e^{1/\lambda+l} \quad (4c)$$

where, as before, θ_r is the residual water content ($L^3 L^{-3}$), θ_s is the saturated water content ($L^3 L^{-3}$), h_e is often referred to as the air-entry value (L), λ is a pore-size distribution index characterizing the width of the soil pore-size distribution, K_s is the saturated hydraulic conductivity (LT^{-1}), l a pore-connectivity parameter assumed to be 2.0 in the original study of Brooks and Corey (1964), and $S_e = S_e(h)$ is effective saturation given by

$$S_e(h) = \frac{\theta(h) - \theta_r}{\theta_s - \theta_r} \quad (5)$$

For completeness we have given here also the expression for the soil water diffusivity, $D(\theta)$. Note that Equations 4b and 4c contain parameters that are also present in Equation 4a, in particular θ_r and θ_s through Equation 5, as well as h_e and λ . The value of λ in Equation 4a reflects the steepness of the retention function and is relatively large for soils with a relatively uniform pore-size distribution (generally coarse-textured soils such as those shown in Figures 1 and 2), but small for soils having a wide range of pore sizes.

One property of Equation 4a is the presence of a sharp break in the retention curve at the air-entry value, h_e . This break (or discontinuity in the slope of the function) is often visible in retention data for coarse-textured soils, but may not be realistic for fine-textured soils and soils having a relatively broad pore- or particle-size distribution. A sharp break is similarly present in the hydraulic conductivity function when plotted as a function of the pressure head, but not versus the water content. As an alternative, van Genuchten (1980) proposed a set of equations that exhibit a more smooth sigmoidal shape. The van Genuchten equations for $\theta(h)$, $K(h)$, and $D(\theta)$ are given by:

$$\theta(h) = \theta_r + \frac{\theta_s - \theta_r}{(1 + |\alpha h|^n)^m} \quad (m = 1 - 1/n; n > 1) \quad (6a)$$

$$K(h) = K_s S_e^l \left[1 - \left(1 - S_e^{1/m} \right)^m \right]^2 \quad (6b)$$

$$D(\theta) = \frac{(1-m)K_s}{\alpha m(\theta_s - \theta_r)} S_e^{l-1/m} \left[\left(1 - S_e^{1/m} \right)^{-m} + \left(1 - S_e^{1/m} \right)^m - 2 \right] \quad (6c)$$

respectively, where α (L^{-1}), n (–), and m ($= 1 - 1/n$) (–) are shape parameters, and l is the pore-connectivity parameter (–). The parameter n in Equation 6 tends to be large for soils with a relatively uniform pore-size distribution and small for soils having a wide range of pore sizes. The pore-connectivity parameter l in Equation 6b was estimated by Mualem (1976) to be about 0.5 as an average for many soils. However, many other values

for l have been suggested in various studies. Based on an analysis of a large data set from the UNSODA database, Schaap and Leij (2000) recommended using l equal to –1 as a more appropriate value for most soil textures.

Equations 6a, 6b, and 6c assume the restrictive relationship $m = 1 - 1/n$, which simplifies the predictive $K(h)$ expression compared to leaving m and n as independent parameters in Equation 6b. In particular, the convex and concave curvatures at the high and low pressure heads in Figure 1 have then a particular relationship with each other. Other restrictions on Equation 6a have been used also. For example, Haverkamp et al. (2005) used the restriction $m = 1 - 2/n$ in connection with Equation 6a and Burdine's (1953) model to produce a different expression for $K(h)$. The restrictions are not formally needed, since they limit the flexibility of Equation 6a in describing experimental data. However, the predicted $K(h)$ function obtained with the theories of Burdine or Mualem becomes then extremely complicated by containing incomplete beta or hypergeometric functions, thus limiting the practicality of the analytical functions.

Rawls et al. (1982) provided average values of the parameters in the Brooks and Corey (1964) soil hydraulic parameters for 11 soil textural classes of the U.S. Department of Agriculture (USDA) textural triangle. Carsel and Parrish (1988) gave similar values for the van Genuchten (1980) parameters for 12 USDA soil textural classes. In Table 1, we list typical van Genuchten hydraulic parameter values for relative coarse-, medium-, and fine-textured soils. The data in this table were actually used to calculate the water retention and hydraulic conductivity functions, shown in Figures 1 and 2, respectively, with Equations 6a, b. Average values such as those given in Table 1, or provided in more detail by Rawls et al. (1982) and Carsel and Parrish (1988), are often referred to as textural class averaged pedotransfer functions. Pedotransfer functions are relationships that use more easily measured of readily available soil data to estimate the unsaturated soil hydraulic parameters or properties (Bouma and van Lanen, 1987; Leij et al., 2002; Pachepsky and Rawls, 2004).

We note that Equations 4 and 6 provide only two examples in which the hydraulic properties are described analytically. Many other combinations (Leij et al., 1997; Kosugi et al., 2002) are possible and have been used. For example, the combination of Equation 6a for $\theta(h)$ with a simple expression like

Hydraulic Properties of Unsaturated Soils, Table 1 Typical values of the soil hydraulic parameters in the analytical functions of van Genuchten (1980) for relatively coarse-, medium-, and fine-textured soils. The parameters were used to calculate the hydraulic properties plotted in Figures 1 and 2 using Equations 6a and 6b, respectively

Soil texture	θ_r (cm day $^{-1}$)	θ_s (cm 3 cm $^{-3}$)	α (cm 3 cm $^{-3}$)	n (cm $^{-1}$)	K_s (–)
Coarse	0.045	0.430	0.145	2.68	712.8
Medium	0.057	0.410	0.124	2.28	350.2
Fine	0.020	0.540	0.0010	1.2	45.0

$$K(h) = K_s S_e^b \quad (7)$$

which is essentially identical to [Equation 4b](#), for $K(h)$ is also very realistic. Another attractive alternative equation for $K(h)$ is of the form (e.g., Vereecken et al., [1989](#))

$$K(h) = \frac{K_s}{1 + |ah|^b} \quad (8)$$

Many alternative expressions have been used also for the soil water diffusivity function, $D(\theta)$, mostly to facilitate simplified analytical analyses of unsaturated flow problems (e.g., Parlange, [1980](#)).

Experimental procedures

A large number of experimental techniques can be used to estimate the hydraulic properties of unsaturated soils. A direct approach for the water retention function would be to measure a number of water content (θ) and pressure head (h) pairs, and then to fit a particular retention function to the data. Direct measurement techniques include methods using a hanging water column, pressure cells, pressure plate extractors, suction tables, soil freezing, and many other approaches. Comprehensive reviews of various methods are given by Gee and Ward ([1999](#)) and Dane and Hopmans ([2002](#)). Once the pairs of θ and h data are obtained, the data may be analyzed in terms of specific analytical water retention and conductivity functions such as those discussed earlier. Several convenient software packages are available for this purpose (van Genuchten et al., [1991](#); Wraith and Or, [1998](#)). Alternatively, the data can be analyzed without assuming specific analytical functions for $\theta(h)$ and $K(h)$ or $K(\theta)$. This could be done using linear, cubic spline, or other interpolation techniques (Kastanek and Nielsen, [2001](#); Bitterlich et al., [2004](#)).

Similar direct measurement approaches involving pairs of conductivity (or diffusivity) and pressure head (or water content) data are also possible for the $K(h)$ and $D(\theta)$ functions, at least in principle (Dane and Topp, [2002](#)), including for the saturated hydraulic conductivity, K_s . The saturated hydraulic conductivity can be measured in the laboratory using a variety of constant or falling head methods, and in the field using single or double ring infiltrometers, constant head permeameters, and various auger-hole and piezometer methods (Dane and Topp, [2002](#)). Unfortunately, because of the strongly nonlinear nature of the soil hydraulic properties, pairs for the $K(h)$ and $D(\theta)$ data are not easily measured directly, especially at relatively low (negative) pressure heads, unless more specialized techniques are used such as centrifuge methods (Nimmo et al., [2002](#)). Even then, the data are generally not distributed evenly over the entire water content range of interest. Consequently, unsaturated hydraulic conductivity properties are most often estimated using inverse or parameter estimation procedures.

Parameter estimation methods generally involve the measurement during some experiment of one or several

capacity or flow attributes (e.g., water contents, pressure heads, boundary fluxes), which are then used in combination with a mathematical solution (generally numerical) to obtain estimates of the hydraulic parameters such as those that appear in [Equations 4](#) and [6](#), or other functions. Popular methods include one-step and multi-step outflow methods (Kool et al., [1987](#); van Dam et al., [1994](#)), tension infiltrometers methods (Šimůnek et al., [1998a](#)), and evaporation methods (Šimůnek et al., [1998b](#)), although many other laboratory and field methods also exist or can be similarly employed (Hopmans et al., [2002](#)). This also pertains to different approaches for minimizing the objective function, including quantification of parameter uncertainty (Abbaspour et al., [2001](#); Vrugt and Robinson, [2007](#)). Very attractive now also is the use of combined hard (e.g., directly measured) and soft (e.g., indirectly estimated) data, including hydrogeophysical measurements and information derived from pedotransfer functions, to extract the most out of available information (e.g., Kowalski et al., [2004](#); Segal et al., [2008](#)).

Hydraulic properties of structured soils

The Richards [equation 1](#) typically predicts a uniform flow process in the vadose zone. Unfortunately, the vadose zone can be extremely heterogeneous at a range of scales, from the microscopic (e.g., pore scale) to the macroscopic (e.g., field or larger scale). Some of these heterogeneities can lead to a preferential (or bypass) flow process that macroscopically is very difficult to capture with the standard Richards equation. One obvious example of preferential flow is the rapid movement of water and dissolved solutes through soil macropores (e.g., between soil aggregates, or created by earthworms or decayed root channels or rock fractures), with much of the water bypassing (short-circuiting) the soil or rock matrix. However, many other causes of preferential flow exist, such as flow instabilities caused by soil textural changes or water repellency (Hendrickx and Flury, [2001](#); Šimůnek et al., [2003](#); Ritsema and Dekker, [2005](#)), and lateral funneling of water along sloping soil layers (e.g., Kung, [1990](#)).

While uniform flow in granular soils is traditionally described with a single-porosity model such as the Richards equation given by [Equation 1](#), flow in structured media can be described using a variety of dual-porosity, dual-permeability, multi-porosity, and/or multi-permeability models (Šimůnek and van Genuchten, [2008](#); Köhne et al., [2009](#)). While single-porosity models assume that a single pore system exists that is fully accessible to both water and solute, dual-porosity and dual-permeability models both assume that the porous medium consists of two interacting pore regions, one associated with the inter-aggregate, macropore, or fracture system, and one comprising the micropores (or intra-aggregate pores) inside soil aggregates or the rock matrix. Whereas dual-porosity models assume that water in the matrix is stagnant, dual-permeability models allow also for water flow within the soil or rock matrix.

To avoid over-parameterization of the governing equations, one useful simplifying approach is to assume instantaneous hydraulic equilibration between the fracture and matrix regions. In that case, the Richards equation can still be used, but now with composite hydraulic properties of the form (e.g., Peters and Klavetter, 1988)

$$\theta(h) = w_f \theta_f(h) + w_m \theta_m(h) \quad (9a)$$

$$K(h) = w_f K_f(h) + w_m K_m(h) \quad (9b)$$

where the subscripts f and m refer to the fracture (macropore) and matrix (micropore) regions, respectively, and where w_i are volumetric weighting factors for the two overlapping regions such that $w_f + w_m = 1$. Rather than using Equations 6a,b directly in Equations 9a and 9b, Durner (1994) proposed a slightly different set of equations for the composite functions as follows

$$S_e(h) = \frac{\theta(h) - \theta_r}{\theta_s - \theta_r} = \frac{w_f}{[1 + |\alpha_f h|^{n_f}]^{m_f}} + \frac{w_m}{[1 + |\alpha_m h|^{n_m}]^{m_m}} \quad (10a)$$

$$K(S_e) = K_s \frac{(w_f S_{e_f} + w_m S_{e_m})^l \left\{ w_f \alpha_f [1 - (1 - S_{e_f}^{1/m_f})^{m_f}] + w_m \alpha_m [1 - (1 - S_{e_m}^{1/m_m})^{m_m}] \right\}^2}{(w_f \alpha_f + w_m \alpha_m)^2} \quad (10b)$$

where α_i , n_i , and $m_i (=1 - 1/n_i)$ are empirical parameters of the separate hydraulic functions ($i=f,m$). An example of composite retention and hydraulic conductivity functions based on Equations 10a and 10b is shown in Figure 2 for the following set of parameters: $\theta_r=0.00$, $\theta_s=0.50$, $l=0.5$, $K_s=1 \text{ cm d}^{-1}$, $\alpha_m=0.01 \text{ cm}^{-1}$, $n_m=1.50$, $w_m=0.975$, $w_f=0.025$, $\alpha_f=1.00 \text{ cm}^{-1}$, and $n_f=5.00$. The fracture domain in this case represents only 2.5% of the entire pore space, but accounts for almost 90% of the hydraulic conductivity close to saturation (Figure 3).

While still leading to uniform flow, models using such composite media properties do allow for faster flow and transport during conditions near saturation, and as such

provide more realistic simulations of field data than the standard approach using unimodal hydraulic properties of the type shown in Figures 1 and 2. In soils, the two parts of the conductivity curves may be associated with soil structure (near saturation) and soil texture (at lower negative pressure heads).

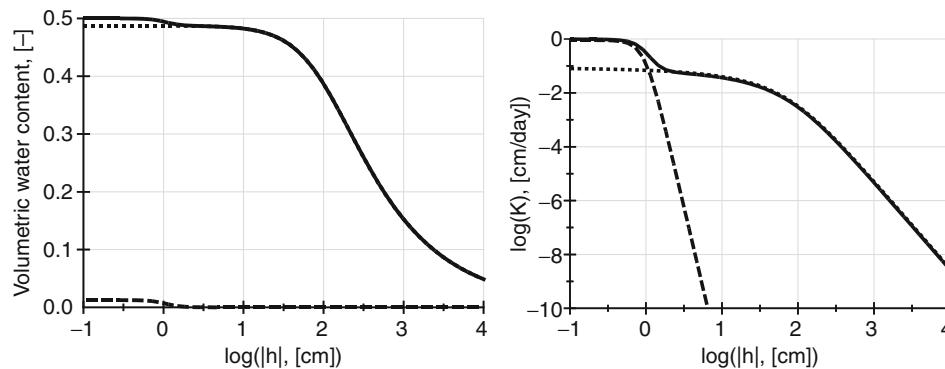

The use of composite hydraulic functions such as those shown in Figure 2 is consistent with field measurements suggesting that the macropore conductivity of soils at saturation is generally about one to two orders of magnitude larger than the matrix conductivity at saturation, depending upon texture. These findings were confirmed by Schaap and van Genuchten (2006) using a detailed neural network analysis of the UNSODA unsaturated soil hydraulic database (Leij et al., 1996). The analysis revealed a relatively sharp decrease in the conductivity away from saturation and a slower decrease afterward. Schaap and van Genuchten (2006) suggested an improved composite function for $K(h)$ to account for the effects of macropores near saturation as follows:

$$K(h) = \left(\frac{K_s}{K_m(h)} \right)^{R(h)} K_m(h) \quad (11a)$$

where

$$R(h) = \begin{cases} 0 & h < -40 \text{ cm.} \\ 0.2778 + 0.00694h & -40 \leq h < -4 \text{ cm} \\ 1 + 0.1875h & -4 \leq h \leq 0 \text{ cm} \end{cases} \quad (11b)$$

and where $K_m(h)$ is the traditional hydraulic conductivity function for the matrix as given by Equation 6b. Equations 11a and 11b were found to produce very small systematic errors between the observed (UNSOADA) and calculated hydraulic conductivities across a wide range of pressure heads between saturation and -150 m . While the macropore contribution was most significant between pressure heads 0 and -4 cm , its influence on the conductivity function extended to pressure heads as low as -40 cm (Equation 11b).

Hydraulic Properties of Unsaturated Soils, Figure 3 Bimodal water retention (left) and hydraulic conductivity (right) functions as described with the composite soil hydraulic model of Durner (1994).

Multiphase constitutive relationships

The use of [Equation 1](#) implies that the air phase has no effect of water flow. This is a realistic assumption for most flow simulations, except near saturation in relatively closed systems where air may not move freely. The resulting situation may need to be described using two flow equations, one for the air phase and one for the liquid phase. The same is true for multiphase air, oil, and water systems in which the fluids are not fully miscible. Flow in such multiphase systems generally require flow equations for each fluid phase involved. Two-phase air-water systems hence could be modeled also using separate equations for air and water. This shows that the standard Richards equation is a simplification of a more complete multiphase (air-water) approach in that the air phase is assumed to have a negligible effect on variably saturated flow, and that the air pressure varies only little in space and time. This assumption appears adequate for most variably saturated flow problems. Similar assumptions, however, are generally not possible when nonaqueous phase liquids (NAPLs) are present. Mathematical descriptions of multiphase flow and transport hence in general require flow equations for each of the fluid phases involved. Assuming applicability of the van Genuchten hydraulic functions and ignoring the presence of residual air and water, the hydraulic conductivity functions for the liquid (wetting) and air phase (non-wetting) phases are given by (e.g., Luckner et al., [1989](#); Lenhard et al., [2002](#)):

$$K_w(S_e) = K_w S_e^l \left[1 - \left(1 - S_e^{1/m} \right)^m \right]^2 \quad (12a)$$

$$K_a(S_e) = K_a (1 - S_e)^l \left[1 - S_e^{1/m} \right]^{2m} \quad (12b)$$

where the subscripts *w* and *a* refer to the water and air phases, respectively, and K_w and K_a are the hydraulic conductivities of the medium to water and air when filled completely with those fluids. A detailed overview of various approaches for measuring and describing the hydraulic properties of multi-fluid systems is given by Lenhard et al. ([2002](#)).

A look ahead

The unsaturated soil hydraulic properties are key factors determining the dynamics and movement of water and its dissolved constituents in the subsurface. Reliable estimates are needed for a broad range of agrophysical applications, including for subsurface contaminant transport studies. A large number of approaches are now available for describing and measuring the hydraulic properties, especially for relatively homogeneous single-porosity soils. This includes direct measurement of discrete $\theta(h)$, and $K(h)$ or $K(\theta)$ data points and fitting appropriate analytical models to the data, and the use of increasingly sophisticated inverse methods.

Considerable challenges remain in the description and measurement of the hydraulic properties of structured

media (macroporous soils and fractured rock). The hydraulic properties of such media may require special provisions to account for the effects of soil texture and soil structure on the shape of the hydraulic functions near saturation, thus leading to dual- or multi-porosity formulations as indicated by Schaap and van Genuchten ([2006](#)) and Jarvis ([2008](#)), among others. Estimation of the effective properties of heterogeneous (including layered) field soil profiles also remains an important challenge. Very promising here is the increased integration of hard (directly measured) data and soft (indirectly estimated) information for improved estimation of field- or larger-scale hydraulic properties, including the use of noninvasive geophysical information. New noninvasive technologies with enormous potential range from neutron and X-ray radiography and magnetic resonance imaging at relatively small (laboratory) scales, to electrical resistivity tomography and ground penetrating radar at intermediate (field) scales, to passive microwave remote sensing at regional or larger scales. Challenges remain on how to optimally integrate, assimilate, or otherwise fuse such information with direct laboratory and field hydraulic measurements (Yeh and Šimunek, [2002](#); Kowalski et al., [2004](#), Looms et al., [2008](#); Ines and Mohanty, [2008](#)), including the optimal and cost-effective use of pedotransfer function and soil texture information, and resultant quantification of uncertainty (Minasny and McBratney, [2002](#); Wang et al., [2003](#)). These various integrated technologies undoubtedly will further advance in the near future, as well as the use of increasingly refined pore-scale modeling approaches (e.g., Tuller and Or, [2001](#)) at the smaller scales for more precise simulation of the basic physical processes governing the retention and movement of water in unsaturated media.

HYDRODYNAMIC DISPERSION

The tendency of a flowing solution in a porous medium that is permeated with a solution of different composition to disperse, due to the non-uniformity of the flow velocity in the conducting pores. The process is somewhat analogous to diffusion, though it is a consequence of convection.

Soil hydrophysical processes; Soil physical processes; Soil water processes; Soil water–soil morphology interactions

Definition

The *hydropedological processes* in the broader sense are all soil processes in which flowing or stagnant water acts as the environment or agent or the vehicle of transport. These processes affect the visible or otherwise discernible morphological features of the soil profile and analogous features on the pedon, polypedon, catena, and soil landscape or soil series scales. These features can be distinguished and categorized according to various pedological classification systems (Lal, 2005) and, vice versa, used to identify and semi-quantify the soil water processes (e.g., Stewart and Howell, 2003) that have produced or affected them. In the narrower sense, only those processes in which water itself (its content, energy status, movement, and balance) is in the focus are regarded as hydropedological processes.

Introduction

Pedology is the branch of soil science dealing with soil genesis, morphology, and classification. In some parts of the world, however, the word *pedology* has been or still is used to denote the whole of soil science. Under these conditions, it was quite natural to name that branch of soil science that deals with soil water (e.g., Stewart and Howell, 2003) and is otherwise referred to, for example, as soil physics, soil water physics, physics of soil water, or soil hydrology as *hydropedology*, notwithstanding its relations (or rather the absence of such relations) to soil

genesis, morphology, and classification. This happened in the fifties of the last century in Czechoslovakia, where the word “hydropedology” was used to denote the discipline of applied soil survey for designing irrigation and drainage systems on agricultural lands (ON 73 6950, 1974; Kutílek et al., 2000). Similar usage may have developed in other countries, too. Recently, the term “hydropedology” was redefined with due regard to both parts of the word, i.e., to the water in the soil and the pedology as defined in the first sentence of this paragraph (Lin, 2003; Lin et al., 2005, 2006a). Hydropedology is thus emerging as a new field, formed from the intertwining branches of soil science, hydrology, and some other closely related disciplines (Lin et al., 2006b, 2008a, b; Lin, 2009). As in hydrogeology, hydroclimatology, and ecohydrology, the emphasis is on connections between hydrology and other spheres of the earth (Wikipedia, 2009), in particular on the pedologic controls on hydrologic processes and properties and hydrologic impacts on soil formation, variability, and functions. Hydropedology emphasizes the *in situ* soils in the context of the landscape (Hydropedology, 2009).

Hydropedological processes in the soil

The soil and the living or dead vegetation on it transforms the precipitation and snowmelt water into overland flow, infiltration, and evaporation (e.g., Lal, 2005). All these three processes depend not only on the state and properties of the soil on the spot but also on the surface run on and subsurface inflow of water from the upslope parts of the landscape, on the arrangement and properties of soil horizons (e.g., Lal, 2005) (lithologically or pedogenetically generated), and on the boundary conditions at the bottom of the soil (bearing in mind how difficult it is to define any “bottom” of the soil).

The overland flow is generated (in most cases) only locally, due either to the insufficiency of the soil infiltration capacity, the lack of soil permeability when the soil is frozen or covered with ice crust, or to shallow groundwater exfiltrating from the soil in the downslope parts of the landscape, where the soils are often stigmatized by hydromorphism (gleyization, peat horizons, salinization). The overland flow is a vehicle of soil erosion and a carrier of eroded soil particles. The eroded particles are deposited in the places where the overland flow loses its carrying capacity. In this way, the overland flow contributes substantially to the thinning of the upland soils and thickening of the lowland soils and the submerged soils in streams, reservoirs, lakes, and seas.

The shallow subsurface downslope flow often occurs as perched groundwater accumulated on the top of less permeable soil horizons, produced by technogenic compaction or translocation of clay particles (illuviation) or iron and aluminum (lateritization) or iron and organic matter (podsolization) or simply because of the lack of organic matter or the absence of tillage that would render the top-soil more permeable than the subsoil.

The infiltration capacity of the soil is affected, among other factors, by the aptitude of the surface soil to crusting, the roughness of the soil surface and the presence and openness of macropores (Stewart and Howell, 2003) (biopores, cracks, and tillage-induced pores).

The key role in the pedological control of landscape hydrology is played by the retention capacity of the soil profile (e.g., Dingman, 2002). Although it is not exactly true that the soil is capable of retaining all water until its field capacity is exceeded, this rule is nevertheless approximately valid. A nonlinear process, referred to as the “soil moisture accounting,” has to be included in hydrological models in order to turn the infiltration input into the shallow subsurface and deep groundwater runoff output (e.g., Kachroo, 1992). The available water capacity of the soil (the field capacity minus the wilting point) plays also a crucial role in supporting vegetation growth and evapotranspiration.

The field-capacity rule is sometimes vitiated by various types of preferential flow, i.e., a fast gravitationally driven downward movement of water through the spots that are either more permeable or more wettable than the rest of the soils or appear as random manifestations of the hydraulic instability at the wetting front (fingering). This phenomenon is a zone of active research (e.g., Roulier and Schulin, 2008). However, the question of where, when, and to which extent these phenomena occur in different soils and rocks (so that we can predict them) remains largely unanswered.

The hydraulic properties of the soil (Stewart and Howell, 2003), such as the soil moisture retention curve, the saturated hydraulic conductivity, the unsaturated hydraulic conductivity function, the shrinkage curve, the wettability parameters, and many other properties, sometimes easy to quantify but sometimes still resisting to quantification, are mutually correlated and, which is advantageous, are also correlated to other, more easily determinable soil properties such as the particle size distribution, bulk density, and organic matter content (Pachepsky and Rawls, 2004; Pachepsky et al., 2006). It is not incidental that the traditional Czechoslovak “hydropedology” (see above) turned in practice mainly into the particle size distribution analysis of command areas. One task of modern hydropedology would be, in this respect, to reinvestigate the spatial distribution of soil texture classes in conjunction with other soil features, such as the soil depth, soil horizons, the position in the landscape, the degree of hydromorphism, etc.

Conclusions

The hydropedological processes as a part of soil-water relation processes belong to a new discipline, hydropedology (Lin et al., 2008c). Hydropedology undergoes burgeoning development. Its new topics and subtopics crop up all the time and many existing hot topics can easily accommodate under its wings. In most cases, the acceptance of hydropedological viewpoints is useful and makes the researcher more interdisciplinary and open to new ideas.

Synonyms

Localized dry spot; Soil water repellency

Definition

Hydrophobic – meaning “water fearing” in Greek.

Hydrophobic soils – repel water, generally resulting in water beaded on the surface.

Hydrophobicity – sometimes refers to a soil–water contact angle $>0^\circ$. These soils absorb less water and more slowly than hydrophilic soils.

Introduction

Hydrophobicity impedes the rate and extent of wetting in many soils. It is caused primarily by organic compounds that either coat soil particles or accumulate as particulate organic matter not associated with soil minerals. Sandy textured soils are more prone to hydrophobicity because their smaller surface area is coated more extensively than soils containing appreciable amounts of clay and silt. The most important effect of hydrophobicity is changes to soil water dynamics. Hydrophobicity causes negative effects through reduced infiltration and water retention, leading to enhanced run-off across the soil surface, preferential flow pathways in the unsaturated zone of the soil, and less plant available water. Many soils that appear to readily take in water have small levels of hydrophobicity.

Reduced wetting rates caused by hydrophobicity may also have a positive impact on soil structural stability. Hydrophobicity can be enhanced by soil drying, heating from fires, soil nutrients, and organic inputs.

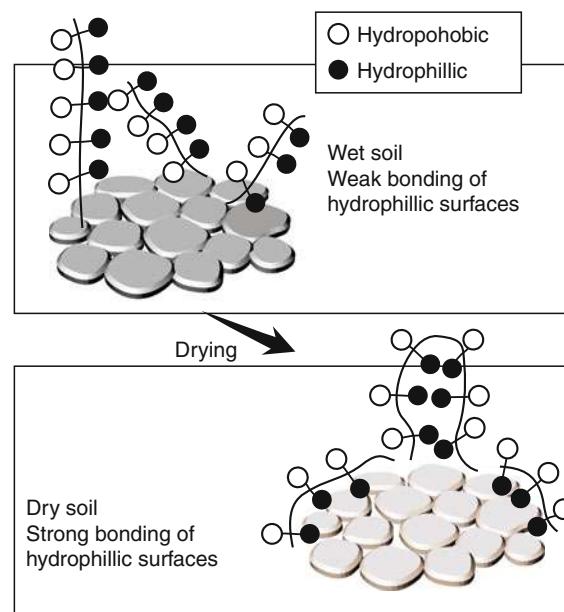

Geographical occurrence of soil hydrophobicity

Before a surge in research beginning in the 1990s, soil hydrophobicity was generally only associated with semi-arid or coastal soils (DeBano, 2000). The hydrophobicity of over 5 million hectares of agricultural soils in Australia can cause production losses of up to 80% (Blackwell, 2000). It is also a known problem of golf course greens and other sports soils (York and Canaway, 2000). Many coniferous forest soils are extremely prone to soil hydrophobicity (Doerr et al., 2009), particularly following wildfires (Mast and Clow, 2008). Since 1990, greater surveying and the development of more sensitive testing techniques identified soil hydrophobicity as a common property of most soils (Tilman et al., 1989; Doerr et al., 2000). It is now known that temperate soils are affected by soil hydrophobicity, including over 75% of land under pasture and cropping in the Netherlands (Dekker and Ritsema, 1994). Soil hydrophobicity has also been found in subtropical soils (Yao et al., 2009) and can be accentuated by hydrocarbon contamination (Roy et al., 1999). Smaller levels of soil hydrophobicity are found in most soils globally, with soil management (Woche et al., 2005), land use, texture (Doerr et al., 2006), and organic matter (Tilman et al., 1989; Capri et al., 1995) known to influence the severity. Hydrophobicity tends to increase with decreasing pH, although it has been found in alkaline soils and peats (Doerr et al., 2006).

Causes of soil hydrophobicity

Long-chain amphiphilic organic compounds produced by a range of biota can induce hydrophobicity in soil (Capri et al., 1995). These compounds can be highly hydrophilic, but drying causes bonding of hydrophilic (polar) ends of the molecules to each other or soil surfaces, resulting in an exposed hydrophobic (nonpolar) organic surface (Figure 1). Exudates and mycelia produced by fungi have been associated with water repellency in many studies (Bond, 1964; White et al., 2000; Feeney et al., 2006). Plant leaves, root mucilage, algae, and bacterial exudates can also cause soil hydrophobicity (Doerr et al., 2000; Ellerbrock et al., 2009; Martinez-Zavala and Jordan-Lopez, 2009; Hallett et al., 2009). The Lotus effect (Barthlott and Neinhuis, 1997) is an example of extreme hydrophobicity (water drops are not attached to the surface) due to specific combination of hydrophobic waxes and roughness on plant leaves of many plant species.

Although soils may have very different amounts of potentially hydrophobic compounds depending on geography, soil type, and management (Piccolo and Mbagwu, 1999), their concentrations are often poorly related to soil hydrophobicity, particularly if grouped as total organic carbon (Doerr et al., 2000). Severe soil hydrophobicity

Hydrophobicity of Soil, Figure 1 The polar hydrophilic ends of amphiphilic organic compounds bond to each other and soil particles when dry, resulting in a hydrophobic surface.
(Reprinted from Hallett, 2008.)

can result if a few grains have a hydrophobic coating in repacked sands (Steenhuis et al., 2005), but in natural soils the effects could be decreased by cracking of the organic surface during drying, relative humidity impacts, and interactions with other organic compounds (Doerr et al., 2000).

The spacing, packing, and roughness of grains also influence soil hydrophobicity. "Superhydrophobicity," where water rests on the tips of particles like a bed of nails, has been shown to be a potential process in soils (McHale et al., 2005).

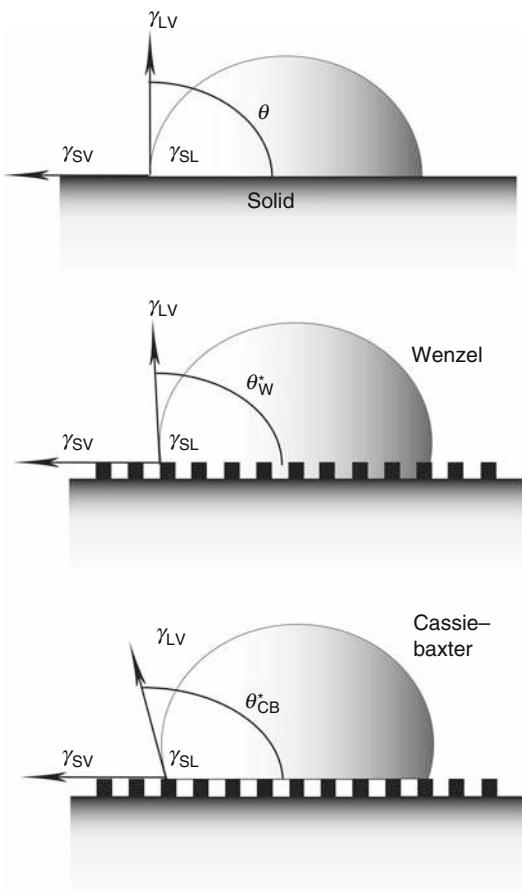

Physics of water repellency

The contact angle, θ , between a drop of water and a solid surface is controlled by the solid–vapor, γ_{sv} , solid–liquid, γ_{SL} and liquid–vapor γ_{LV} interfacial tensions (Figure 2). The Young's equation

$$\cos \theta = (\gamma_{\text{sv}} - \gamma_{\text{SL}})/\gamma_{\text{LV}} \quad (1)$$

describes the relation between the contact angle and the interfacial tensions for perfectly flat solid surfaces.

Although contact angles may vary continuously depending on the surface tension of the solid, it is convenient to think in terms of three different wetting situations. Complete wetting, for which the ideal θ is zero (perfectly wettable) and the liquid forms a very thin film, partial wetting with $0^\circ < \theta \leq 90^\circ$ (subcritical water repellency), and non-wetting (severe water repellency) with $\theta > 90^\circ$. Roughness of soil particles and pore surfaces can increase θ for already hydrophobic soils by either increasing

Hydrophobicity of Soil, Figure 2 Interaction between a drop of water and solid surface. The solid–vapor, γ_{SV} , solid–liquid, γ_{SL} , and liquid–vapor, γ_{LV} interfacial tensions control contact angle, θ . Surface roughness can increase θ through Wenzel or Cassie–Baxter processes.

the solid–liquid contact area (Wenzel) or if air within asperities increases the liquid–vapor area at the solid–liquid interface (Cassie–Baxter) (Bachmann and McHale, 2009). These processes can lead to superhydrophobicity and help explain why dry soils are more hydrophobic than wet soils (McHale et al., 2005).

The rate that soil absorbs water is defined by sorptivity, S and it will be influenced by θ as

$$S = S_i \cdot \cos(\theta), \quad (2)$$

where S_i is the intrinsic sorptivity (Philip, 1957). For a totally non-repellent soil, $S = S_i$ as $\cos(0^\circ)$ is 1. Capillarity is influenced by θ as

$$z\rho g = \frac{2\gamma \cdot \cos(\theta)}{r}, \quad (3)$$

where z is capillary rise, γ is the surface tension of water, ρ is water density, g is gravity, and r is the pore radius. A contact angle of 30–60° is not uncommon in soils that

are not recognized as hydrophobic but are to a certain extent water repellent (Woche et al., 2005) and this represents a greater than sixfold drop in sorptivity. Consequently, the observed capillarity rise may be considerably smaller than theoretically expected from Equation 3 with $\theta = 0$.

Measuring water repellency

Numerous approaches exist to measure water repellency in soil (Table 1). The water drop penetration time test (WDPT) is the most commonly used because of its simplicity, suitability for field measurements, and ability to measure the persistence of water repellency over periods of several hours (Dekker et al., 2009). As water repellency is influenced by the hydration status of soil, Dekker et al. (2001) extended the WDPT approach to measure “potential water repellency” using tests on soils equilibrated to different water contents in the laboratory. Usually soil is most water repellent when it is close to its air-dry water content (Dekker and Ritsema, 1994). Severity classes of water repellency can be determined from the WDPT, although some disagreement of critical thresholds exists in the literature. Table 2 provides the most widely accepted WDPT classifications.

The molarity of an ethanol droplet test (MED) is a suitable method for field measurements and indicates how strongly a water drop is repelled by a soil at the time of application (King, 1981). In the MED test, defined surface tensions of water are achieved by varying the molarity with the addition of different amounts of ethanol. The critical surface tension is taken as the minimum ethanol concentration where infiltration occurs in <5 s (Doerr, 1998).

A direct measurement of the soil–water contact angle based on the Sessile Drop method can be achieved using a Goniometer (Bachmann et al., 2000; Diehl and Schaumann, 2007). The capillary rise method (CRM) compares the infiltration rates of water and a liquid (usually hexane) not influenced by hydrophobicity (Bachmann et al., 2003) and is the standard approach used to measure the wetting of powders. A similar concept forms the basis of the intrinsic sorptivity test, where a water repellency index is assessed by comparing the sorptivity of water and ethanol measured with tension infiltrometers (Tilman et al., 1989). The hydrophobicity of individual soil aggregates can be measured by adapting either the CRM (Goebel et al., 2008) or intrinsic sorptivity (Hallett and Young, 1999) methods to assess wetting over smaller surface areas. The approach used to assess the water repellency index can also evaluate the apparent soil–water contact angle (Czachor, 2006). Error in the calculation of apparent soil–water contact angle by CRM or intrinsic sorptivity methods results because of pore roughness and heterogeneity impacts.

Implications

Soil hydrophobicity is a fundamental physical property of soil that has potentially severe implications to the environment, food security, and land-based industries.

Hydrophobicity of Soil, Table 1 Major approaches used to assess the hydrophobicity of soil

Test	Approach	Advantages	Disadvantages	Reference
Contact angle “Capillary rise”	Compares wetting rate of water and hexane into a packed column of soil	Physically meaningful Quantifies apparent contact angle	Time consuming Soil is disturbed when packed into columns	Bachmann et al. (2003)
Intrinsic sorptivity or repellency index, R	Compares sorptivity of water and ethanol measured with infiltrometer	Physically meaningful Miniature infiltrometers allow measurements of individual soil aggregates	Interaction between ethanol and soil may influence results	Tilman et al. (1989), Hallett and Young (1999)
Molarity of an ethanol droplet (MED)	Different concentrations of ethanol in water applied as drops to soil surface Critical minimum “molarity” where rapid infiltration occurs	Quick and easy (10 s per test)	Physical meaning requires greater investigation Surface roughness influences results	King (1981), Dekker et al. (2001), Roy and McGill (2002)
Sessile drop	Optical measure of contact angle of water drop on soil surface using Goniometer or light microscope	Measures contact angle directly	Affected by surface roughness Difficult to measure on wettable soils	Bachmann et al. (2000), Diehl and Schaumann (2007)
Water drop penetration time (WDPT)	Infiltration time of a drop of water placed on the surface of soil	Easily measures the persistence of hydrophobicity	Affected by pore structure Takes considerable time in repellent soil Not sensitive enough for low levels of hydrophobicity	Dekker et al. (2009)
Wilhelmy plate method (WPM)		Measures both advancing and receding contact angles	Uses a disturbed sample. Impact of adhesive and glass slide	Woche et al. (2005)

Hydrophobicity of Soil, Table 2 Classes of water repellency defined by Dekker et al. (2001) for the water drop penetration time (WDPT) test

Class	Severity	WDPT
0	Wettable, non-repellent	<5 s
1	Slightly water repellent	5–60 s
2	Strongly water repellent	60–600 s
3	Severely water repellent	600–3,600 s
4	Extremely water repellent	1–3 h
5		3–6 h
6		>6 h

The decreased rate of water infiltration and retention caused by hydrophobicity results in greater overland flow, less water retention, and the development of preferential flow paths and patchy dry spots in soil. Conventional soil physics approaches to describe water transport and retention require extensions to be effective in soils exhibiting even small levels of hydrophobicity (Deurer and Bachmann, 2007).

On golf courses, soil hydrophobicity is prominent and exacerbated by nutrient inputs and the small surface area of sand grains used to form putting greens (York and Canaway, 2000). Drought-stressed grass develops over hydrophobic soils as plant available water is reduced severely. In severely water stressed countries, the long-term irrigation of soil with treated effluent (waste water)

can present a serious challenge if hydrophobicity causes poor delivery and retention of water in the root zone (Wallach et al., 2005; Gruber et al., 2006; Vogeler, 2009).

Increased overland flow due to hydrophobicity accentuates soil erosion (Scott and Van Wyk, 1990; Shakesby et al., 2000; Benavides-Solorio and MacDonald, 2005), particularly following forest fires (Osborn et al., 1964). The impact follows seasonal shifts in hydrophobicity, with the impacts greatest during the summer (Witter et al., 1991; Jungerius and ten Harkel, 1994). Raindrops on hydrophobic soils produce fewer, slow-moving ejection droplets compared to wettable soils but remove more sediment (Terry and Shakesby, 1993). With successive drops, the surface of hydrophobic soils remain dry and noncohesive, leading to displacement by rain splash despite the overlying film of water (Doerr et al., 2003; Leighton-Boyce et al., 2007).

There is anecdotal evidence that heavy precipitation following dry periods can lead to flooding due to soil hydrophobicity. With increasing drought and severe weather predicted with climate change, this could have severe implications, particularly if predicted increases in the frequency and severity of soil wetting and drying occur.

Not all implications of soil hydrophobicity are deleterious to the environment or food production. Slower wetting rates of soil caused by hydrophobicity can result in increased soil aggregate stability (Goebel et al., 2005). Evaporation is also decreased by hydrophobic surface soil

(Shokri et al., 2009) and this mechanism is used by microbiotic crusts to conserve water in extremely arid environments (Issa et al., 2009).

Amelioration

Physical, chemical, and biological approaches have been developed to combat problems associated with hydrophobic soils. As soil hydrophobicity is pH dependent, lime application can reduce acidity of soils and is a very common amelioration strategy. Wetting agents are also in widespread use (Oostindie et al., 2008), particularly on amenity soils (Cisar et al., 2000) but also increasingly on agricultural land (Miyamoto, 1985). They can improve water distribution and infiltration rates by either acting as surfactants that decrease the surface tension of water or by altering the contact angle of soil surfaces (Kostka, 2000). A common approach on hydrophobic agricultural soils is the addition of clay to cover hydrophobic surfaces and make them hydrophilic (Blackwell, 2000). Kaolinitic clays are the most effective in reducing repellency (Ma'shum et al., 1989; Ward and Oades, 1993; McKissock et al., 2002; Dlapa et al., 2004), but relatively large quantities of clay are required to achieve the desired effect (100 t ha^{-1}) (Blackwell, 1993), so the approach is only economical if the clays occur naturally on site. Furrows can also help combat the impact of hydrophobicity by harvesting water and diverting it to the root zone (Blackwell, 2000).

Intensive cultivation decreases soil hydrophobicity as organic coatings are abraded and new soil surfaces are exposed. However, the shift in microbial dynamics and carbon mineralization that ensues can lead to hydrophobicity developing again (Feeney et al., 2006). Zero or reduced tillage, on the other hand, can decrease soil hydrophobicity by maintaining greater soil moisture (Blackwell, 2000) and potentially by altering the functional capacity of microbes to degrade hydrophobic compounds (Roper, 2005). Wax degrading bacteria have been isolated that have been demonstrated to reduce soil hydrophobicity (Roper, 2004).

HYPOBARIC STORAGE

Hypobaric storage involves the cold storage of fruit under partial vacuum. Typical conditions include pressures as low as 80 and 40 millimetres of mercury and temperatures of 5° C (40° F). Hypobaric conditions reduce ethylene production and respiration rates; the result is an extraordinarily high-quality fruit even after months.

HYSTERESIS IN FOODS

Matthew Caurie

Department of Home Economics Education, University of Education, Winneba, Ghana

Hysteresis in foods is the phenomenon by which at constant water activity (Aw) and temperature, a food adsorbs a smaller amount of water during adsorption than during a subsequent desorption process. Previous hypotheses to explain the phenomenon (Zsigmondy, 1911; Cohan, 1938, 1944; Everett, 1967; McBain, 1935; Kraemer, 1930) have been based on capillary condensation but the phenomenon is exhibited in foods and other substances believed to have negligible capillaries or pores. Current explanation (Caurie, 2007) states that sites adsorb moisture appropriate to their surface energies. During adsorption, micro-cracks and fissures form in the food to expose additional sites. Exposed sites unable to adsorb moisture on the way up to higher water activities (Aws) because of inappropriate surface energies adsorb additional moisture on return to lower Aws at appropriate Aw and surface energies to exhibit a hysteresis loop.

Hysteresis in Foods, Figure 1 Types of hysteresis.

The equation derived to fit the above interpretation of hysteresis has the form (Caurie, 2007)

$$m\left(\frac{1}{a} - 1\right) = K \exp\left(B \frac{Q}{T}\right), \quad (1)$$

where m = percent moisture content at water activity a ; Q = surface energy (keal/mole); T = absolute temperature; K, B = constants.

Soil water hysteresis

Definition

Hysteresis in soil is defined as the difference in the relationship between the water content of the soil and the corresponding water potential obtained under wetting and drying process.

The relationship between soil water content and soil water potential is called soil water retention curve (SWRC). This dependency manifests itself through hysteresis. It was shown by Haines in 1930 (Haines, 1930). This means that water content in the drying (or drainage) branch of water potential – water content relationship – is larger than water content in the wetting branch for the same value of water potential. For hygroscopic water, this effect is due to differences of water content at increasing and decreasing vapor tension in soil. During the increase of vapor tension, the water content in soil is lower than during the vapor tension decrease. For capillary water, the hysteresis phenomena result from pore shape irregularity. Irregular soil capillary is characterized by volume V and minimal r and maximal R radiiuses. Empty capillary is filled with water at under pressure corresponding to radius R . After filling with water, the meniscus is created, corresponding to radius r and the same capillary can be emptying at much higher water under pressure. The hysteresis region is called hysteresis loop. The wetting and

drying curves can be of the first or higher orders depending on actual soil water potential at which the wetting or drying process is started. Numerous models describing soil water hysteresis were developed. These models can be categorized into two main groups: the conceptual models and empirical models. The conceptual models are basically based on the domain theory. The independent domain theory of soil water hysteresis assumes that each soil water domain wets and dries at the characteristic water potentials irrespective of neighboring domains. This theory has been developed by Néel (1942, 1943). The modification of this theory takes into account interaction between particular domains and in literature is referred as dependent domain theory (Poulovassilis and Childs, 1971; Topp, 1971; Mualem and Dagan, 1975). Empirical models are mainly related to the analysis of the shape and properties of water retention curves.

ICE EROSION (GLACIAL EROSION, THERMAL EROSION)

Ice erosion occurs in several forms: Glacial, melt, ice movement, and thermal. Glacial erosion is the best known form of ice erosion, in which glaciers crush and shift large amounts of soil, their weight undercutting soil structures and also creating a range of vertical sides to the areas which they pass, which in turn erode through gravity and landslides. Ice melt causes the formation of solutions of materials which wash away, eroding soil and rock. Ice movement is abrasive on other surfaces, creating weak points, a mini glacial action. Thermal erosion is caused by expansion and contraction of soils and rocks affected by ice.

IMAGE ANALYSIS IN AGROPHYSICS

Magnus Persson

Department of Water Resources Engineering,
Lund University, Lund, Sweden

Definition

Image analysis can be defined as extraction of useful information from images by means of digital image processing techniques. In agrophysics, image analysis can be used to measure specific features of the soil or vegetation.

Introduction

An image can be considered as a large data matrix, where each element (often called pixel) contains information about the brightness (in black and white images) or color of a small area of the motif. Features of the image such as color or structures present can be related to physical properties of the motif (or parts of it). Using image analysis, it is possible to find patterns and boundaries, track objects, analyze colors, etc., in an automated way, making image analysis ideal for various applications such as surveillance, robotics, astronomy, remote sensing, and agrophysics.

Images can be captured in several different ways. Nowadays, digital cameras are used in most applications since they instantly produce digital images that directly can be analyzed mathematically. The wavelength of the recorded light can be different, normally cameras record visible light (roughly 400–700 nm), but longer or shorter wavelength are also used (IR, UV, or even X-ray). The scales of images can also vary; microscale images can be obtained through microscopes while satellite images almost can cover entire continents.

There is a great potential of using image analysis application in agrophysics. Both characteristics of the crops and the soil material can be assessed or measured using image analysis. In this article, I will focus on image analysis for determining soil characteristics since image analysis related to crops can be found elsewhere (e.g., Zheng and Moskal, 2009); (see *Plant Disease Symptoms, Identification from Colored Images; Plant Drought Stress: Detection by Image Analysis; Visible and Thermal Images for Fruit Detection*). For X-ray computed tomography imaging and other related methods, see, for example, Taina et al. (2008).

In soil science, image analysis has become increasingly popular during the last decade. There are many interesting applications such as determining the size and shapes of macroporosity (e.g., Czachor and Lipiec, 2004), root mass and root length (Kimura et al., 1999), organic matter content (Chen et al., 2000), soil albedo (Post et al., 2000), water content (Persson, 2005b), and solute concentration (Forrer et al., 2002).

Images are generally analyzed to determine either color of an object or to find and analyze shapes and patterns. There are many more types of analyses that can be done to extract useful information from images related to agrophysics. Some examples are Fourier transforms, fractal dimension analysis, texture analysis, etc. It should be noted that various image enhancing processes are applied in the image analysis process, for example, various kinds of digital filters, etc. One important process often used as one of the first steps in image analysis is segmentation. Segmentation means that the image is partitioned into segments containing multiple pixels corresponding to structural elements or other objects of interest. The purpose of segmentation is to reduce an image to information. One simple example is thresholding of a gray scale image to produce a binary image. Pixels with brightness above a certain threshold are given the value 1, all other pixels are given the value 0.

It should be noted that even if image analysis can be automated, it contains several steps which can be affected by subjectivity. Different operators are likely to come to slightly different conclusions based on the same images. Thompson et al. (1992) discussed this problem and suggested some types of standardization. Unfortunately, very few of his suggestions have been implemented. Therefore, caution should be taken when results from different investigators are compared.

Some applications

Dye tracers have been used for many years by soil scientists investigating the effects of soil heterogeneity as they allow visualization of spatial flow patterns (see, e.g., Flury and Flühler, 1995). This method has proven very useful for detecting preferential flow paths in the soil. Traditionally, image analysis of the dye photographs has only involved separation between stained and non-stained soil.

However, image analysis improved to the extent that the estimation of dye concentration from soil color was possible (e.g., Ewing and Horton, 1999; Forrer et al., 2002).

Physically, the wavelength of light determines its color. The color of an object is determined both by the spectrum of the incident illumination and on the reflectance spectrum of the surface. A color model (color space) is an abstract mathematical model describing the way colors can be represented as tuples of numbers. Some examples are RGB (red, green, and blue), CMYK (cyan, magenta, yellow, and black), and HSV (hue, saturation, and value). In the RGB color space, which is the one used by most digital cameras and computer screens, all colors can be represented by mixing various amounts of red, green, and blue. In most applications, each channel contains 8 bits of data $2^8 = 255$. Thus, $255^3 = 16,581,375$ different colors can be described.

Color consistency means that an image of an object should have the same color regardless of the ambient lighting conditions. Factors affecting the color of an object are inhomogeneous illumination, color temperature, and image noise. Any image can be transferred to a common norm by correcting for color temperature and inhomogeneous illumination (see Persson, 2005a). Image noise, however, is random and cannot be corrected for. Using high-end cameras and a powerful light source will in most cases reduce the image noise sufficiently. Different averaging filters can also be used.

The color as expressed in a specific color space of the corrected images can then be related to dye concentration. In most cases, an empirical polynomial equation is adopted to model the relationship between RGB or HSV values and dye concentration (Ewing and Horton, 1999; Aeby et al., 2001; Persson et al., 2005). Other more complex models like neural networks have also been used (Persson, 2005a).

Different types of dye tracers have been used, from various types of food dye to fluorescent tracers. Multiple tracer experiments have been carried out to study the transport and sorption of different compounds.

The same fundamental principle of color consistency can also be used for determining other physical characteristics of soil material like organic matter content (Chen et al., 2000), soil albedo (Post et al., 2000), or water content (Persson, 2005b).

There are several ways to describing the shape-related features of an object, for example, form factor, roundness, and elongation. Each of these is strictly mathematically described. By defining the limits for these parameters, different kinds of objects can be separated from each other.

Image analysis of the soil pore space is normally done on small-scale samples impregnated with a resin. Different types of resin have been used; usually, the resin contains some sort of dye so that it stands out from the color of the soil grains. Using fluorescent resins and light sources with different wavelengths, even more information can be extracted from the images. After hardening,

the sample is cut into thin sections that are photographed (e.g., Bouma et al., 1977; Protz et al., 1992; Ringrose-Voase, 1996). After segmentation, the pore space can be analyzed to find the shape and size of pores between the grains. Furthermore, characteristics such as connectivity of pores, types of soil material, and identification of earth worm channels, can be determined.

Some studies about automated classification of soils using image analysis have been presented. Marschallinger (1997) showed how image analysis could be used for classifying minerals in rock samples. Maragos et al. (2004) presented an automated system for estimation of the bioecological quality of soils using sophisticated image analysis. Generally, these applications require large computational efforts, but with the development of computers and image analysis software, usage of these applications will likely increase in the near future.

Interesting attempts on relating microscale characteristics of the pore network determined using image analysis to the transport of water and solutes. Pioneering work had been carried out already by Bullock and Thomasson (1979) who compared the characterization of macroporosity and water retention data. Walker and Trudgill (1983) studied the relationship between image analysis of pore network and dispersivity.

Image analysis for determining root length and diameter has received a lot of attention. Previous analysis methods (manual inspection) were very labor intensive and several commercial image analysis software packages have been developed (e.g., Kirchhof, 1992; van der Weele et al., 2003; French et al., 2009).

Conclusion

Image analysis and especially its application to agrophysics is still a young science. Most research within the field has been done during the last decades. Some applications are already routinely used, whereas many potential applications have received little attention yet. Especially interesting is automated image analysis for soil classification and studies, where pore scale soil properties are related to macroscopic features like water retention or soil fertility. Another area where I expect further development is the use of automated image analysis to study dynamic processes, for example, solute transport or root growth.

Last, I have to point out the great potential of using images and image analysis for educational purposes. Learning and understanding complicated processes is greatly enhanced when they can be visualized. Therefore image analysis applications are ideal for teaching or when communicating with the public.

IMBIBITION

The absorption or adsorption of water by a solid (e.g., grains) or colloid that results in swelling.

INDICATOR PLANTS

Plants characteristically associated with specific soil or site conditions, such as soil acidity, alkalinity, wetness, or a chemical element.

INFILTRABILITY

The flux of infiltration resulting when water at atmospheric pressure is applied and maintained at the soil surface. Infiltrability is relatively high when water is first applied to a dry soil, but diminishes in time and, if the soil is deep, it eventually tends asymptotically toward a constant rate called the soil's "steady infiltrability."

Infiltration: Water entry into the soil, generally by downward flow through all or part of the soil surface.

INFILTRATION IN SOILS

Miroslav Kutílek
 Prague 6, Czech Republic

Definition

Infiltration denotes the entry of water into the soil through its surface. The source of water is either free accumulated water on the surface as, e.g., in lakes, puddles, or it is a rain. We shall restrict our concept just to the vertical flow.

Basic concepts

Considering the water cycle, the infiltration process separates rain into two parts. One part stored within the soil supplies water to the roots of vegetation and recharges ground waters. The other part, which does not penetrate the soil surface, is responsible for surface runoff. Infiltration is therefore a pivotal point within the hydrologic cycle. The flux density of water across a topographical soil surface is the infiltration rate, q , dimensionally $[LT^{-1}]$, in units usually mm/s or cm/h. It was earlier not properly denoted as infiltration velocity, infiltration capacity, or infiltrability. The total amount of water that infiltrated from the start of the process to time t is called cumulative infiltration I , [L], usually in mm, or cm. It is a monotonously increasing function $I(t)$. We shall omit details of a simple and rarely occurring type of steady infiltration of known $q = \text{const.}$, completed by the definition of the position of the ground water level. Since the infiltration rate is given, we solve only the pressure head distribution between the soil surface and the ground water level by solving the Darcy–Buckingham equation. Or, vice versa, we could obtain q when the pressure head distribution $h(z)$ is measured. We shall discuss unsteady infiltration in two sections according to the boundary conditions governing the type of infiltration. When the soil surface is instantaneously and excessively ponded as it is in an infiltration test performed with a ring infiltrometer or after initial ponding of the alluvium, or after flooding the irrigation basin, we have to solve infiltration with the Dirichlet's boundary condition (DBC). When infiltration occurs under natural rainfall or under the sprinkler irrigation, we meet Neuman's boundary condition (NBC) for the full duration of the rain.

Unsteady infiltration with Dirichlet's boundary condition (DBC)

We are assuming that a soil surface is flooded with a constant small depth of water $h = h_o$ at time $t \geq 0$ with $\theta = \theta_S$ at $z = 0$ again at $t \geq 0$, where θ_S denotes the saturated soil water content. Before the soil surface is flooded ($t \leq 0$), the pressure head $h = 0$ with the initial soil water content $\theta = \theta_i$. The vertical axis z is oriented positively downward with $z = 0$ at the soil topographic surface.

Semi-analytical solutions

We assume a homogeneous soil without layering. For a physically based understanding of infiltration, the principles of Philip's (1957 and 1969) semi-analytical solution will be presented. Richards' equation in the diffusivity form

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z} \left[D(\theta) \frac{\partial \theta}{\partial z} \right] + \frac{dK}{d\theta} \frac{\partial \theta}{\partial z}$$

is solved for the given boundary conditions. Diffusivity D is

$$D(\theta) = K(\theta) \frac{dh}{d\theta}$$

$K(\theta)$ is the unsaturated conductivity; h is the pressure head (soil water potential).

The second term on the right side of the Richards' equation is deleted in the first step of the procedure and thus this first step solution is valid for the horizontal infiltration with space variable x . When solving it, the Boltzmann transformation

$$\eta(\theta) = xt^{-1/2}$$

is introduced in order to transform the partial differential equation into the ordinary one. This procedure transforms many soil water profiles during horizontal infiltration $\theta_n[x(t_n)]$ into single one $\theta(\eta)$. The area below the curve θ/x is the total water content in the wetted part of the soil column [L] and it is the cumulative infiltration, denoted by I . Then with the term sorptivity S [$LT^{-1/2}$] is

$$S = \int_{\theta_i}^{\theta_s} \eta(\theta) d\theta$$

and

$$I = St^{1/2}$$

or for infiltration rate $q = dI/dt$ is

$$q = 1/2 St^{-1/2}$$

and therefore $q(t \rightarrow 0) \rightarrow \infty$. Sorptivity depends not only upon the $D(\theta)$ function but upon θ_i . The value of S decreases with increasing θ_i and as $\theta_i \rightarrow \theta_s$, $S \rightarrow 0$. When S is measured for a particular θ_{i1} , we can linearly interpolate between θ_{i1} and θ_s in order to obtain a first approximation of S for $\theta_{i2} > \theta_{i1}$. Sorptivity is an integral part of most investigations describing vertical infiltration. It is the first approximation of the solution of infiltration if gravity is neglected. In order to include the influence of gravity, i.e., the second term of the basic Richards' equation, we have to correct the approximation (i.e., the horizontal infiltration) by the term y , i.e., $z = z_1 + y$. However, because an exact value of y cannot be obtained, its approximation y_1 defines another correction u , i.e., $y = y_1 + u$. Again, instead of an exact u we can only find still another

estimate u_1 . Hence, Philip (1957) obtained the infinite series solution

$$z(\theta, t) = \eta_1(\theta)t^{1/2} + \eta_2(\theta)t + \eta_3(\theta)t^{3/2} + \dots + \eta_n(\theta)^{n/2}$$

Since except of large times the series converges, the simplified form of Philip's equation is used

$$I = St^{1/2} + At$$

with A an empirical constant, usually $A = mK_S$ with m in ranges between 0.2 to 0.67, and very simplified $m = 2/3$. Since the infiltration rate q is obtained from the cumulative infiltration $q = dI/dt$ then the infiltration rate $q(t)$ is

$$q = \frac{1}{2} St^{-1/2} + A$$

Another approximation by Kutílek and Krejča (1987) is extending the Philip's solution to the form

$$I = St^{1/2} + C_2 t + C_3 t^{3/2}$$

where C_2 and C_3 are determined from the time t_C denoting the time when the infiltration rate q is in field conditions approaching constant. Then

$$C_3 = \frac{S}{3t_C}$$

$$C_2 = K_S - (3SC_3)^{1/2}$$

Brutsaert (1977) also began with the horizontal solution of Philip (1957) and sought a correction for the gravitational force. He obtained

$$I = K_S t + \frac{S^2}{BK_S} \left\{ 1 - \frac{1}{[1 + (BK_S t^{1/2})/S]} \right\}$$

The value of S in previous equations is advantageously obtained using the approximate expression of Parlange (1975)

$$S^2 = \int_{\theta_i}^{\theta_s} (\theta_s + \theta - 2\theta_i) D(\theta) d\theta$$

More semi-analytical solutions were developed; see, e.g., Kutílek and Nielsen (1994). However, the numerical solutions are preferred for field conditions, where we meet the nonhomogeneous soil profiles.

Empirical equations

Empirical equations have been used to describe a decreasing infiltration rate q as a function of time t . The shape of a smooth curve drawn through measured values of $q(t)$ was simply compared with that of an analytic function. Inasmuch as both equations and

experiments were empirical, it is useless to try to physically interpret the coefficients of the equations. The coefficients have the character of fitting parameters only with no scientific merit.

Kostiakov's (1932) equation of $q(t)$ is the hyperbola

$$q = c_1 t^{-\alpha}$$

and

$$I = \frac{c_1}{1 - \alpha} t^{(1-\alpha)}$$

where c_1 and α are empirical coefficients. The value of c_1 should equal q_1 , the infiltration rate at one unit of time (usually 1 min), and $0 < \alpha < 1$. The equation does not describe infiltration at large times in as much as $q \rightarrow 0$ when $t \rightarrow \infty$.

Mezencev (1948) overcame this inconvenience by shifting the q -axis

$$q = c_2 + c_3 t^{-\beta}$$

and

$$I = c_2 t + \frac{1}{1 - \beta} c_3 t^{(1-\beta)}$$

where c_2 , c_3 and β are empirical coefficients. With the shift, as $t \rightarrow s$, $c_2 \rightarrow q_c$, the constant infiltration rate is reached, and hence, $q_c \approx K_s$. The infiltration rate after the first time unit $q_1 = (c_2 + c_3)$.

Horton's equation (1940) represents an exponential decay of $q(t)$

$$q = c_4 + c_5 \exp(-\gamma t)$$

and

$$I = c_4 t + \frac{c_5}{\gamma} [1 - \exp(-\gamma t)]$$

where c_4 , c_5 and γ are empirical coefficients. In contradiction to the theory of infiltration for a DBC, q has a finite value at $t = 0$. As $t \rightarrow \infty$, $c_4 \rightarrow q_c$, which yields a value of $c_4 \approx K_s$. With this approximation for K_s , the value of $c_5 = [q(0) - K_s]$ where $q(0)$ is q at $t = 0$. As Horton derived his equation for infiltration of a high intensity rainfall, the physical objection against a finite value of $q(t=0)$ is largely eliminated

Unsteady infiltration with Neuman's boundary condition (NBC)

When we describe rainfall infiltration, we do not describe individual raindrop events, but consider the rain as a continuous flux with the intensity of the rain q_r , the flux density passing either totally or at least partially through the surface of the soil, i.e., we keep the principle of the representative elementary volume, REV. The boundary

condition at $z = 0$ and $t \geq 0$ is formulated by the Darcy-Buckingham equation

$$q = -K \frac{\partial H}{\partial z}$$

or in the diffusivity form

$$q = K(\theta) - D(\theta) \frac{\partial \theta}{\partial z}$$

Neuman's boundary condition describes not only rainfall infiltration, but infiltration caused by sprinkler irrigation or by rain simulator, or by a special flux controlled technique, e.g., by a peristaltic pump providing a constant flux through a membrane placed upon the soil surface. It does not describe satisfactorily the drip irrigation since it has to be defined as two-dimensional process. The initial condition is kept the same as that for the DBC. We distinguish three types of cases: (1) constant rain intensity $q_r > K_s$, (2) constant rain intensity $q_r < K_s$, and (3) rain intensity $q_r(t)$. In all three categories soil water profiles $\theta(z)$ at intermediate times do not resemble $\theta(z)$ during early stages of infiltration. The distinguishing feature is that the soil water content $\theta_o(t)$ increases at the surface with time.

Constant rain intensity $q_r \geq K_s$. The value of the soil water content of the surface θ_o increases steeply with time until it reaches θ_s . The greater is q_r , the steeper is $\theta_o(t)$. If rain continues, water ponds on the surface; the start of ponding is called ponding time t_p . If surface runoff is prevented, the depth of water on the surface $h_o(t)$ increases with time and $h_o > 0$ for $t > t_p$. With the increase of h_o being time dependent, $dh_o/dt < q_r$. The shape of the soil water profile at $t < t_p$ depends upon both q_r and the hydraulic functions of the soil. Generally, the soil water content is below full saturation for all $t < t_p$. The ponding time t_p decreases with an increase of q_r and $t_p > t_x$ where t_x is the intersection of q_r and q_D . Index D denotes infiltration by DBC. With the assumption that the soil water profiles $\theta(z, t_p)_N$ and $\theta(z, t_x)_D$ are identical and with

$$q_r(t_p) = q_D(t_x)$$

we obtain using the algebraic Philip's equation (Kutilek and Nielsen, 1994)

$$t_p = \left(\frac{S}{A} \right)^2 \frac{2Q - 1}{4Q(Q - 1)^2}$$

where $Q = q_r/A$. At $t \leq t_p$ the infiltration rate $q_o = q_r$. At $t > t_p$ the infiltration rate $q_o < q_r$ and it can be approximated by shifting $q_D(t)$ by $(t_p - t_x)$.

For *constant rain intensity $q_r \leq K_s$* , the flow is governed by NBC and the term t_p does not exist. On the soil surface the value of q_o is always less than that of q_s and therefore $\theta_o < \theta_s$, the surface is never saturated by water.

For nonconstant rain intensity $q_r(t)$, we formulate the functional dependence $q_r(t)$ in the NBC and in the solution. The mathematical steps in the analysis are identical to the steady rain infiltration, but the time dependency has to be defined. For the study of natural rains infiltration, the numerical procedures are applied. The process is usually complicated by the nonconstant values of hydraulic parameters and functions mainly of the surface thin layer, where the soil is puddled, pore size distribution substantially changed causing a change in saturated conductivity in the order of magnitude and a change of all functional relationships.

Summary

The entry of water into the soil through its surface is denoted as infiltration. There are two types of infiltration processes: one is defined with constant pressure head on the surface and it is realized as unsteady flow approaching after large time constant flux. Practical example is the flooding of the surface and the following infiltration from this source. In the second type of infiltration, the flux is defined on the surface. Practical example is the infiltration from rain when the rainwater is not accumulating on the surface.

[Sorptivity of Soils](#)

INSOLATION

Exposure to the radiation of the sun and the action of the sun's rays on soils or other materials or bodies exposed to such. Applied particularly to the effect of temperature change on mechanical weathering.

INSTITUTE OF AGROPHYSICS IN LUBLIN: PROGRESS IN AGROPHYSICS

Józef Horabik, Grzegorz Józefaciuk

Institute of Agrophysics, Polish Academy of Sciences,
Lublin, Poland

Introduction

Institute of Agrophysics of Polish Academy of Sciences was created in 1968. It is located almost in the centre of Europe, in Lublin, in southeastern Poland. The Institute was established by Professor Bohdan Dobrzański, Rector of Maria Curie Skłodowska University and of Agricultural Academy in Lublin, who was also the first Director of the Institute. During 40 years activity, the Institute has employed over 150 workers. It promoted over 20 professors, 30 DScs, and 40 PhDs. The Institute has the authorization to confer PhD and DSc degrees in Agronomy–Agrophysics. The Institute promotes knowledge at all levels of education presenting the latest achievements of science to great groups of viewers, organizing classes for students from southeast Poland universities and experimental presentations illustrating natural processes in primary and secondary schools, corresponding to topics of lessons of biology, chemistry, mathematics, and physics. The Institute conducts PhD studies in the field of agronomy–agrophysics and Joint Doctoral Courses with University of Life Sciences in Lublin.

The Institute has longstanding cooperation with over 60 scientific partners all over the world. Continuously new scientific links are created as well. Cooperation with Polish small and medium enterprises, industry, and local administration is additional and important part of the Institute activity. As a result of its activity and cooperation, Institute of Agrophysics realized over 100 national projects and participated in 20 of EU FP5 and FP6 projects, including domestic projects founded by EU, all related to environment and food research. Overall, the Institute researchers published over 4000 scientific papers, 100 monographs, organized over 40 international and

50 domestic conferences, and a number of workshops, seminars, and schools. The Institute has published three journals: International Agrophysics, Acta Agrophysica, and Polish Journal of Soil Science.

Agrophysics, the main area of the Institute activity, concerns applications of physics in agriculture. It places particular attention to sustainable plant production and modern processing technologies.

At present over 60 researchers, representing various disciplines work in six departments, specializing in solving a broad range of agrophysical problems related to properties and processes occurring in soils, plants, and granular materials, including water, salt, and energy exchange in soil environment, physicochemical properties of porous bodies, and related sorption equilibria, soil degradation (organic matter lost, heavy metal pollution, acidification, alkalinization, salinization, structure destruction, erosion, soil translocation, and stresses under machinery wheels), time and spatial variability of soil parameters, soil aeration, stability of nitrogen and carbon in soil, emission of greenhouse gases, soil biological activity, redox potential, mechanical characteristics and damage of cellular structures, plant growth and root functions, plant and soil properties under stress, grain quality at harvest, drying and storage, physical properties of agricultural materials and food powders, diagnosis of mechanical parameters of fruits and vegetables important for storage, handling, and processing, physical processes in granular materials of plant origin, and many others. Special attention is directed to measurements, monitoring and modeling of the early stages of food chain, i.e., all initial subsequent steps of healthy food production starting from recognizing soil conditions and ending on assessment of raw agricultural products quality.

The Institute has elaborated a set of unique measuring methods and equipment for identification and diagnosis of agricultural materials properties, description of parameters, data interpretation, and gathering datasets concerning actual state and history of systems as well as physical-mathematical, phenomenological, and statistical models for simulation and prognosis of environmental and anthropogenic processes in soils, plants, and raw agricultural products.

Department of metrology and modeling of agrophysical processes

The department developed a set of tools to study and control physical, hydrophysical, and thermophysical properties of soils and their relation with mass and energy transport in the soil-plant-atmosphere system. Two basic methods of physical modeling, phenomenological and theoretical physical-mathematical are employed on the basis of physical and physicochemical properties of the soil solid phase to study hydrophysical properties of soils (water retention curve and hydraulic conductivity coefficient) and processes of mass and heat transport in the soil medium with the use of numerical techniques. Soil moisture and its spatiotemporal evolution are studied and the

data are provided for numerical weather and climate models. The department elaborated a reflectometric meter and a probe measuring at the same time and from the same sample of soil its moisture, temperature, and salinity that can work in a field system monitoring of those values and communicating with the user by Internet server where the acquired data are stored. Thermography (remote noncontact evaluation of surface temperature distribution) is used for determination of plant water stress and evapotranspiration in the field, detection of plant cover areas attacked by diseased and insects, evaluation of fruit quality and seed germination capacity, controlling thermal conditions in greenhouses in the aspect of their optimum exploitation. The pulse-phase thermography is used for studies of internal intrusions such as bruises and water core in fruit, or military mines in soil.

Department of natural environment biogeochemistry

This department studies the interlocking roles of biological, chemical, and physical forces in controlling processes vital to sustaining life with special attention placed on the role of microorganisms. The methods were developed to study aeration of soil profile at various environmental conditions, oxygen availability for plant roots, plant response on oxygen stress, and protective mechanisms of plants at low soil oxygen level. Extensive studies are focused on the effect of redox potential on biological activity and emission and sink of greenhouse gases from soils. Soil microbial indicators are used for monitoring soil biological activity and evaluation of impacts of both environmental and anthropogenic factors. Oxygenology, a new scientific discipline within the environmental sciences related to the presence and role of oxygen in nature on Earth has been defined in this department. It comprises issues of storage, transport, generation, absorption, turnover, functions, and measurement of oxygen content in the environment.

Department of microstructure and mechanics of biomaterials

This department developed experimental and theoretical tools to study structural (from nano- to macroscale) determinants of mechanical properties of fruits and vegetables for quality control and optimization of processing. Atomic force, confocal laser scanning, tandem scanning reflected light microscope, transmission optical microscope and macroscope techniques, image analysis, fracture and acoustic emission analysis, physical and numerical models are applied for microstructure quantification of cellular (plants) and granular structures (soil). New method of spatial-temporal reflected laser light scatters correlation (biospeckle) was introduced for monitoring living processes within biomaterials that is used for estimation a state of the fruit or vegetables during vegetation or storage. The structure of real cell walls of fruit and vegetables is simulated by artificial cellulose

produced by bacteria *Gluconacetobacter xylinus*. Its physical dimensions are useful for mechanical testing, thus can be used for investigation of influence of various external factors, like temperature, humidity, and food additives on cell wall properties.

Department of soil and plant system

This department elaborated methods for studies and description of soil management effects on plant growth and functions, and water uptake by roots in relation to soil structure. Field and model studies of soil erosion allowed to construct models for establishing soil susceptibility to erosion, prognosis of water erosion of soils and soil translocation rates under various tillage implements, erosion impact on soil productivity, and pollution of surface waters. Simulations of stresses and strains in soils were used for quantitative estimation of the effect of pore and aggregate structure on soil compaction under varying climate conditions and cropping practices, and under machinery wheels. The laboratory system maintaining constant soil water potential and allowing to measure daily water uptake by plant roots was elaborated to control process of root growth and estimation of crop demands. The system is used to measure water uptake by roots growing within various density horizontal soil layers in split root system.

Department of physical chemistry of porous materials

This department developed methods to apply physicochemical soil properties as surface area, adsorption energy, fractal dimension, pore size distribution, surface charge, surface acidity, and surface free energy as indicators of changes in soil under various environmental conditions. Physicochemical methods of description of soil degradation processes as organic matter lost, heavy metal pollution, acidification, alkalization, salinization, and structure destruction were elaborated and physicochemical methods of soil amelioration and detoxification were established. Surface chemistry methods were introduced as new tools to analyze surface properties of plant roots and their changes under stress conditions. Formation and stability of soil structure and microstructure were described using analysis of surface energetic and geometric heterogeneity, organomineral interactions in soils, soil porosity, wettability, and surface free energy components.

Department of physical and technological properties of agricultural materials

Laboratory of physical bases of grain quality evaluation

This laboratory elaborated methods for establishing susceptibility of cereal grains to emerging of endosperm cracks in preharvest period, and of digital analysis of X-ray images to recognition of growth and develop of grain weevil in wheat grain. Recognition of the growth stage of weevil larvae is used to localize an infection point during grain transport history that is particularly important

to establish responsibility for infection in imported grain. New method in studies of physical properties of gluten via analysis of gluten membranes expansion as a function of temperature was introduced to estimate ability of fixing fermentation gas bubbles within cake that is a key parameter for sponginess and crumb structure fixation of bread in baking technology.

Laboratory of physical properties of crops

This laboratory develops measuring methods and introduces new techniques of the estimation of physical properties of crops and their damages and losses during harvest, handling, and storage, and the effect of injuries on the reproducible and consumption quality of raw material. Factors affecting quality of fruits and vegetables, and seeds of oil and leguminous plants are studied to introduce new technologies enhancing the quality of food materials, products, and fodders. Technology of virgin type rape oil production, online fruit quality control in sorting line, and production of chain saw lubricant from mustard oil are implemented.

Laboratory of physics of granular plant materials
